W. W. NORTON & COMPANY
Independent Publishers Since 1923

W. W. Norton & Company
Independent Publishers Since 1923

W. W. Norton & Company has been independent since its founding in 1923, when William Warder Norton and Mary D. Herter Norton first published lectures delivered at the People's Institute, the adult education division of New York City's Cooper Union. The firm soon expanded its program beyond the Institute, publishing books by celebrated academics from America and abroad. By midcentury, the two major pillars of Norton's publishing program—trade books and college texts—were firmly established. In the 1950s, the Norton family transferred control of the company to its employees, and today—with a staff of five hundred and hundreds of trade, college, and professional titles published each year—W. W. Norton & Company stands as the largest and oldest publishing house owned wholly by its employees.

Preface

Since early 2020, the field of immunology has moved to an unexpectedly prominent place in daily life. As SARS-CoV-2 spread around the globe, basic questions about how the immune system combats viruses moved into the forefront of public attention. Why were individual responses to the virus so variable? Why were outcomes in older patients so much more dire than in younger infected individuals? And, most important, how quickly would a vaccine be available, would it provide adequate protection, and for how long? While some questions have been answered, notably observing the most rapid vaccine development in human history, many other questions remain outstanding. Clearly, the need for continued research into basic mechanisms controlling human immunity is undeniable.

Though somewhat overshadowed during the COVID-19 pandemic, there has been a dramatic rise in the use of various other immunotherapies in the years since the last edition of *Janeway's Immunobiology*. Multiple methods for manipulating immune responses have significantly altered the practice of clinical medicine, benefiting patients who present with a diagnosis of cancer, autoimmune disease, or chronic inflammatory disorder. In large part, these clinical advances arose from decades of basic research aimed at uncovering the molecules and pathways that regulate immune cells at steady-state conditions or during infection, inflammation, or autoimmunity.

This Tenth Edition of *Janeway's Immunobiology* strives to carry on Charlie Janeway's legacy of providing a comprehensive, up-to-date textbook focused on the mechanisms underlying the responses to infection. In keeping with this mission, this edition's text and figures have been updated throughout. The immune response to SARS-CoV-2 and the multiple vaccine strategies utilized against this infection are introduced in Chapter 1 and further discussed in Chapters 12, 16, and Appendix I. Chapter 3 now includes a detailed explanation of the mechanism by which mutations in innate sensors of infection can lead to autoimmunity. New developments in the identification of ligands for γδ T cells are highlighted in Chapter 4, and the new cryo-electron microscopy (cryo-EM) structure of the RAG-1:RAG-2 complex bound to DNA is described in Chapter 5. Recently discovered structural features of the peptide-loading machinery for antigen presentation to T cells are included in Chapter 6. The treatment of antigen receptor signaling in Chapter 7 now includes discussion of lymphocyte metabolism, a topic also revisited in the revised Chapters 9 and 11. Additionally, new information in Chapter 7 highlights the pathways targeted by checkpoint blockade immunotherapy and describes the signaling modules used to engineer chimeric antigen receptors (CARs) for cell-based therapies, a topic also elaborated in Chapter 16. The latest findings on T-cell localization and dynamics during priming interactions with dendritic cells are covered in Chapter 9, while Chapter 11 describes new insights into the development and functions of tissue-resident memory T cells. Chapter 12, which focuses on immunity at the barrier surfaces, has undergone a major overhaul and includes an expanded discussion of immune interactions with commensal microorganisms and a detailed discussion of the roles of diverse epithelial cell types in the intestine, respiratory tract, and the skin. Chapter 12 also includes a new section on respiratory virus infections, including influenza and SARS-CoV-2. Chapter 16 brings vaccines to the forefront and includes a detailed discussion of the new vaccine approaches used for SARS-CoV-2 and poliovirus vaccines. The Immunologist's Toolbox (Appendix I) has been updated with new sections on single-cell technologies such as single-cell RNA-seq and lineage-tracing approaches, antigen tetramers for identifying antigen-specific B cells, and parabiosis used to determine lymphocyte tissue residency. Also included in Appendix I is a new description of an analytic technique used to measure antibody responses to SARS-CoV-2 in infected or vaccinated individuals. End-of-chapter study questions have been reworked in the Tenth Edition, and an online learning platform for student self-assessment, InQuizitive, has been created.

We have benefited greatly from the major contribution of Gregory Barton, an expert in innate immune signaling, who has revised and updated Chapter 3. Many additional people deserve special thanks, including our thoughtful colleagues who reviewed the Ninth Edition and provided insights that helped direct revisions in this new edition. We benefited from the eagle-eyed accuracy reviewers who provided feedback on Tenth Edition chapters. All of these individuals are cited in the Acknowledgments section, and we express our gratitude for their efforts.

We have the good fortune to work with an outstanding editorial group at W. W. Norton. We thank Denise Schanck, our editorial advisor, who coordinated the entire project, guiding us gently but firmly back on track throughout the process. We thank Betsy Twitchell, our editor, who contributed her guidance, support, and wisdom. Sincere thanks also go to Judith Kromm, our developmental editor, and Christopher Curioli, our copyeditor, for their insights and attention to detail. As in all previous editions, Matt McClements has contributed his genius—and patience—reinterpreting the authors' sketches into elegant illustrations. Our editing, production, and permissions teams provided their expertise throughout; they are Maggie Stephens, David Bradley, Ben Reynolds, Stephanie Romeo, and Patricia Wong. Our media experts, Kate Brayton, Jasmine Ribeaux, Alexandra Malakhoff, and Kara Zaborowsky, created our excellent supplements package. The authors wish to thank their most important partners—Theresa, Cindy Lou, and Charles—colleagues in life who have supported this effort with their generosity of time, their own editorial insights, and their infinite patience.

We hope this Tenth Edition will continue to inspire students to appreciate immunology's beautiful subtlety—just as Charlie did. We encourage all readers to share with us their views on where we have come up short, so the next edition will further approach the asymptote. Happy reading and learning!

Kenneth Murphy
Casey Weaver
Leslie Berg

What's New in the Tenth Edition

New Coauthor

Janeway's Immunobiology is the premier text for immunology, giving students at all levels a current and authoritative understanding of immunology research. Leslie Berg joins Ken Murphy and Casey Weaver in comprehensively updating the textbook.

New Online Assessment in InQuizitive

InQuizitive for *Janeway's Immunobiology* is an award-winning, adaptive learning tool that gives students personalized learning pathways as they work through the material. Through a variety of question types and answer-specific feedback, students learn the necessary vocabulary to succeed in the immunology course and practice applying that vocabulary to core concepts.

New Norton Teaching Tools Support Classroom Instruction

The Norton Teaching Tools site for *Janeway's Immunobiology* gives instructors ready access to primary literature suggestions for each chapter, active learning activities, lecture PowerPoint files, descriptions of all the animations and videos, and much more.

New Coverage of the COVID-19 Pandemic

COVID-19 coverage has been incorporated in Chapters 1, 12, 16, and Appendix I and is highlighted on the front cover with a new illustration of the novel mRNA vaccination strategy.

Highlights of New Research

Chapter 1:

- Brief introduction to coronavirus, which is then elaborated in later chapters.

Chapter 3:

- Latest research on the Toll-like receptors and cGAS–STING pathway.
- Discussion of mutations in RIG-I, MDA-5, and cGAS–STING pathways that lead to autoimmune disorders.
- Latest information on inflammasome activation and gasdermin pore formation in secretion of inflammatory cytokines.

Chapter 5:

- New cryo-EM structure of the RAG-1:RAG-2 tetrameric complex bound to recombination signal sequences in the DNA.
- Discussion of the latest research on the evolutionary origins of RAG-dependent V(D)J recombination.

Chapter 6:

- Newly discovered structural features of the peptide-loading machinery for TAP and the peptide-loading complex (PLC).

Chapter 7:

- Latest findings on the metabolic impact of antigen receptor stimulation.
- Up-to-date research on immune checkpoint therapy with CTLA-4 and PD-1 blockade.
- New section on chimeric antigen receptors for CAR T-cell cancer immunotherapy (CAR-T therapy).

Chapter 8:

- New discussion of development of ILCs and nonconventional T cells, including regulatory T cells, iNKT cells, and CD8αα intraepithelial lymphocytes.

Chapter 9:

- Addition of new information on dendritic-cell subsets.
- New section on metabolic control of T-cell activation and differentiation.
- Latest developments in spatiotemporal control of T-cell priming by dendritic cells.
- New insights into how IL-2 signaling regulates T-cell differentiation.

Chapter 11:

- New emphasis on the relationship between antibody isotypes and immune effector modules.
- Updates on T_{FH} cells and tissue-resident memory T cells.
- New research on T-cell metabolic reprograming in formation and maintenance of T-cell memory.

Chapter 12:

- Major revision that includes more than 25 new or revised illustrations.
- Detailed discussion of the emergence of the COVID-19 pandemic and basis for viral tropism for host cells.
- Major expansion of discussion of mucosal immunity in the intestines, lungs, and skin.
- Expanded consideration of the interplay of barrier tissues with the commensal microbiota.
- Enhanced treatment of specialized epithelial cell types in barrier tissues, including tuft cells, goblet cells, Paneth cells, enteroendocrine cells, and others.
- Extended treatment of intraepithelial lymphocytes (IELs).
- New section introducing the latest findings in neuroimmune regulation.

Chapter 13:

- Expanded treatment and new figures on HIV/AIDS, including the latest findings on CCR5- and CXCR4-tropic HIV variants and use of combination antiretroviral therapy (cART).
- Latest structural information on broadly neutralizing antibodies against HIV envelope protein.
- Expanded and updated coverage of immune evasion by pathogens, including targeting of complement and interferon pathways.
- New section on viral mechanisms promoting exhaustion of T cells and NK cells.
- Updated research on mechanisms used by viral pathogens to subvert host cytokine and chemokine responses.

Chapter 16:

- Vaccines are brought to the forefront, illustrating new vaccine approaches to COVID-19 and modern vaccine technologies for poliovirus eradication.
- New discussion of checkpoint blockade and CAR T-cell technology for cancer immunotherapy.

Appendix I:

- Multiplex bead assay for flow cytometric analysis of antibody responses and its use to measure serum antibodies to SARS-CoV-2.
- Description of antigen tetramers for identification of antigen-specific B cells.
- New description of parabiosis for analysis of lymphocyte tissue residency.
- New discussion of cell lineage tracing techniques.
- Description of techniques for single-cell molecular analyses.

Resources for Instructors and Students

Instructor Resources

Instructor resources for *Janeway's Immunobiology* are available at wwnorton.com

Art of *Janeway's Immunobiology*, Tenth Edition
All the images from the book are available in both labeled and unlabeled versions in PowerPoint and JPEG formats.

PowerPoint Lecture Slides
The section headings, concept headings, and figures from the text have been integrated into customizable PowerPoint presentations.

InQuizitive
InQuizitive is Norton's award-winning, easy-to-use adaptive learning tool that personalizes the learning experience for students, helping them to master—and retain—key learning objectives. The InQuizitive course for *Janeway's Immunobiology*, Tenth Edition, includes dynamic question types focused on vocabulary and critical thinking, with clickable glossary definitions throughout. Through a variety of question types, answer-specific feedback, and pedagogical elements that promote metacognition, students are motivated to keep working until they've mastered both the concepts and the tough terminology critical to success in the immunology course. As a result, students arrive better prepared for class, giving instructors more time for discussion and activities. Because InQuizitive motivates students to keep working on a chapter until they've mastered the content, assigning it consistently can help improve course performance. A robust activity report makes it easy to identify challenging concepts, and the convenience of learning management system (LMS) integration saves time by allowing InQuizitive scores to report directly to an LMS gradebook.

Norton Teaching Tools
Searchable by chapter, phrase, or topic, the Norton Teaching Tools site is focused on resources for active learning. Each chapter offers primary literature papers with questions for classroom discussion, concept map activities to help students connect and understand complex immunological processes, relevant animations with suggestions on how to integrate them into a course, and more. For instructors looking to seamlessly weave case studies into their course, there are case study companion PowerPoints with integrated clicker questions, which will also be included in *Squarecap*, a next-generation classroom response system that promotes a high level of student engagement in the classroom through quality assessment.

Test Bank
Written by Debby Walser-Kuntz, Samira Aghlara-Fotovat, Omid Veiseh, and Cynthia Leifer, the revised and expanded Test Bank includes more than 900 questions in a variety of question formats. Questions are classified by section and difficulty, making it easy to construct tests and quizzes that are meaningful and diagnostic. Norton Testmaker brings Norton's high-quality testing materials online. Create assessments for a course from anywhere with an Internet connection, without downloading files or installing specialized software. Search and filter Test Bank questions by chapter, question type, difficulty, learning objective, and Bloom's Taxonomy. Instructors can also edit questions or create their own. Then, easily export tests to Microsoft Word or Common Cartridge files for import into an LMS.

Resources for an LMS
Easily add high-quality Norton digital resources to an online, hybrid, or lecture course. Get started building a course with our easy-to-use integrated resources; all activities can be accessed right within an existing learning management system.

Student Resources

Student resources for *Janeway's Immunobiology* are available at digital.wwnorton.com/janeway10

Ebook for *Janeway's Immunobiology*
Norton Ebooks offer an enhanced reading experience at a fraction of the cost of a print textbook. They provide an active reading experience, enabling students to take notes, bookmark, search, highlight, and even read offline. Students can access the animations directly from the ebook, and clickable key terms are linked to their definitions. Instructors can even add notes that students see as they read the text. Norton Ebooks can be viewed on—and synced across—all computers and mobile devices and can be made available for offline reading.

***Case Studies in Immunology*, Seventh Edition Ebook**
by Raif Geha and Luigi Notarangelo

Case Studies in Immunology: A Clinical Companion presents major topics of immunology through a selection of clinical cases that reinforce and extend the basic science. Each case history is preceded by essential scientific facts about the immunological mechanisms of that specific disorder. The cases themselves demonstrate how immunological problems are deconstructed in the clinic, and each one is followed by a concise summary of the clinical finding with questions that serve as discussion points. Cases are color coded to correspond to *Janeway's Immunobiology*, allowing instructors to easily find cases that complement the material in the main text. In *Janeway's Immunobiology*, diseases covered in *Case Studies* are indicated by an icon in the margin. Access to the *Case Studies in Immunology* ebook is free with every purchase of *Janeway's Immunobiology*, Tenth Edition. It is also available for purchase separately.

Animations
A set of more than three dozen animations covers some of the most important immunology concepts, such as innate recognition of pathogens, V(D)J recombination, TCR signaling, and many more. Animation-based questions in InQuizitive allow students to practice their understanding of the information presented in the animations, while links to animations in the ebook help bring these topics to life as the student reads.

Acknowledgments

We thank our spouses, families, friends, and colleagues for their continuing patience and support, without which the writing of this new edition of our textbook would not be possible. As always, we are also indebted to a large number of scientists whose generous help has been essential for making the text as clear, up to date, and accurate as possible.

Deserving special credit is Gregory Barton (University of California, Berkeley), who accepted the task of drafting Chapter 3.

In what follows, we aim to acknowledge and thank the scientists whose suggestions for the text have helped us to prepare this edition.

Chapter 1: Kenneth Frauwirth (University of Maryland), Stephen Jameson (University of Minnesota), Michael Roner (University of Texas at Arlington).

Chapter 2: Kenneth Frauwirth (University of Maryland), Teizo Fujita (Fukushima Medical University), Lora Hooper (University of Texas, Southwestern), John Hourcade (Washington University at Saint Louis), Stephen Jameson (University of Minnesota), Thomas Langmann (University of Cologne), Jenna Macciochi (University of Sussex), Rodney Newberry (University of Washington at Saint Louis), Shanna Nifoussi (University of Wisconsin–Superior), Michael Roner (University of Texas at Arlington), Frederick Sheedy (Trinity College Dublin), Kiyoshi Takeda (Osaka University Medical School), Andrea Tenner (University of California, Irvine).

Chapter 3: Mary Dinauer (Washington University at Saint Louis), Shanna Nifoussi (University of Wisconsin–Superior), David Raulet (University of California, Berkeley), Caetano Reis e Sousa (Cancer Research UK), Michael Roner (University of Texas at Arlington), Frederick Sheedy (Trinity College Dublin), Joseph Sun (Memorial Sloan Kettering Cancer Center), Tada Taniguchi (University of Tokyo), Eric Vivier (Centre d'Immunologie de Marseille–Luminy).

Chapter 4: Bob Brennan (University of Central Oklahoma), Kenneth Frauwirth (University of Maryland), K. Christopher Garcia (Stanford University School of Medicine), Paul Klenerman (Nuffield Department of Medicine, University of Oxford), Ellis Reinherz (Dana Farber Cancer Institute, Boston), Michael Roner (University of Texas at Arlington), Robyn Stanfield (The Scripps Research Institute).

Chapter 5: Bob Brennan (University of Central Oklahoma), Martin Flajnik (University of Maryland School of Medicine), Kenneth Frauwirth (University of Maryland), Paul Klenerman (Nuffield Department of Medicine, University of Oxford), Michael Krangel (Duke University School of Medicine), Michael Lieber (Keck School of Medicine, University of Southern California), Eugene Oltz (The Ohio State University), Michael Roner (University of Texas at Arlington), David Schatz (Yale School of Medicine).

Chapter 6: Peter Cresswell (Yale School of Medicine), Kenneth Frauwirth (University of Maryland), Dale Godfrey (University of Melbourne), Mitchell Kronenberg (La Jolla Institute for Immunology), Jacques Neefjes (Leiden University), Hans-Georg Rammansee (University of Tübingen), Kenneth Rock (University of Massachusetts Medical School), Michael Roner (University of Texas at Arlington), Natalie C. Steinel (University of Massachusetts Lowell), Jose Villadangos (University of Melbourne), Kai Wucherpfennig (Dana Farber Cancer Center).

Chapter 7: Michael Dustin (University of Oxford), Kenneth Frauwirth (University of Maryland), Lawrence Kane (University of Pittsburgh), Susan Pierce (National Institutes of Health), Hans-Georg Rammansee (University of Tübingen), Michael Roner (University of Texas at Arlington), Lawrence Samelson (National Cancer Institute), Andrey Shaw (Genentech), Natalie C. Steinel (University of Massachusetts Lowell), Arthur Weiss (University of California, San Francisco), Kai Wucherpfennig (Dana Farber Cancer Center), Rose Zamoyska (The University of Edinburgh).

Chapter 8: Michael Cancro (University of Pennsylvania School of Medicine), Kenneth Frauwirth (University of Maryland), Fotini Gounari (University of Chicago), Eric Huseby (University of Massachusetts Medical School), Kristin Hogquist (University of Minnesota Medical School), Joonsoo Kang (University of Massachusetts Medical School), Barbara Kee (University of Chicago), Bernard Malissen (Centre d' Immunologie de Marseille–Luminy), Diane Mathis (Harvard University), Kees Murre (University of California, San Diego), Hans-Georg Rammansee (University of Tübingen), Ellen Robey (University of California, Berkeley), Michael Roner (University of Texas at Arlington), Ellen Rothenberg (California Institute of Technology), Natalie C. Steinel (University of Massachusetts Lowell).

Chapter 9: Francis Carbone (University of Melbourne), Kenneth Frauwirth (University of Maryland), Laurie Harrington (University of Alabama at Birmingham Heersink School of Medicine), Bill Heath (University of Melbourne), Marc Jenkins (University of Minnesota Medical School), Stephanie Justice-Bitner (King's College), David Masopust (University of Minnesota Medical School), K. Kai McKinstry (University of Central Florida), James Moon (Massachusetts General Hospital), John O'Shea (National Institutes of Health), Esperanza Perucha (King's College London), Tania Watts (University of Toronto).

Chapter 10: Deepta Battacharya (The University of Arizona), John Cambier (University of Colorado School of Medicine), Michael Cancro (University of Pennsylvania School of Medicine), Marcus Clark (University of Chicago Medicine), Kenneth Frauwirth (University of Maryland), Christopher Goodnow (Garvan Institute of Medical Research), Ann Haberman (Yale University), John Kearney (University of Alabama at Birmingham Heersink School of Medicine), Stephanie Justice-Bitner (King's College), K. Kai McKinstry (University of Central Florida), David Tarlinton (Monash University), Gabriel Victora (The Rockefeller University).

Chapter 11: Kenneth Frauwirth (University of Maryland), Michael Gerner (University of Washington), Stephanie Justice-Bitner (King's College), Susan Kaech (Yale School of Medicine), David Masopust (University of Minnesota Medical School), Matthew Pipkin (The Scripps Research, Florida), Stephen McSorley (University of California, Davis, Veterinary Medicine), Dean T. Nardelli (University of Wisconsin–Milwaukee), John O'Shea (National Institutes of Health),

Gregory Sonnenberg (Weill Cornell Medicine), Sing Sing Way (Cincinnati Children's Hospital), Allan Zajac (University of Alabama at Birmingham Heersink School of Medicine).

Chapter 12: Richard Blumberg (Brigham and Women's Hospital, Harvard University), Kenneth Frauwirth (University of Maryland), Gunjan Gakhar (Washington State University Vancouver), Gunnar Hansson (University of Gothenburg), Lora Hooper (UT Southwestern Medical Center), Alessio Iannetti (Newcastle University), Stephen Jameson (University of Minnesota), Tom MacDonald (Blizard Institute–Barts and The London), Daniel Mucida (The Rockefeller University), Rodney Newberry (Washington University at Saint Louis), Dana Philpott (University of Toronto), Maria Rescigno (Humanitas University), Michael Roner (University of Texas at Arlington), Michael Russell (State University of New York, Buffalo), Phillip Smith (University of Alabama at Birmingham Heersink School of Medicine), Ramnik Xavier (Broad Institute).

Chapter 13: Shizuo Akira (Osaka University), Mary Collins (Okinawa Institute of Science and Technology), Kenneth Frauwirth (University of Maryland), Paul Goepfert (University of Alabama at Birmingham Heersink School of Medicine), Stephanie Justice-Bitner (King's College), Paul Klenerman (Nuffield Department of Medicine, University of Oxford), Scott Laster (North Carolina State University), Jordan Orange (Columbia University College of Physicians and Surgeons), Sarah L. Rowland-Jones (Nuffield Department of Medicine, University of Oxford), Tara Strutt (University of Central Florida).

Chapter 14: Cezmi Akdis (Swiss Institute of Allergy and Asthma Research), Larry Borish (University of Virginia Health), Joseph Dolence (University of Nebraska at Kearney), Kenneth Frauwirth (University of Maryland), Stephanie Justice-Bitner (King's College), Daniel Kaplan (University of Pittsburgh), Barry Kay (Deceased, Imperial College London), Brian Kim (Washington University at Saint Louis), Cathryn Nagler (University of Chicago), Steven Van Dyken (Washington University at Saint Louis), Marsha Wills-Karp (Johns Hopkins University).

Chapter 15: Robert Fairchild (Cleveland Clinic), Kenneth Frauwirth (University of Maryland), Rikard Holmdahl (Karolinska Institute), Stephanie Justice-Bitner (King's College).

Chapter 16: Tanya R. DaSylva (York University), Kenneth Frauwirth (University of Maryland), Stephanie Justice-Bitner (King's College), Joseph Larkin (University of Florida), Ken Nally (School of Biochemistry and Cell Biology, University College Cork).

Appendix I: Kenneth Frauwirth (University of Maryland), Stephanie Justice-Bitner (King's College), Lawrence Stern (University of Massachusetts Medical School), Ross Kedl (University of Colorado Anschutz School of Medicine).

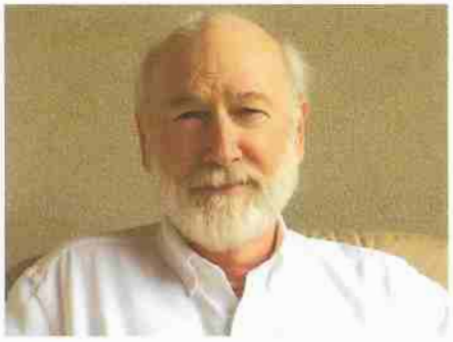
We thank those scientists who were instrumental in writing and reviewing the media supplements accompanying this edition:

Samira Aghlara-Fotovat (Rice University), Paul Allen (Washington University School of Medicine), Nancy Bigley (Wright State University), William Carr (Medgar Evers College), Liliana Clemenza (University of Toronto), Maurizio Costabile (University of South Australia), Tanya R. DaSylva (York University), Mark Drew (The Ohio State University), Kenneth Frauwirth (University of Maryland), Rachel Gerstein (University of Massachusetts Medical School), Deanna Gibson (University of British Columbia), Demelza Ireland (University of Western Australia), Nuran Kumbaraci (Stevens Institute of Technology), Cynthia Leifer (Cornell University), Alan Levine (Case Western Reserve University), Adam Matthews (Wellesley College), Yanice Mendez (University of New Haven), Esperanza Perucha (King's College London), Nicholas Pullen (University of Northern Colorado), Stuart Ray (Johns Hopkins University School of Medicine), Amy Stone (Touro University Nevada), Courtney Sulentic (Wright State University), Alexander Tsygankov (Lewis Katz School of Medicine, Temple University), Omid Veiseh (Rice University), Debby Walser-Kuntz (Carleton College).

About the Authors

Kenneth Murphy is the Eugene Opie First Centennial Professor in the Department of Pathology & Immunology, Washington University School of Medicine in St. Louis. His research focuses on how the immune system selects the correct type of response appropriate for eliminating different kinds of pathogens.

Casey Weaver is the Wyatt and Susan Haskell Chair of Medical Excellence in the Department of Pathology at the University of Alabama at Birmingham Heersink School of Medicine. His research is focused on mechanisms by which CD4 T cells diverge along different developmental paths and how these cells contribute to host defense or are dysregulated in immune-mediated disease.



Leslie Berg is Professor and Chair of the Department of Immunology & Microbiology at the University of Colorado Anschutz School of Medicine. Her research focuses on understanding T-cell receptor signaling and how variations in T-cell receptor signal strength regulate T-cell development, activation, and effector-cell differentiation.

PART I AN INTRODUCTION TO IMMUNOBIOLOGY AND INNATE IMMUNITY

Chapter 1 Basic Concepts in Immunology 1

The origins of vertebrate immune cells. 2

Principles of innate immunity. 3
1-1 Commensal organisms cause little host damage while pathogens damage host tissues by a variety of mechanisms. 3
1-2 Anatomic and chemical barriers are the first defense against pathogens. 5
1-3 The immune system is activated by inflammatory inducers that indicate the presence of pathogens or tissue damage. 6
1-4 The myeloid lineage comprises most of the cells of the innate immune system. 7
1-5 Sensor cells express pattern-recognition receptors that provide an initial discrimination between self and nonself. 8
1-6 Sensor cells induce an inflammatory response by producing mediators such as chemokines and cytokines. 9
1-7 Innate lymphoid cells and natural killer cells are effector cells that share similarities with lymphoid lineages of the adaptive immune system. 11
Summary. 11

Principles of adaptive immunity. 11
1-8 The interaction of antigens with antigen receptors induces lymphocytes to acquire effector and memory activity. 12
1-9 Antibodies and T-cell receptors are composed of constant and variable regions that provide distinct functions. 13
1-10 Antibodies and T-cell receptors recognize antigens by fundamentally different mechanisms. 13
1-11 Antigen-receptor genes are assembled by somatic gene rearrangements of incomplete receptor gene segments. 14
1-12 Lymphocytes activated by antigen give rise to clones of antigen-specific effector cells that mediate adaptive immunity. 15
1-13 Lymphocytes with self-reactive receptors are normally eliminated during development or are functionally inactivated. 16
1-14 Lymphocytes mature in the bone marrow or the thymus and then congregate in lymphoid tissues throughout the body. 16
1-15 Adaptive immune responses are initiated by antigen and antigen-presenting cells in peripheral lymphoid tissues. 17
1-16 Lymphocytes encounter and respond to antigen in the peripheral lymphoid organs. 18
1-17 Mucosal surfaces have specialized immune structures that orchestrate responses to environmental microbial encounters. 20
1-18 Lymphocytes activated by antigen proliferate in the peripheral lymphoid organs, generating effector cells and immunological memory. 22
Summary. 24

The effector mechanisms of immunity. 25
1-19 Innate immune responses can select from several effector modules to protect against different types of pathogens. 26
1-20 Antibodies protect against extracellular pathogens and their toxic products. 27
1-21 T cells orchestrate cell-mediated immunity and regulate B-cell responses to most antigens. 29
1-22 Inherited and acquired defects in the immune system result in increased susceptibility to infection. 31
1-23 Understanding adaptive immune responses is important for the control of allergies, autoimmune disease, and the rejection of transplanted organs. 32
1-24 Vaccination is the most effective means of controlling infectious diseases. 33
1-25 Emerging pathogens present new challenges for the immune system. 33
Summary. 34
Summary to Chapter 1. 35
References. 35

Chapter 2 Innate Immunity: The First Lines of Defense 37

Anatomic barriers and initial chemical defenses. 38
2-1 Infectious diseases are caused by diverse living agents that replicate in their hosts. 38
2-2 Epithelial surfaces of the body provide the first barrier against infection. 42
2-3 Infectious agents must overcome innate host defenses to establish a focus of infection. 44
2-4 Epithelial cells and phagocytes produce several kinds of antimicrobial molecules. 45
Summary. 49

The complement system and innate immunity. 49
2-5 The complement system recognizes features of microbial surfaces and marks them for destruction by coating them with C3b. 51
2-6 The lectin pathway uses soluble receptors that recognize microbial surfaces to activate the complement cascade. 54
2-7 The classical pathway is initiated by activation of the C1 complex and is homologous to the lectin pathway. 57
2-8 Complement activation is largely confined to the surface on which it is initiated. 58

2-9 The alternative pathway is an amplification loop for C3b formation that is accelerated by properdin in the presence of pathogens. 59
2-10 Membrane and plasma proteins that regulate the formation and stability of C3 convertases determine the extent of complement activation. 61
2-11 Complement developed early in the evolution of multicellular organisms. 62
2-12 Surface-bound C3 convertase deposits large numbers of C3b fragments on pathogen surfaces and generates C5 convertase activity. 63
2-13 Ingestion of complement-tagged pathogens by phagocytes is mediated by receptors for the bound complement proteins. 64
2-14 The small fragments of some complement proteins initiate a local inflammatory response. 66
2-15 The terminal complement proteins polymerize to form pores in membranes that can kill certain pathogens. 66
2-16 Complement-control proteins regulate all three pathways of complement activation and protect the host from their destructive effects. 68
2-17 Genetic and acquired disorders in complement regulation can produce various inflammatory conditions. 71
2-18 Pathogens produce several types of proteins that can inhibit complement activation. 73

Chapter 3 Cellular Mechanisms of Innate Immunity 79

Pathogen recognition by cells of the innate immune system. 79
3-1 After entering tissues, many microbes are recognized, ingested, and killed by phagocytes. 80
3-2 G protein–coupled receptors on phagocytes link microbe recognition with increased efficiency of intracellular killing. 83
3-3 Microbial recognition and tissue damage initiate an inflammatory response. 87
3-4 Toll-like receptors represent an ancient pathogen-recognition system. 90
3-5 Mammalian Toll-like receptors are activated by many different pathogen-associated molecular patterns. 90
3-6 TLR-4 recognizes bacterial lipopolysaccharide in association with the host accessory proteins MD-2 and CD14. 94
3-7 TLRs activate NFκB, AP-1, and IRF transcription factors to induce the expression of inflammatory cytokines and type I interferons. 95
3-8 The RIG-I–like receptors detect cytoplasmic viral RNAs and activate MAVS to induce type I interferon production and pro-inflammatory cytokines. 96
3-9 Cytosolic DNA activates the cGAS–STING pathway to induce production of type I interferons. 100
3-10 NLRs comprise a large family of intracellular sensors with diverse functions. 102
3-11 Certain NLR proteins react to infection or cellular damage by forming an inflammasome that induces cell death and secretion of inflammatory cytokines. 103
3-12 Activation of innate sensors in macrophages and dendritic cells triggers changes in gene expression that have far-reaching effects on the immune response. 106
3-13 Toll signaling in *Drosophila* is downstream of a distinct set of pathogen-recognition molecules. 107
3-14 TLR and NOD genes have undergone extensive diversification in both invertebrates and some primitive chordates. 108
Summary. 109

Consequences of innate immune activation. 109
3-15 Cytokines and their receptors fall into distinct families of structurally related proteins. 110
3-16 Cytokine receptors of the hematopoietin superfamily are associated with the JAK family of tyrosine kinases, which activate STAT transcription factors. 112
3-17 Chemokines released by macrophages and dendritic cells recruit effector cells to sites of infection. 114
3-18 Cell-adhesion molecules control interactions between leukocytes and endothelial cells during an inflammatory response. 116
3-19 Neutrophils make up the first wave of cells that cross the blood vessel wall to enter an inflamed tissue. 118
3-20 TNF-α is an important cytokine that triggers local containment of infection but induces shock when released systemically. 120
3-21 Cytokines made by macrophages and dendritic cells induce a systemic reaction known as the acute-phase response. 122
3-22 Interferons induced by viral infection make several contributions to host defense. 124
3-23 Several types of innate lymphoid cells provide protection in early infection. 126
3-24 NK cells are activated by type I interferon and macrophage-derived cytokines. 128
3-25 NK cells express activating and inhibitory receptors to distinguish between healthy and infected cells. 129
3-26 NK-cell receptors belong to several structural families. 130
3-27 NK cells express activating receptors that recognize ligands induced on infected cells or tumor cells. 133
Summary. 134
Summary to Chapter 3. 134
Discussion questions. 135

PART II THE RECOGNITION OF ANTIGEN

Chapter 4 Antigen Recognition by B-cell and T-cell Receptors 141

The structure of a typical antibody molecule. 142
4-1 IgG antibodies consist of four polypeptide chains. 143
4-2 Immunoglobulin heavy and light chains are composed of constant and variable regions. 144

4-3 The domains of an immunoglobulin molecule have similar structures. 144
4-4 The antibody molecule can readily be cleaved into functionally distinct fragments. 146
4-5 The hinge region of the immunoglobulin molecule allows flexibility in binding to multiple antigens. 147
Summary. 147

Structural variation in immunoglobulin constant regions. 148
4-6 Different classes of immunoglobulins are distinguished by the structure of their heavy-chain constant regions. 148
4-7 The constant region confers functional specialization on the antibody. 150
4-8 IgM and IgA can form polymers by interacting with the J chain. 151
Summary. 152

The interaction of the antibody molecule with specific antigen. 152
4-9 Localized regions of hypervariable sequence form the antigen-binding site. 152
4-10 Antibodies bind antigens via contacts in CDRs that are complementary to the size and shape of the antigen. 153
4-11 Antibodies bind to conformational shapes on the surfaces of antigens using a variety of noncovalent forces. 155
4-12 Antibody interaction with intact antigens is influenced by steric constraints. 156
4-13 Some species generate antibodies with alternative structures. 157
Summary. 158

Antigen recognition by T cells. 159
4-14 The TCR$\alpha\beta$ heterodimer is very similar to a Fab fragment of immunoglobulin. 159
4-15 A T-cell receptor recognizes antigen in the form of a complex of a foreign peptide bound to an MHC molecule. 161
4-16 There are two classes of MHC molecules with distinct subunit compositions but similar three-dimensional structures. 162
4-17 Peptides are stably bound to MHC molecules and also serve to stabilize the MHC molecule on the cell surface. 164
4-18 MHC class I molecules bind short peptides of 8–10 amino acids by both ends. 165
4-19 The length of the peptides bound by MHC class II molecules is not constrained. 166
4-20 The crystal structures of several peptide:MHC:T-cell receptor complexes show a similar orientation of the T-cell receptor over the peptide:MHC complex. 168
4-21 The CD4 and CD8 cell-surface proteins of T cells directly contact MHC molecules and are required to make an effective response to antigen. 169
4-22 The two classes of MHC molecules are expressed differentially on cells. 172
4-23 A distinct subset of T cells bears an alternative receptor made up of γ and δ chains. 173
Summary. 174
Summary to Chapter 4. 174
Discussion questions. 175

Chapter 5 The Generation of Lymphocyte Antigen Receptors 179

Primary immunoglobulin gene rearrangements and expression. 180
5-1 Complete immunoglobulin genes are generated by the somatic recombination of separate gene segments. 180
5-2 Multiple contiguous V gene segments are present at each immunoglobulin locus. 182
5-3 Rearrangement of V, D, and J gene segments is guided by flanking DNA sequences. 184
5-4 The reaction that recombines V, D, and J gene segments involves both lymphocyte-specific and ubiquitous DNA-modifying enzymes. 189
5-5 The diversity of the immunoglobulin repertoire is generated by four main processes. 190
5-6 The multiple inherited gene segments are used in different combinations. 191
5-7 Variable addition and subtraction of nucleotides at the junctions between gene segments contributes to the diversity of the third hypervariable region. 191
5-8 IgM and IgD are derived from the same pre-mRNA transcript and are both expressed on the surface of mature B cells. 193
5-9 Transmembrane and secreted forms of immunoglobulin are generated from different heavy-chain mRNA transcripts. 194
Summary. 196

T-cell receptor gene rearrangement. 196
5-10 The T-cell receptor gene segments are arranged in a pattern similar to that of immunoglobulin gene segments and are rearranged by the same enzymes. 196
5-11 T-cell receptors concentrate diversity in the third hypervariable region. 199
5-12 $\gamma\delta$ T-cell receptors are also generated by gene rearrangement. 200
Summary. 201

Evolution of the adaptive immune response. 201
5-13 Some invertebrates generate extensive diversity in a repertoire of immunoglobulin-like genes. 202
5-14 Agnathans possess an adaptive immune system that uses somatic gene rearrangement to diversify receptors built from LRR domains. 203
5-15 RAG-dependent adaptive immunity based on a diversified repertoire of immunoglobulin-like genes appeared abruptly in the cartilaginous fishes. 205
5-16 Different species generate immunoglobulin diversity in different ways. 207
5-17 Both $\alpha\beta$ and $\gamma\delta$ T-cell receptors are present in cartilaginous fishes. 210
5-18 MHC class I and class II molecules are also first found in the cartilaginous fishes. 210
Summary. 211
Summary to Chapter 5. 211

Discussion questions. 212

Chapter 6 Antigen Presentation to T Lymphocytes 217

The generation of αβ T-cell receptor ligands. 218
6-1 Antigen presentation functions both in arming effector T cells and in triggering their effector functions to attack pathogen-infected cells. 218
6-2 Peptides are generated from ubiquitinated proteins in the cytosol by the proteasome. 220
6-3 Peptides from the cytosol are transported by TAP into the endoplasmic reticulum and further processed before binding to MHC class I molecules. 222
6-4 Newly synthesized MHC class I molecules are retained in the endoplasmic reticulum until they bind a peptide. 224
6-5 Dendritic cells use cross-presentation to present exogenous proteins on MHC class I molecules so as to prime CD8 T cells. 226
6-6 Peptide:MHC class II complexes are generated in acidified endocytic vesicles from proteins obtained through endocytosis, phagocytosis, and autophagy. 227
6-7 The invariant chain directs newly synthesized MHC class II molecules to acidified intracellular vesicles. 229
6-8 The MHC class II–like molecules HLA-DM and HLA-DO regulate exchange of CLIP for other peptides. 230
6-9 Cessation of MHC class II antigen processing occurs after dendritic-cell activation through reduced expression of the MARCH-1 E3 ligase. 233
Summary. 234

The major histocompatibility complex and its function. 235
6-10 Many proteins involved in antigen processing and presentation are encoded by genes within the MHC. 235
6-11 The protein products of MHC class I and class II genes are highly polymorphic. 238
6-12 MHC polymorphism affects antigen recognition by T cells by influencing both peptide binding and the contacts between the T-cell receptor and MHC molecule. 240
6-13 Alloreactive T cells recognizing nonself MHC molecules are very abundant. 243
6-14 Many T cells respond to superantigens. 245
6-15 MHC polymorphism extends the range of antigens to which the immune system can respond. 246
Summary. 246

Recognition of nonpeptide ligands by unconventional T-cell subsets. 247
6-16 A variety of genes with specialized functions in immunity are also encoded in the MHC. 247
6-17 Specialized MHC class I molecules act as ligands for the activation and inhibition of NK cells and unconventional T-cell subsets. 249
6-18 Members of the CD1 family of MHC class I–like molecules present lipid-based antigens to NKT cells. 251
6-19 The nonclassical MHC class I molecule MR1 presents microbial riboflavin metabolites to MAIT cells. 253
6-20 γδ T cells can recognize a variety of diverse ligands. 254
Summary. 255
Summary to Chapter 6. 255
Discussion questions. 256

PART III THE DEVELOPMENT OF MATURE LYMPHOCYTE RECEPTOR REPERTOIRES

Chapter 7 Lymphocyte Receptor Signaling 261

General principles of signal transduction and propagation. 261
7-1 Transmembrane receptors convert extracellular signals into intracellular biochemical events. 262
7-2 Intracellular signal propagation is mediated by large multiprotein signaling complexes. 263
7-3 Small G proteins act as molecular switches in many different signaling pathways. 264
7-4 Signaling proteins are recruited to the membrane by a variety of mechanisms. 265
7-5 Post-translational modifications of proteins can both activate and inhibit signaling responses. 266
7-6 The activation of many receptors generates small-molecule second messengers. 267
Summary. 268

Antigen receptor signaling and lymphocyte activation. 268
7-7 Antigen receptors consist of variable antigen-binding chains associated with invariant chains that carry out the signaling function of the receptor. 268
7-8 Antigen recognition by the T-cell receptor and its co-receptors transduces a signal across the plasma membrane to initiate signaling. 270
7-9 Antigen recognition by the T-cell receptor and its co-receptors leads to phosphorylation of ITAMs by Src family kinases, generating the first intracellular signal in a signaling cascade. 272
7-10 Phosphorylated ITAMs recruit and activate the tyrosine kinase ZAP-70. 273
7-11 ITAMs are also found in other receptors on leukocytes that signal for cell activation. 274
7-12 Activated ZAP-70 phosphorylates adaptor proteins and promotes PI 3-kinase activation. 275
7-13 Activated PLC-γ generates the second messengers diacylglycerol and inositol trisphosphate that lead to transcription factor activation. 276
7-14 Ca^{2+} entry activates the transcription factor NFAT. 277
7-15 Ras activation stimulates the mitogen-activated protein kinase (MAPK) relay and induces expression of the transcription factor AP-1. 278
7-16 Protein kinase C activates the transcription factors NFκB and AP-1. 280
7-17 PI 3-kinase activation up-regulates cellular metabolic pathways via the serine/threonine kinase Akt. 281
7-18 T-cell receptor signaling leads to enhanced integrin-mediated cell adhesion. 283
7-19 T-cell receptor signaling induces cytoskeletal reorganization by activating the small GTPase Cdc42. 283
7-20 The logic of B-cell receptor signaling is similar to that of T-cell receptor signaling, but some of the signaling components are specific to B cells. 285

7-21 Antigen receptor signaling is a dynamic process that evolves over time. 287
Summary. 288
Co-stimulatory and inhibitory receptors modulate antigen receptor signaling in T and B lymphocytes. 288
7-22 The cell-surface protein CD28 is a required co-stimulatory signaling receptor for naive T-cell activation. 289
7-23 Maximal activation of PLC-γ, which is important for transcription factor activation, requires a co-stimulatory signal induced by CD28. 290
7-24 TNF receptor superfamily members augment T-cell and B-cell activation. 291
7-25 Inhibitory receptors on lymphocytes down-regulate immune responses by interfering with co-stimulatory signaling pathways. 292
7-26 Inhibitory receptors on lymphocytes down-regulate immune responses by recruiting protein or lipid phosphatases. 293
7-27 Knowledge of lymphocyte receptor signaling pathways can be exploited to engineer chimeric antigen receptors. 295
Summary. 296
Summary to Chapter 7. 297
Discussion questions. 297
References. 298

Chapter 8 The Development of B and T Lymphocytes 301

Development of B lymphocytes. 303
8-1 Lymphocytes derive from hematopoietic stem cells in the bone marrow. 303
8-2 Commitment to B cell, T cell, or innate lymphoid cell lineages is regulated by distinct networks of transcription factors. 305
8-3 B-cell development begins by rearrangement of the heavy-chain locus. 305
8-4 The pre-B-cell receptor tests for successful production of a complete heavy chain and signals for the transition from the pro-B cell to the pre-B cell stage. 308
8-5 Pre-B-cell receptor signaling inhibits further heavy-chain locus rearrangement and enforces allelic exclusion. 310
8-6 Pre-B cells rearrange the light-chain locus and express cell-surface immunoglobulin. 310
8-7 Immature B cells are tested for autoreactivity before they leave the bone marrow. 312
8-8 Lymphocytes that encounter sufficient quantities of self antigens in the periphery are eliminated. 313
8-9 Newly formed B cells arriving in the spleen turn over rapidly and require cytokines and positive signals through the B-cell receptor for maturation and long-term survival. 314
8-10 B-1 B cells are an innate lymphocyte subset that arises early in development. 316
Summary. 317
Development of T lymphocytes. 319
8-11 T-cell progenitors originate in the bone marrow, but all the important events in T-cell development occur in the thymus. 320
8-12 T-cell precursors proliferate extensively in the thymus, but most die there. 321
8-13 Successive stages in the development of thymocytes are marked by changes in cell-surface molecules. 321
8-14 Commitment to the T-cell lineage occurs in the thymus after Notch signaling. 322
8-15 After T-cell commitment, thymocyte development is regulated by T-cell receptor rearrangement, expression, and signaling. 325
8-16 Thymocytes at different developmental stages are found in distinct parts of the thymus. 326
8-17 T cells with αβ or γδ receptors arise from a common progenitor. 326
8-18 T cells expressing γδ T-cell receptors arise in two distinct phases during development. 327
8-19 Successful synthesis of a rearranged β chain allows the production of a pre-T-cell receptor that triggers cell proliferation and blocks further β-chain gene rearrangement. 329
8-20 T-cell α-chain genes undergo successive rearrangements until positive selection or cell death intervenes. 331
Summary. 332
Positive and negative selection of T cells. 333
8-21 Overview of positive and negative selection of αβ lineage T cells. 333
8-22 Only thymocytes whose receptors interact with self peptide:self MHC complexes can survive and mature. 334
8-23 Positive selection coordinates the expression of CD4 or CD8 with the specificity of the T-cell receptor and the potential effector functions of the T cell. 335
8-24 Thymic cortical epithelial cells mediate positive selection of developing thymocytes. 337
8-25 T cells that react strongly with self antigens are deleted in the thymus. 338
8-26 The specificity and/or the strength of signals for negative and positive selection must differ. 339
8-27 αβ T cells diverge into multiple lineages at the $CD4^+$ and $CD8^+$ single-positive stage in the thymic medulla. 339
8-28 Thymic emigration is controlled by signaling through a G protein–coupled receptor. 340
8-29 T cells that encounter sufficient quantities of self antigens for the first time in the periphery are eliminated or inactivated. 341
Summary. 341
Summary to Chapter 8. 341
Discussion questions. 342
References. 343

PART IV THE ADAPTIVE IMMUNE RESPONSE

Chapter 9 T Cell–Mediated Immunity 347

Development and function of secondary lymphoid organs—sites for the initiation of adaptive immune responses. 349
9-1 Secondary lymphoid structures are specialized to facilitate the interaction of circulating T and B lymphocytes with antigen. 349

9-2 The development of secondary lymphoid tissues is initiated by lymphoid tissue inducer cells and cytokines of the tumor necrosis factor family. 351
9-3 T-cell entry into lymphoid tissues occurs across specialized small blood vessels and is mediated by the sequential actions of adhesion molecules and chemokine receptors. 353
9-4 T cells are highly motile within T-cell zones as they survey dendritic cells for cognate antigen. 356
9-5 The exit of T cells from T-cell zones of lymphoid tissues is controlled by a chemotactic lipid. 357
9-6 Activation of conventional dendritic cells stimulates their maturation and migration to T-cell zones to induce naive T-cell activation. 359
9-7 Subsets of conventional dendritic cells are specialized for different modes of antigen presentation. 364
Summary. 366
Naive T-cell activation, clonal expansion, and differentiation into effector and memory T cells. 367
9-8 Conventional dendritic cells deliver multiple signals for the activation of naive T cells. 368
9-9 T-cell activation induces metabolic changes that prepare the T cell for rapid clonal expansion and differentiation. 369
9-10 The rapid expression of interleukin-2 and the high-affinity component of its receptor allow activated T cells to respond to this cytokine coincident with entry into the cell cycle. 372
9-11 Additional co-stimulatory and inhibitory receptors are engaged after initial T-cell activation to control clonal expansion and contraction. 373
9-12 Proliferating T cells differentiate into effector T cells that are programmed for altered tissue homing and loss of a requirement for co-stimulation to act. 375
9-13 CD8 T cells can be activated in different ways to become cytotoxic effector cells. 376
9-14 CD4 T cells differentiate into several functionally distinct subsets. 378
9-15 Cytokines play a central role in guiding the differentiation of CD4 T cells down distinct pathways. 381
9-16 CD4 T-cell subsets can cross-regulate each other's differentiation through the cytokines they produce. 385
9-17 Regulatory T cells are a subset of CD4 T cells that restrains immune responses to maintain self-tolerance. 386
Summary. 388
General properties of effector T cells and their cytokines. 389
9-18 An immunological synapse can form between effector T cells and their targets to direct the release of effector molecules. 389
9-19 The effector functions of T cells are determined by the array of effector molecules they produce, which can act locally or at a distance. 391
9-20 Effector T cells express several TNF family cytokines. 392
Summary. 394
T cell–mediated cytotoxicity. 394
9-21 Cytotoxic T cells induce target cells to undergo programmed cell death via extrinsic or intrinsic pathways of apoptosis. 394
9-22 Cytotoxic effector proteins that trigger apoptosis are contained in the granules of cytotoxic CD8 T cells. 398
9-23 Cytotoxic T cells are selective serial killers of targets expressing a specific antigen. 399
9-24 Cytotoxic T cells also act by releasing cytokines. 400
Summary. 400
Summary to Chapter 9. 400
Discussion questions. 401
References. 402
Chapter 10 The Humoral Immune Response 405
B-cell activation by antigen and helper T cells. 406
10-1 Activation of B cells by antigen involves signals from the B-cell receptor and either helper T cells or microbial antigens. 406
10-2 Linked recognition of antigen by T cells and B cells promotes robust antibody responses. 408
10-3 B cells that encounter their antigens migrate toward the boundaries between B-cell and T-cell areas in secondary lymphoid tissues. 409
10-4 T cells express surface molecules and cytokines that activate B cells, which in turn promote T_{FH} cell development. 412
10-5 Some activated B cells differentiate into antibody-secreting plasmablasts and plasma cells. 413
10-6 The second phase of a primary B-cell immune response occurs when activated B cells migrate into follicles and proliferate to form germinal centers. 414
10-7 Germinal center B cells undergo V-region somatic hypermutation, and cells with mutations that improve affinity for antigen are selected. 417
10-8 Positive selection of germinal center B cells involves contact with T_{FH} cells and CD40 signaling. 419
10-9 Activation-induced cytidine deaminase introduces mutations into genes transcribed in B cells. 420
10-10 Mismatch and base-excision repair pathways contribute to somatic hypermutation after initiation by AID. 421
10-11 AID initiates class switching to allow the same assembled V_H exon to be associated with different C_H genes in the course of an immune response. 423
10-12 Cytokines made by T_H cells direct the choice of isotype for class switching in T-dependent antibody responses. 425
10-13 B cells that survive the germinal center reaction eventually differentiate into either plasma cells or memory cells. 426
10-14 Some antigens do not require T-cell help to induce antibody responses. 427
Summary. 429
The distributions and functions of immunoglobulin classes. 430
10-15 Antibodies of different classes operate in distinct places and have distinct effector functions. 431
10-16 Polymeric immunoglobulin receptor binds to the Fc regions of IgA and IgM and transports them across epithelial barriers. 432
10-17 The neonatal Fc receptor carries IgG across the placenta and prevents IgG excretion from the body. 433
10-18 High-affinity IgG and IgA antibodies can neutralize toxins and block the infectivity of viruses and bacteria. 434

10-19 Antigen:antibody complexes activate the classical pathway of complement by binding to C1q. 436
10-20 Complement receptors and Fc receptors both contribute to removal of immune complexes from the circulation. 438
Summary. 439
The destruction of antibody-coated pathogens via Fc receptors. 440
10-21 The Fc receptors of accessory cells are signaling receptors specific for immunoglobulins of different classes. 440
10-22 Fc receptors on phagocytes are activated by antibodies bound to the surface of pathogens and enable the phagocytes to ingest and destroy pathogens. 441
10-23 Fc receptors activate NK cells to destroy antibody-coated targets. 443
10-24 Mast cells and basophils bind IgE antibody via the high-affinity Fcε receptor. 444
10-25 IgE-mediated activation of accessory cells has an important role in resistance to parasite infection. 445
Summary. 446
Summary to Chapter 10. 446
Discussion questions. 447
References. 448
Chapter 11 Integrated Dynamics of Innate and Adaptive Immunity 453
Integration of innate and adaptive immunity in response to specific types of pathogens. 454
11-1 The course of an infection can be divided into several distinct phases. 454
11-2 The effector mechanisms that are recruited to clear an infection can be organized into immune modules. 458
11-3 Subsets of ILCs are early responders of the immune response. 460
Summary. 462
Effector CD4 T cells augment the effector functions of innate immune cells. 462
11-4 Effector T cells are guided to specific tissues and sites of infection by changes in their expression of adhesion molecules and chemokine receptors. 463
11-5 Pathogen-specific effector T cells are progressively enriched at sites of infection where they may undergo further maturation to acquire full effector function. 467
11-6 T_H1 cells coordinate and amplify the host response to intracellular pathogens through classical activation of macrophages. 467
11-7 Activation of macrophages by T_H1 cells must be tightly regulated to avoid tissue damage. 469
11-8 Chronic activation of macrophages by T_H1 cells mediates the formation of granulomas to contain intracellular pathogens that cannot be cleared. 471
11-9 Defects in type 1 immunity reveal its important role in the elimination of intracellular pathogens. 471
11-10 T_H2 cells coordinate type 2 responses to expel intestinal helminths and repair tissue injury. 472
11-11 T_H17 cells coordinate type 3 responses to enhance the clearance of extracellular bacteria and fungi. 475
11-12 Effector T cells continue to respond to maturational and maintenance signals as they carry out their effector functions in target tissues. 476
11-13 Effector T cells can be activated to release cytokines independently of antigen recognition. 478
11-14 Effector CD4 T cells demonstrate plasticity and cooperativity that enable adaptation during antipathogen responses. 479
11-15 Integration of cell- and antibody-mediated immunity is critical for protection against many types of pathogens. 480
11-16 Resolution of an infection is accompanied by the death of most effector T cells and persistence of a small number of long-lived memory T cells. 482
Summary. 483
Immunological memory. 484
11-17 Immunological memory is long lived after infection or vaccination. 484
11-18 MHC tetramers and adoptive transfers of clonal T-cell populations have enabled the study of T-cell memory. 485
11-19 The developmental origins of memory T cells parallel those of effector T cells. 486
11-20 Memory T cells are heterogeneous and include central memory, effector memory, and tissue-resident subsets. 488
11-21 Circulating memory T cells acquire heightened sensitivity to IL-7 and/or IL-15 and undergo metabolic reprogramming to survive long-term. 491
11-22 CD4 T-cell help is required for CD8 T-cell memory and involves CD40 and IL-2 signaling. 492
11-23 Memory B-cell responses are more rapid and have higher affinity for antigen compared with responses of naive B cells. 494
11-24 Memory B cells can reenter germinal centers and undergo additional somatic hypermutation and affinity maturation during secondary immune responses. 496
11-25 In immune individuals, secondary and subsequent responses are mainly attributable to memory lymphocytes. 496

Chapter 12 The Barrier Immune System 505
Organization of the mucosal immune system. 505
12-1 The mucosal immune system protects the internal surfaces of the body. 506
12-2 Immune cells of the mucosal immune system are located both within and outside of specialized lymphoid tissues in proximity to the epithelium. 510
12-3 Maturation of the gut-associated lymphoid tissue is driven by acquisition of the commensal microbiota. 516
Summary. 519
Innate immune defenses of the intestinal immune system. 520
12-4 The intestines are lined by a diversity of epithelial cell types that develop from a common progenitor and play distinct roles in mucosal immunity. 520

12-5 The intestinal epithelium contains conventional and unconventional T cells that are focused on barrier maintenance and defense. 528
12-6 Innate lymphoid cells and unconventional lymphocytes are present in GALT and in the lamina propria and are rapid responders to microbes that breach the epithelium. 534
Summary. 535
The role of adaptive immunity in regulating the intestinal mucosal immune system at homeostasis. 536
12-7 The mucosal immune system must establish and maintain tolerance to harmless foreign antigens. 536
12-8 Macrophages and dendritic cells have complementary roles in the maintenance of immune tolerance in the intestines. 537
12-9 The intestines have multiple routes for uptake and delivery of antigen to antigen-presenting cells. 540
12-10 Intestinal dendritic cells favor the induction of antigen-specific T_{reg} cells that are critical for the maintenance of mucosal immune homeostasis. 543
12-11 Lymphocytes primed within the mucosal immune system are directed to return to the mucosal tissue by tissue-specific adhesion molecules and chemokine receptors. 546
12-12 Secretory IgA is the dominant class of antibody associated with the mucosal immune system at homeostasis. 547
12-13 T cell–independent processes can contribute to IgA production in some species. 550
12-14 IgA deficiency is relatively common in humans but may be compensated for by secretory IgM. 551
12-15 Large numbers of antigen-experienced T cells are present in the intestinal lamina propria even in the absence of disease. 551
12-16 Priming of lymphocytes in one mucosal tissue may induce protective immunity at other mucosal surfaces. 552
Summary. 553
The intestinal immune response in host defense and immune-mediated disease. 553
12-17 Enteric pathogens elicit 'danger signals' by activating pattern-recognition receptors that are sequestered in the intestinal epithelium. 554
12-18 Pathogens induce inflammatory adaptive immune responses when innate defenses have been breached. 556
12-19 Effector T-cell responses in the intestine protect the function of the epithelium. 557
12-20 Noninvasive and invasive enteric bacterial pathogens use different strategies to colonize the intestines. 557
12-21 Dysregulated immune responses to commensal bacteria provoke intestinal disease. 563
Summary. 564
Immunity at other barrier tissues. 564
12-22 Anatomy and mucosal immunity of the airways. 564
12-23 Respiratory immunity to inhaled pathogens; respiratory viruses. 567
12-24 Cutaneous immunity. 574
12-25 The sensory nervous system communicates with the immune system to enhance defense against infections in the skin. 577

PART V THE IMMUNE SYSTEM IN HEALTH AND DISEASE

Chapter 13 Failures of Host Defense Mechanisms 587
Immunodeficiency diseases. 588
13-1 Primary immunodeficiency diseases are caused by inherited gene variants that typically cause recurrent infections early in life. 588
13-2 Defects in T-cell development can result in severe combined immune deficiencies. 589
13-3 SCID can also be due to defects in the purine salvage pathway. 592
13-4 Defects in antigen receptor gene rearrangement can result in SCID. 593
13-5 Defects in signaling from T-cell antigen receptors can cause severe immunodeficiency. 594
13-6 Genetic defects in thymic development or function that block T-cell development result in combined immunodeficiencies. 594
13-7 Defects in B-cell development result in deficiencies in antibody production that cause an inability to clear extracellular bacteria. 596
13-8 Combined immunodeficiencies (CIDs) can be caused by defects in T-cell differentiation and function that impair activation of B cells, dendritic cells and macrophages, and innate effector cells. 598
13-9 B cell–specific activation defects cause hyper IgM syndromes that are limited to defects in the antibody response. 600
13-10 Common variable immunodeficiency results from a variety of inherited defects that cause more limited defects in the antibody response. 600
13-11 Unidentified genetic defects cause isotype-specific antibody deficiencies. 601
13-12 Normal pathways for host defense against different infectious agents are pinpointed by genetic deficiencies of cytokine pathways central to type 1/T_H1 and type 3/T_H17 responses. 601
13-13 Inherited defects in the cytolytic pathway of lymphocytes can cause uncontrolled lymphoproliferation and inflammatory responses to viral infections. 603
13-14 X-linked lymphoproliferative syndrome is associated with fatal infection by Epstein–Barr virus and the development of lymphomas. 605
13-15 Immunodeficiency is caused by inherited defects in the development of dendritic cells. 606
13-16 Defects in complement components and complement-regulatory proteins cause defective humoral immune function and tissue damage. 607
13-17 Defects in phagocytic cells result in widespread bacterial infections. 608
13-18 Mutations in the molecular regulators of inflammation can cause uncontrolled inflammatory responses that result in 'autoinflammatory disease.' 612

13-19 Factor-replacement therapies, hematopoietic stem-cell transplantation, and gene therapy can be used successfully to correct genetic defects. 613
13-20 Noninherited, secondary immunodeficiencies are major predisposing causes of infection and death. 615
Summary. 616
Evasion and subversion of immune defenses. 616
13-21 Extracellular bacterial pathogens have evolved different strategies to avoid detection by pattern-recognition receptors and destruction by antibody, complement, and antimicrobial peptides. 617
13-22 Intracellular bacterial pathogens can evade the immune system by seeking shelter within phagocytes. 622
13-23 Immune evasion is also practiced by protozoan parasites. 623
13-24 Many viruses target type I and type III interferon pathways to impair host antiviral defense. 625
13-25 RNA viruses use different mechanisms of antigenic variation to keep a step ahead of the adaptive immune system. 625
13-26 DNA viruses use multiple mechanisms to subvert CTL and NK-cell responses. 628
13-27 Viruses that establish latency persist *in vivo* by ceasing to replicate until immunity wanes. 631
13-28 DNA and RNA viruses can induce exhaustion of CTL and NK cell responses, thereby impairing the antiviral response. 633
Summary. 633
Acquired immune deficiency syndrome. 634
13-29 HIV is a retrovirus that establishes a chronic infection that slowly progresses to AIDS. 636
13-30 HIV infects and replicates within cells of the immune system. 636
13-31 Activated CD4 T cells are the major source of HIV replication. 638
13-32 There are several routes by which HIV is transmitted and establishes infection. 641
13-33 HIV variants with tropism for different co-receptors play different roles in transmission and progression of disease. 641
13-34 A genetic deficiency of the co-receptor CCR5 confers resistance to HIV infection. 644
13-35 An immune response controls but does not eliminate HIV. 644
13-36 Lymphoid tissue is the major reservoir of HIV infection. 646
13-37 Genetic variation in the host can alter the rate of HIV disease progression. 647
13-38 The destruction of immune function as a result of HIV infection leads to increased susceptibility to opportunistic infection and eventually to death. 649
13-39 Drugs that block HIV replication lead to a rapid decrease in titer of infectious virus and an increase in CD4 T cells. 649
13-40 In the course of infection, HIV accumulates many mutations, which can result in the outgrowth of drug-resistant variants. 652
13-41 HIV treatment and prophylaxis are leading to a decline in the spread of HIV and AIDS. 652
13-42 Vaccination against HIV remains an attractive solution but poses many difficulties. 653
Summary. 655
Summary to Chapter 13. 656
Discussion questions. 656

Chapter 14 Allergic Diseases and Hypersensitivity Reactions 663
IgE and IgE-mediated allergic diseases. 664
14-1 Sensitization involves class switching to IgE production on first contact with an allergen. 665
14-2 Although many types of antigens can cause allergic sensitization, proteases are common sensitizing agents. 666
14-3 Genetic factors contribute to the development of IgE-mediated allergic disease. 667
14-4 Environmental factors may interact with genetic susceptibility to cause allergic disease. 669
Summary. 671
Effector mechanisms in IgE-mediated allergic reactions. 671
14-5 Most IgE is cell-bound and engages effector mechanisms of the immune system by pathways different from those of other antibody isotypes. 671
14-6 Mast cells reside in tissues and orchestrate allergic reactions. 673
14-7 Eosinophils and basophils cause inflammation and tissue damage in allergic reactions. 675
14-8 IgE-mediated allergic reactions have a rapid onset but can also lead to chronic responses. 677
14-9 Allergen introduced into the bloodstream can cause anaphylaxis and urticaria. 679
14-10 Allergen inhalation is associated with the development of rhinitis and asthma. 681
14-11 Allergy to particular foods causes systemic reactions as well as symptoms limited to the gut. 682
14-12 IgE-mediated allergic disease can be treated by inhibiting effector pathways or by desensitization to restore biological tolerance. 684
Summary. 686
Non-IgE-mediated allergic diseases. 686
14-13 Non-IgE-dependent drug-induced hypersensitivity reactions in susceptible individuals occur by binding of the drug to the surface of circulating blood cells. 687
14-14 Systemic disease caused by immune-complex formation can follow the administration of large quantities of poorly catabolized antigens. 687
14-15 Hypersensitivity reactions can be mediated by T_H1 cells and cytotoxic CD8 T cells. 689
14-16 Celiac disease has features of both an allergic response and autoimmunity. 692
Summary. 694
Summary to Chapter 14. 694
Discussion questions. 695
References. 695
Chapter 15 Autoimmunity and Transplantation 699
The making and breaking of self-tolerance. 699
15-1 Multiple mechanisms normally contribute to prevent autoimmunity. 699

15-2 Lymphocytes that bind self antigens with relatively low affinity usually ignore them but in some circumstances become activated. 702
15-3 Antigens in immunologically privileged sites do not induce immune attack but can serve as targets. 703
15-4 Autoimmune responses can be controlled at various stages by regulatory T cells. 704
Summary. 705
Autoimmune diseases and pathogenic mechanisms. 706
15-5 Autoimmunity can be classified into either organ-specific or systemic disease. 706
15-6 Multiple components of the immune system are typically recruited in autoimmune disease. 707
15-7 Chronic autoimmune disease develops through positive feedback from inflammation, inability to clear the self antigen, and a broadening of the autoimmune response. 709
15-8 Both antibody and effector T cells can cause tissue damage in autoimmune disease. 711
15-9 Autoantibodies against blood cells promote their destruction. 713
15-10 The fixation of sublytic doses of complement to cells in tissues stimulates a powerful inflammatory response. 713
15-11 Autoantibodies against receptors cause disease by stimulating or blocking receptor function. 714
15-12 Autoantibodies against extracellular antigens cause inflammatory injury. 715
15-13 T cells specific for self antigens can cause direct tissue injury and sustain autoantibody responses. 717
Summary. 721
The genetic and environmental basis of autoimmunity. 721
15-14 Autoimmune diseases have a strong genetic component. 722
15-15 Monogenic defects of immune tolerance. 722
15-16 MHC genes have an important role in controlling susceptibility to autoimmune disease. 727
15-17 Genetic variants that impair innate immune responses can predispose to T cell–mediated chronic inflammatory disease. 727
15-18 Cross-reactivity between foreign molecules on pathogens and self molecules can promote autoimmune disease. 730
Summary. 731
Responses to alloantigens and transplant rejection. 732
15-19 Transplant rejection is mediated primarily by T-cell responses to MHC molecules. 732
15-20 Rejection of MHC-identical grafts is caused by peptides from other alloantigens bound to graft MHC molecules. 734
15-21 Alloreactive T cells reject transplanted organs by direct and indirect allorecognition. 735
15-22 Antibodies that react with endothelium cause hyperacute graft rejection. 737
15-23 Late failure of transplanted organs is caused by chronic injury to the graft. 737
15-24 A variety of organs are transplanted routinely in clinical medicine. 738
15-25 The converse of graft rejection is graft-versus-host disease. 740
15-26 The fetus is an allograft that is tolerated repeatedly. 741
Summary. 742
Summary to Chapter 15. 743
Discussion questions. 744

Chapter 16 Manipulation of the Immune Response 749
Fighting infectious diseases with vaccination. 749
16-1 Vaccines can be based on attenuated pathogens or material from killed organisms. 750
16-2 Most effective vaccines generate antibodies that prevent damage caused by toxins or that neutralize pathogens and stop infection. 752
16-3 Effective vaccines must induce long-lasting protection while being safe and inexpensive. 753
16-4 Live-attenuated viral vaccines are usually more potent than 'killed' vaccines. 753
16-5 Live-attenuated viral vaccines can be made safer by the use of recombinant DNA technology. 754
16-6 Vaccines against bacteria or parasites can be developed using nonpathogenic or disabled bacteria or genetically attenuated parasites (GAPs). 755
16-7 Conjugate vaccines rely on linked recognition between T and B cells. 756
16-8 Adjuvants enhance the immunogenicity of vaccines, but few are approved for use in humans. 758
16-9 Protective immunity can be induced by RNA- and DNA-based vaccination. 759
16-10 The route of vaccination is an important determinant of success. 760
16-11 *Bordetella pertussis* vaccination illustrates the importance of the perceived safety of a vaccine. 761
16-12 Peptide-based vaccines can elicit protective immunity, but they require adjuvants and must be targeted to the appropriate cells and cell compartment to be effective. 762
16-13 Vaccination and checkpoint blockade may be useful in controlling existing chronic infections. 763
Summary. 763
Using the immune response to attack tumors. 764
16-14 The development of transplantable tumors in mice led to the discovery of protective immune responses to tumors. 764
16-15 Tumors are 'edited' by the immune system as they evolve and can escape rejection in many ways. 765
16-16 Tumor-rejection antigens can be recognized by T cells and form the basis of immunotherapies. 769
16-17 Checkpoint blockade can augment immune responses to existing tumors. 771
16-18 T cells expressing chimeric antigen receptors are an effective treatment in some leukemias. 773
16-19 Monoclonal antibodies against tumor antigens, alone or linked to toxins, can control tumor growth. 774
16-20 Enhancing the immune response to tumors by vaccination holds promise for cancer prevention and therapy. 776
Summary. 777

Treatment of unwanted immune responses. 778
16-21 Corticosteroids are powerful anti-inflammatory drugs that alter the transcription of many genes. 779
16-22 Cytotoxic drugs cause immunosuppression by killing dividing cells and have serious side effects. 780
16-23 Cyclosporin A, tacrolimus, and rapamycin are effective immunosuppressive agents that interfere with various T-cell signaling pathways. 781
16-24 JAK inhibitors can be used to treat autoimmune and inflammatory diseases. 783
16-25 Antibodies against cell-surface molecules can be used to eliminate lymphocyte subsets or to inhibit lymphocyte function. 783
16-26 Antibodies can be engineered to reduce their immunogenicity in humans. 784
16-27 Monoclonal antibodies can be used to prevent allograft rejection. 785
16-28 Depletion of autoreactive lymphocytes can treat autoimmune disease. 787
16-29 Biologics that block TNF-α, IL-1, or IL-6 can alleviate autoimmune diseases. 788
16-30 Biologics can block cell migration to sites of inflammation and reduce immune responses. 789
16-31 Blockade of co-stimulatory pathways that activate lymphocytes can be used to treat autoimmune disease. 790
16-32 Some commonly used drugs have immunomodulatory properties. 791
16-33 Controlled administration of antigen can be used to manipulate the nature of an antigen-specific response. 791

PART I
AN INTRODUCTION TO IMMUNOBIOLOGY AND INNATE IMMUNITY

1 Basic Concepts in Immunology
2 Innate Immunity: The First Lines of Defense
3 Cellular Mechanisms of Innate Immunity

Basic Concepts in Immunology

1

Immunology is the study of the body's defense against infection. We are continually exposed to microorganisms, many of which cause disease, and yet become ill only rarely. How does the body defend itself? When infection does occur, how does the body eliminate the invader and cure itself? And why do we develop long-lasting immunity to many infectious diseases encountered once and overcome? These are the questions addressed by immunology, which we study to understand our body's defenses against infection at the cellular and molecular levels.

IN THIS CHAPTER

The origins of vertebrate immune cells.

Principles of innate immunity.

Principles of adaptive immunity.

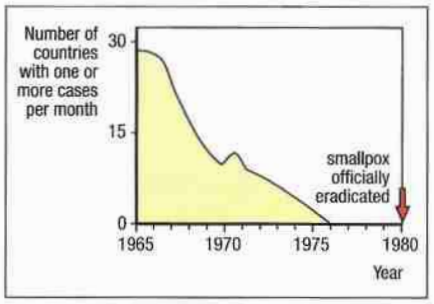
The effector mechanisms of immunity.

The beginning of immunology as a science is usually attributed to Edward Jenner for his work in the late 18th century (Fig. 1.1). The notion of immunity—that surviving a disease confers greater protection against it later—was known since ancient Greece. **Variolation**—the inhalation or transfer into superficial skin wounds of material from smallpox pustules—had been practiced since at least the 1400s in the Middle East and China as a form of protection against that disease and was known to Jenner. Jenner had observed that the relatively mild disease of cowpox seemed to confer protection against the often fatal disease of smallpox, and in 1796, he demonstrated that inoculation with cowpox protected the recipient against smallpox. His scientific proof relied on the deliberate exposure of the inoculated individual to infectious smallpox material 2 months after inoculation. This scientific test was his original contribution.

Fig. 1.1 Edward Jenner. Portrait by John Raphael Smith.

Jenner called the procedure **vaccination**. This term is still used to describe the inoculation of healthy individuals with weakened or attenuated strains of disease-causing agents in order to provide protection from disease. Although Jenner's bold experiment was successful, it took almost two centuries for smallpox vaccination to become universal. This advance enabled the World Health Organization to announce in 1980 that smallpox had been eradicated (Fig. 1.2), arguably the greatest triumph of modern medicine.

Jenner's strategy of vaccination was extended in the late 19th century by the discoveries of many great microbiologists. Robert Koch proved that infectious diseases are caused by specific microorganisms. In the 1880s, Louis Pasteur



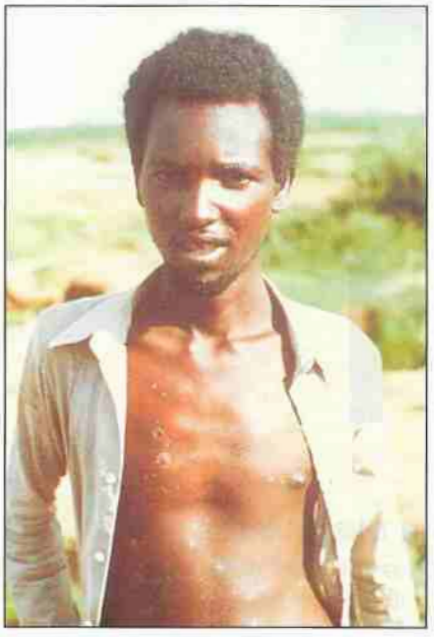


Fig. 1.2 The eradication of smallpox by vaccination. After a period of 3 years in which no cases of smallpox were recorded, the World Health Organization was able to announce in 1980 that smallpox had been eradicated, and vaccination stopped (upper panel). A few laboratory stocks have been retained, however, and some fear that these are a source from which the virus might reemerge. Ali Maow Maalin (lower panel) contracted and survived the last case of smallpox in Somalia in 1977.

devised a vaccine against cholera in chickens and also developed a rabies vaccine that proved to be a spectacular success upon its first trial in a boy bitten by a rabid dog.

These practical triumphs led to a search for vaccination's mechanism of protection and to the development of the science of immunology. In the early 1890s, Emil von Behring and Shibasaburo Kitasato discovered that the serum of animals immune to diphtheria or tetanus contained a specific 'antitoxic activity' that could confer short-lived protection against the effects of diphtheria or tetanus toxins in unimmunized animals and people. This activity was later determined to be due to the proteins we now call **antibodies**, which bind specifically to the toxins and neutralize their activity. That these antibodies might have a crucial role in immunity was reinforced by Jules Bordet's discovery in 1899 of **complement**, a component of serum that acts in conjunction with antibodies to destroy pathogenic bacteria.

A specific response against infection by potential pathogens, such as the production of antibodies against a particular pathogen, is known as **adaptive immunity**, because it develops during the lifetime of an individual as an adaptation to infection with that pathogen. Adaptive immunity is distinguished from **innate immunity**, which—at the time von Behring was developing serum therapy for diphtheria—was already known chiefly through the work of the great Russian immunologist Élie Metchnikoff, who discovered that many microorganisms could be engulfed and digested by phagocytic cells, which thus provide defenses against infection that are nonspecific. Whereas these cells—which Metchnikoff called 'macrophages'—are always present and ready to act, adaptive immunity requires time to develop but is highly specific.

It was soon clear that specific antibodies could be induced against a vast range of substances called **antigens** because they could stimulate *anti*body *gen*eration. Paul Ehrlich advanced the development of an **antiserum** as a treatment for diphtheria and developed methods to standardize therapeutic serums. Today the term 'antigen' refers to any substance recognized by the adaptive immune system. Typically antigens are common proteins, glycoproteins, and polysaccharides of pathogens, but they can include a much wider range of chemical structures; for example, metals such as nickel, drugs such as penicillin, and organic chemicals such as the urushiol (a mix of pentadecylcatechols) in the leaves of poison ivy. Metchnikoff and Ehrlich shared the 1908 Nobel Prize for their respective work on immunity.

This chapter introduces the principles of innate immunity and adaptive immunity, the cells of the immune system, the tissues in which they develop, and the tissues through which they circulate. We then outline the specialized functions of the different types of cells by which they eliminate infection.

The origins of vertebrate immune cells.

The body is protected from infectious agents, their toxins, and the damage they cause by a variety of effector cells and molecules that together make up the **immune system**. Both innate and adaptive immune responses depend on the activities of white blood cells, or **leukocytes**. Most cells of the immune system arise from the **bone marrow**, where many of them develop and mature. But some, particularly certain tissue-resident macrophage and lymphocyte populations (for example, the microglia of the central nervous system), originate from the yolk sac or fetal liver during embryonic development. They seed tissues before birth and are maintained throughout life as independent, self-renewing populations.

After birth, all the cellular elements of blood, including the red blood cells that transport oxygen, the platelets that trigger blood clotting in damaged tissues, and the white blood cells of the immune system, ultimately derive from the **hematopoietic stem cells (HSCs)** of the bone marrow. Because these can give rise to all the different types of blood cells, they are often known as **pluripotent** (or multipotent) hematopoietic stem cells. The hematopoietic stem cells give immediate rise to cells of more limited developmental potential, which are the progenitors of red blood cells, platelets, and the two main categories of white blood cells, the **lymphoid** and **myeloid** lineages. Once mature, immune cells reside within peripheral tissues, circulate in the bloodstream, or circulate in a specialized system of vessels called the **lymphatic system**. The lymphatic system drains extracellular fluid and immune cells from tissues and transports them as **lymph**, which is eventually emptied back into the blood system. The different types of blood cells and their lineage relationships are summarized in Fig. 1.3.

Principles of innate immunity.

In this part of the chapter we will outline the principles of innate immunity and describe the molecules and cells that provide continuous defense against invasion by pathogens. Although a subset of white blood cells, known as **lymphocytes**, possesses the most powerful ability to recognize and target pathogenic microorganisms, these cells need the participation of the innate immune system to initiate and mount their offensive. Indeed, the adaptive immune response and the innate immune response use many of the same destructive mechanisms to eliminate invading microorganisms.

1-1 Commensal organisms cause little host damage while pathogens damage host tissues by a variety of mechanisms.

We recognize four broad categories of disease-causing microorganisms, or **pathogens**: **viruses**, **bacteria** and archaea, **fungi**, and the unicellular and multicellular eukaryotic organisms collectively termed **parasites** (Fig. 1.4). These microorganisms vary tremendously in size and in how they damage host tissues. The smallest are viruses, which range from five to a few hundred nanometers in size and are obligate intracellular pathogens. Viruses can kill cells directly by inducing lysis during viral replication. Somewhat larger are intracellular bacteria and mycobacteria. These can kill cells directly or damage cells by producing toxins. Many single-celled intracellular parasites, such as members of the *Plasmodium* genus that cause malaria, also directly kill infected cells. Pathogenic bacteria and fungi growing in extracellular spaces can induce shock and sepsis by releasing toxins into the blood or tissues. The largest pathogens—parasitic worms, or helminths—are too large to infect host cells but can injure tissues by forming cysts that induce damaging cellular responses in the tissues into which the worms migrate.

Not all microbes are pathogens. Many tissues, especially those at the barriers of the body, such as the skin, oral mucosa, conjunctiva, and gastrointestinal tract, are constantly colonized by microbial communities—called the **microbiome**—that consist of archaea, bacteria, and fungi but cause no damage to the host. These are also called **commensal microorganisms**, because they can have a **symbiotic** relationship with the host. Indeed, some commensal organisms perform important functions, as in the case of the bacteria that aid in cellulose digestion in the stomachs of ruminants. The difference between commensal organisms and pathogens lies in whether they induce damage. Even enormous numbers of microbes in the intestinal microbiome normally cause no damage and are confined within the intestinal lumen by a protective

Fig. 1.3 All the cellular elements of the blood, including the cells of the immune system, arise from multipotent hematopoietic stem cells in the bone marrow. These multipotent cells divide to produce two types of stem cells. A common lymphoid progenitor gives rise to the lymphoid lineage (blue background) of white blood cells, or leukocytes—the innate lymphoid cells (ILCs) and natural killer (NK) cells and the T and B lymphocytes. A common myeloid progenitor gives rise to the myeloid lineage (pink and yellow backgrounds), which comprises the rest of the leukocytes, the erythrocytes (red blood cells), and the megakaryocytes that produce platelets important in blood clotting. T and B lymphocytes are distinguished from the other leukocytes by having antigen receptors and from each other by their sites of differentiation—the thymus and bone marrow, respectively. After encounter with antigen, B cells differentiate into antibody-secreting plasma cells, while T cells differentiate into effector T cells with a variety of functions. Unlike T and B cells, ILCs and NK cells lack antigen specificity. The remaining leukocytes are the monocytes, the dendritic cells, and the neutrophils, eosinophils, and basophils. The last three of these circulate in the blood and are termed granulocytes, because of the cytoplasmic granules whose staining gives these cells a distinctive appearance in blood smears, or polymorphonuclear leukocytes, because of their irregularly shaped nuclei. Immature dendritic cells (yellow background) are phagocytic cells that enter the tissues; they mature after they have encountered a potential pathogen. The majority of dendritic cells are derived from the common myeloid progenitor cells, but some may also arise from the common lymphoid progenitor. Monocytes enter tissues, where they differentiate into phagocytic macrophages or dendritic cells. Mast cells also enter tissues and complete their maturation there.

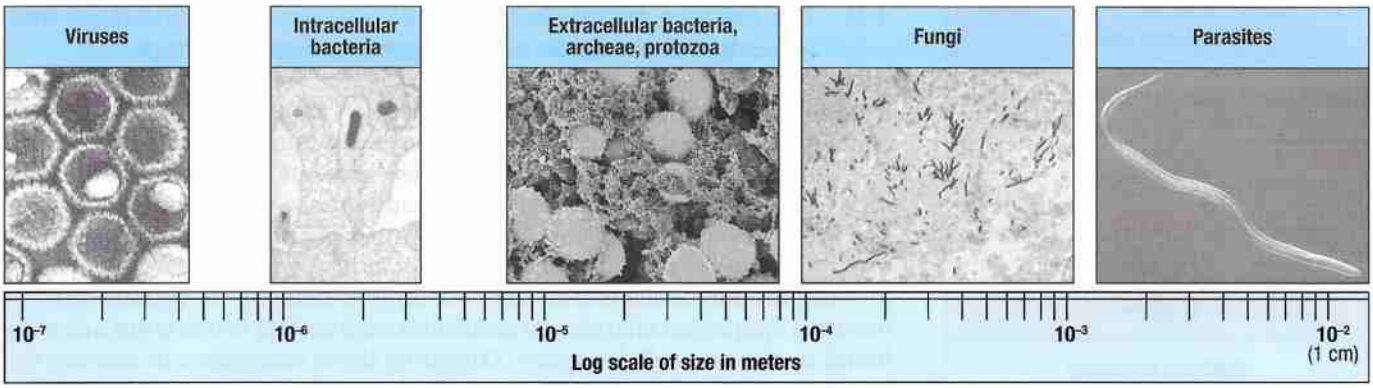

Fig. 1.4 Pathogens vary greatly in size and lifestyle. Intracellular pathogens include viruses, such as herpes simplex (first panel), and various bacteria, such as *Listeria monocytogenes* (second panel). Many bacteria, such as *Staphylococcus aureus* (third panel), or fungi, such as *Aspergillus fumigatus* (fourth panel), can grow in the extracellular spaces and directly invade tissues, as do some archaea and protozoa (third panel). Many parasites, such as the nematode *Strongyloides stercoralis* (fifth panel), are large multicellular organisms that can move throughout the body in a complex life cycle.

layer of mucus, whereas pathogenic bacteria can penetrate this barrier, injure intestinal epithelial cells, and spread into the underlying tissues.

1-2 Anatomic and chemical barriers are the first defense against pathogens.

The host can adopt three strategies to deal with the threat posed by microbes: **avoidance, resistance**, and **tolerance**. Avoidance mechanisms prevent exposure to microbes and include both anatomic barriers and behavior modifications. If an infection is established, resistance is aimed at reducing or eliminating pathogens. To defend against the great variety of microbes, the immune system has numerous molecular and cellular functions, collectively called mediators, or **effector mechanisms**, suited to resist different categories of pathogens. Their description is a major aspect of this book. Finally, tolerance involves responses that enhance a tissue's capacity to resist damage induced by microbes. This meaning of the term 'tolerance' has been used extensively in the context of disease susceptibility in plants rather than animal immunity. For example, increasing growth by activating dormant meristems, the undifferentiated cells that generate new parts of the plant, is a common tolerance mechanism in response to damage. This should be distinguished from the term **immunological tolerance**, which refers to mechanisms that prevent an immune response from being mounted against the host's own tissues.

Anatomic and chemical barriers are the initial defenses against infection (Fig. 1.5). The skin and mucosal surfaces represent a kind of avoidance strategy that prevents exposure of internal tissues to microbes. At most anatomic barriers, additional resistance mechanisms further strengthen host defenses. For example, mucosal surfaces produce a variety of **antimicrobial proteins** that act as natural antibiotics to prevent microbes from entering the body.

If these barriers are breached or evaded, other components of the innate immune system can immediately come into play. We mentioned earlier the discovery by Jules Bordet of complement, which acts with antibodies to lyse bacteria. Complement is a group of around 30 different plasma proteins that act together and are one of the most important effector mechanisms in serum and interstitial tissues. Complement not only acts in conjunction with antibodies but can also target foreign organisms in the absence of a specific antibody; thus it contributes to both innate and adaptive responses. We will examine anatomic barriers, the antimicrobial proteins, and complement in greater detail in Chapter 2.

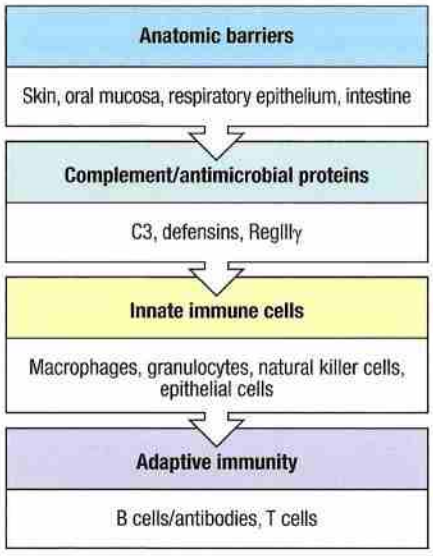

Fig. 1.5 Protection against pathogens relies on several levels of defense. The first is the anatomic barrier provided by the body's epithelial surfaces. Second, various chemical and enzymatic systems, including complement, act as an immediate antimicrobial barrier near these epithelia. If epithelia are breached, various nearby innate lymphoid and myeloid cells can coordinate a rapid cell-mediated defense. If the pathogen overcomes these barriers, the slower-acting defenses of the adaptive immune system are brought to bear.

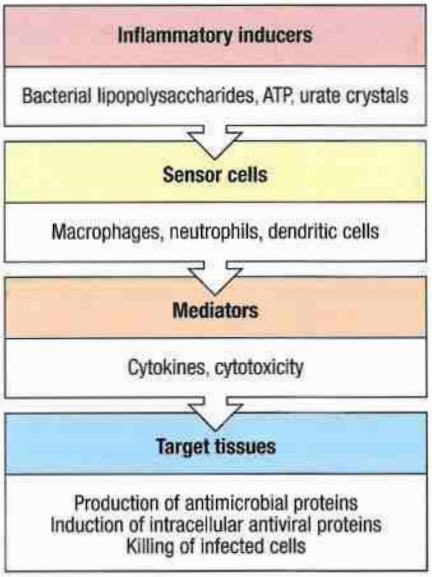

Fig. 1.6 Cell-mediated immunity proceeds in a series of steps. Inflammatory inducers are chemical structures that indicate the presence of invading microbes or the cellular damage produced by them. Sensor cells detect these inducers by their various innate recognition receptors and in response produce a variety of inflammatory mediators that act directly in defense or that further propagate the immune response. The mediators include many cytokines, and they act on various target tissues (such as epithelial cells) to induce antimicrobial proteins and resist intracellular viral growth or on other immune cells (such as ILCs), which produce other cytokines that amplify the immune response.

1-3 The immune system is activated by inflammatory inducers that indicate the presence of pathogens or tissue damage.

A pathogen that breaches the host's anatomic and chemical barriers will encounter the cellular defenses of innate immunity. Cellular immune responses are initiated when various types of **sensor cells** detect **inflammatory inducers** (Fig. 1.6) through their many **innate recognition receptors**, which are encoded by a relatively small number of genes that remain constant over an individual's lifetime. Inflammatory inducers that trigger these receptors include molecular components unique to bacteria or viruses, such as bacterial lipopolysaccharides, or molecules such as ATP, which is not normally found in the extracellular space. Triggering these receptors can activate the innate immune sensor cells to produce various **inflammatory mediators** that either act directly to destroy invading microbes or act on other cells to propagate the immune response. For example, macrophages can ingest microbes and produce toxic chemical mediators, such as degradative enzymes or reactive oxygen intermediates, to kill them. Dendritic cells may produce cytokine mediators, including many cytokines that activate target tissues, such as epithelial or other immune cells, to resist or kill invading microbes more efficiently. We will discuss these receptors and mediators briefly below and in much greater detail in Chapter 3.

Innate immune responses occur rapidly on exposure to an infectious organism (Fig. 1.7). In contrast, responses by the adaptive immune system take days rather than hours to develop. However, the adaptive immune system is capable of eliminating infections more efficiently because of the exquisite specificity of antigen recognition by its lymphocytes. In contrast to a limited repertoire

Phases of the immune response			
Response		**Typical time after infection to start of response**	**Duration of response**
Innate immune response	Inflammation, complement activation, phagocytosis, and destruction of pathogen	Minutes	Days
Adaptive immune response	Interaction between antigen-presenting dendritic cells and antigen-specific T cells: recognition of antigen, adhesion, co-stimulation, T-cell proliferation and differentiation	Hours	Days
	Activation of antigen-specific B cells	Hours	Days
	Formation of effector and memory T cells	Days	Weeks
	Interaction of T cells with B cells, formation of germinal centers. Formation of effector B cells (plasma cells) and memory B cells. Production of antibody	Days	Weeks
	Emigration of effector lymphocytes from peripheral lymphoid organs	A few days	Weeks
	Elimination of pathogen by effector cells and antibody	A few days	Weeks
Immunological memory	Maintenance of memory B cells and T cells and high serum or mucosal antibody levels. Protection against reinfection	Days to weeks	Can be lifelong

Fig. 1.7 Phases of the immune response.

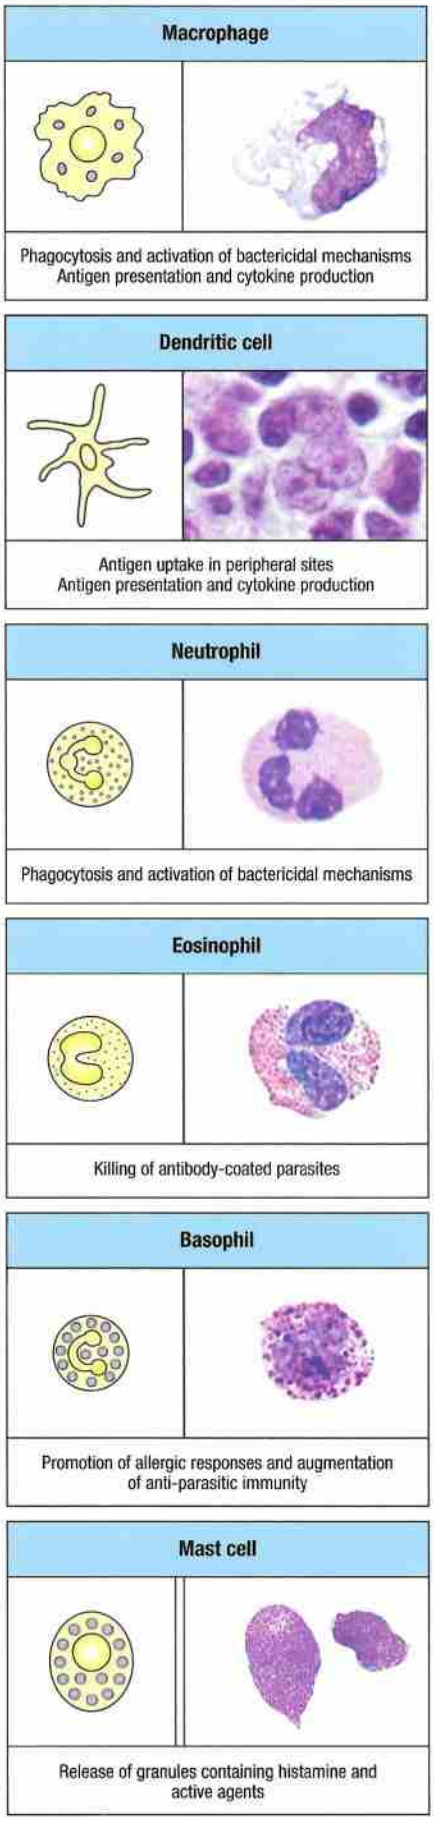
of receptors expressed by innate immune cells, lymphocytes express highly specialized **antigen receptors** that collectively possess a vast repertoire of specificity. This enables the adaptive immune system to respond to virtually any pathogen and effectively focus resources to eliminate pathogens that have evaded or overwhelmed innate immunity. But the adaptive immune system interacts with, and relies on, cells of the innate immune system for many of its functions. The next several sections will introduce the major components of the innate immune system and prepare us to consider adaptive immunity later in the chapter.

1-4 The myeloid lineage comprises most of the cells of the innate immune system.

The **common myeloid progenitor (CMP)** is the precursor of the macrophages, granulocytes (the collective term for the white blood cells called neutrophils, eosinophils, and basophils), mast cells, and dendritic cells of the innate immune system. Macrophages, granulocytes, and dendritic cells make up the three classes of phagocytes in the immune system. The CMP also generates megakaryocytes and red blood cells, which will not concern us here. The cells of the myeloid lineage are shown in Fig. 1.8.

Macrophages are resident in almost all tissues. Many tissue-resident macrophages arise during embryonic development, but some macrophages that arise from the bone marrow in the adult animal are the mature form of **monocytes**, which circulate in the blood and continually migrate into tissues, where they differentiate. Macrophages are relatively long-lived cells and perform several different functions throughout the innate immune response and the subsequent adaptive immune response. One is to engulf and kill invading microorganisms. This phagocytic function provides a first defense in innate immunity. Macrophages also dispose of pathogens and infected cells targeted by an adaptive immune response. Both monocytes and macrophages are phagocytic, but most infections occur in the tissues, and so it is primarily macrophages that perform this important protective function. An additional and crucial role of macrophages is to orchestrate immune responses: they help induce inflammation, which, as we shall see, is a prerequisite to a successful immune response, and they produce many inflammatory mediators that activate other immune-system cells and recruit them into an immune response.

Local inflammation and the phagocytosis of invading bacteria can also be triggered by the activation of complement. Bacterial surfaces can activate the complement system, inducing a cascade of proteolytic reactions that coat the microbes with fragments of specific proteins of the complement system. Microbes coated in this way are recognized by specific **complement receptors** on macrophages and neutrophils, taken up by phagocytosis, and destroyed.



Macrophage
Phagocytosis and activation of bactericidal mechanisms
Antigen presentation and cytokine production
Dendritic cell
Antigen uptake in peripheral sites
Antigen presentation and cytokine production
Neutrophil
Phagocytosis and activation of bactericidal mechanisms
Eosinophil
Killing of antibody-coated parasites
Basophil
Promotion of allergic responses and augmentation of anti-parasitic immunity
Mast cell
Release of granules containing histamine and active agents

Fig. 1.8 Myeloid cells in innate and adaptive immunity. In the rest of the book, these cells will be represented in the schematic form shown on the left. A photomicrograph of each cell type is shown on the right. Macrophages and neutrophils are primarily phagocytic cells that engulf pathogens and destroy them in intracellular vesicles, a function they perform in both innate and adaptive immune responses. Dendritic cells are phagocytic when they are immature and can take up pathogens; after maturing, they function as specialized cells that present pathogen antigens to T lymphocytes in a form they can recognize, thus activating T lymphocytes and initiating adaptive immune responses. Macrophages can also present antigens to T lymphocytes and can activate them. The other myeloid cells are primarily secretory cells that release the contents of their prominent granules upon activation via antibody during an adaptive immune response. Eosinophils are thought to be involved in attacking large antibody-coated parasites such as worms; basophils are also thought to be involved in anti-parasite immunity. Mast cells are tissue cells that trigger a local inflammatory response to antigen by releasing substances that act on local blood vessels. Mast cells, eosinophils, and basophils are also important in allergic responses. Original magnification ×15,000.

In addition to their specialized role in the immune system, macrophages act as general scavenger cells in the body, clearing it of dead cells and cell debris.

The **granulocytes** are named for the densely staining granules in their cytoplasm; they are also called **polymorphonuclear leukocytes** because of their oddly shaped nuclei. The three types of granulocytes—neutrophils, eosinophils, and basophils—are distinguished by the different staining properties of their granules, which serve distinct functions. Granulocytes are generally relatively short-lived, surviving for only a few days. They mature in the bone marrow, and their production increases during immune responses, when they migrate to sites of infection or inflammation. The phagocytic **neutrophils** are the most numerous and important cells in innate immune responses: they take up a variety of microorganisms by phagocytosis and efficiently destroy them in intracellular vesicles by using degradative enzymes and other antimicrobial substances stored in their cytoplasmic granules. Hereditary deficiencies in neutrophil function open the way to overwhelming bacterial infection, which is fatal if untreated. Their role is discussed further in Chapter 3.

Eosinophils and **basophils** are less abundant than neutrophils, but like neutrophils, they have granules containing a variety of enzymes and toxic proteins, which are released when these cells are activated. Eosinophils and basophils are thought to be important chiefly in defense against parasites, which are too large to be ingested by macrophages or neutrophils. They can also contribute to allergic inflammatory reactions, in which their effects are damaging rather than protective.

Mast cells begin development in the bone marrow but migrate as immature precursors that mature in peripheral tissues, especially skin, intestines, and airway mucosa. Their granules contain many inflammatory mediators, such as histamine and various proteases, which play a role in protecting the internal surfaces from pathogens, including parasitic worms. Because of their localization in barrier tissues, mast cells also function as early sensors of infection or injury and, in this role, contribute to the initiation of inflammation. We cover eosinophils, basophils, and mast cells and their role in allergic inflammation further in Chapters 10 and 14.

ANIMATION 1.1

Dendritic cells were discovered in the 1970s by Ralph Steinman, a finding for which he shared the 2011 Nobel Prize. These cells form the third class of phagocytic cells of the immune system and include several related lineages whose distinct functions are still being clarified. Most dendritic cells have elaborate membranous processes, like the dendrites of nerve cells. Immature dendritic cells migrate through the bloodstream from the bone marrow to enter tissues. They take up particulate matter by phagocytosis and also continually ingest large amounts of the extracellular fluid and its contents by a process known as **macropinocytosis**. They degrade the pathogens that they take up, but their main role in the immune system is not the clearance of microorganisms. Instead, dendritic cells are a major class of sensor cells whose encounter with pathogens triggers them to produce mediators that activate other immune cells. Dendritic cells were discovered because of their role in activating a particular class of lymphocytes—T lymphocytes—of the adaptive immune system, and we will return to this activity when we discuss T-cell activation in Section 1-15. But dendritic cells and the mediators they produce also play a critical role in controlling responses of cells of the innate immune system.

1-5 Sensor cells express pattern-recognition receptors that provide an initial discrimination between self and nonself.

Long before the mechanisms of innate recognition were discovered, it was recognized that purified antigens such as proteins often did not evoke an immune response in an experimental immunization; that is, they were not

immunogenic. Rather, the induction of strong immune responses against purified proteins required the inclusion of microbial constituents, such as killed bacteria or bacterial extracts, famously called the immunologist's 'dirty little secret' by Charles Janeway (see Appendix I, Section A-1). This additional material was termed an **adjuvant**, because it helped intensify the response to the immunizing antigen (*adjuvare* is Latin for 'to help'). We know now that adjuvants are needed, at least in part, to activate innate receptors on various types of sensor cells to help activate T cells in the absence of an infection.

Macrophages, neutrophils, and dendritic cells are important classes of sensor cells that detect infection and initiate immune responses by producing inflammatory mediators, although other cells, even cells of the adaptive immune system, can serve this function. As mentioned in Section 1-3, these cells express a limited number of invariant innate recognition receptors as a means of detecting pathogens or the damage induced by them. Also called **pattern-recognition receptors (PRRs)**, they recognize simple molecules and regular patterns of molecular structure known as **pathogen-associated molecular patterns (PAMPs)** that are part of many microorganisms but not of the host body's own cells. Such structures include mannose-rich oligosaccharides, peptidoglycans, and lipopolysaccharides of the bacterial cell wall, as well as unmethylated CpG DNA (unmethylated cytosine–guanine dinucleotide in DNA), which is common to many pathogens. All of these microbial elements have been conserved during evolution, making them excellent targets for recognition because they do not change (Fig. 1.9).

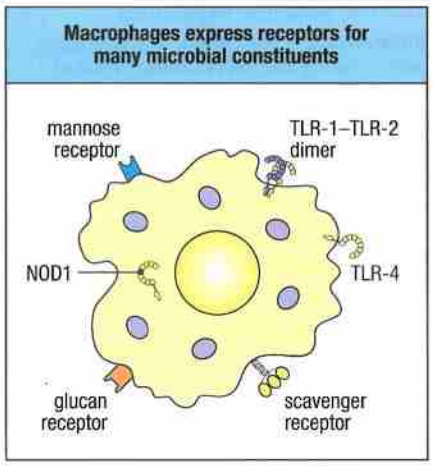


Fig. 1.9 Macrophages express a number of receptors that allow them to recognize different pathogens. Macrophages express a variety of receptors, each of which is able to recognize specific components of microbes. Some, like the mannose and glucan receptors and the scavenger receptor, bind cell-wall carbohydrates of bacteria, yeast, and fungi. The Toll-like receptors (TLRs) are an important family of pattern-recognition receptors present on macrophages, dendritic cells, and other immune cells. TLRs recognize different microbial components; for example, a heterodimer of TLR-1 and TLR-2 binds certain lipopeptides from pathogens such as Gram-positive bacteria, while TLR-4 binds both lipopolysaccharides from Gram-negative and lipoteichoic acids from Gram-positive bacteria. Other pattern-recognition receptors are intracellular, such as the nucleotide-binding and oligomerization domain (NOD)-like receptors. NOD1, for example, binds to diaminopimelic acid, a component of the cell wall of most Gram-negative bacteria.

Some PRRs are transmembrane proteins, such as the **Toll-like receptors (TLRs)** that detect PAMPs derived from extracellular bacteria or bacteria taken into vesicular pathways by phagocytosis. The role of the Toll receptor in immunity was discovered first in *Drosophila melanogaster* by Jules Hoffmann and later extended to homologous TLRs in mice by Charles Janeway and Bruce Beutler. (Hoffmann and Beutler shared the 2011 Nobel Prize along with Ralph Steinman—see Section 1-4—for their work in the activation of innate immunity.) Other PRRs are cytoplasmic proteins, such as the **NOD-like receptors (NLRs)** that sense intracellular bacterial invasion. Yet other cytoplasmic receptors detect viral infection on the basis of differences in the structures and locations of the host mRNA and virally derived RNA species and the differences between host and microbial DNA. Some receptors expressed by sensor cells detect cellular damage induced by pathogens, rather than the pathogens themselves. Much of our knowledge of innate recognition has emerged only within the past two decades and is still an active area of discovery. We describe these innate recognition systems further in Chapter 3 and discuss how adjuvants are used as a component of vaccines in Chapter 16.

1-6 Sensor cells induce an inflammatory response by producing mediators such as chemokines and cytokines.

Activation of PRRs on sensor cells such as macrophages and neutrophils can directly induce effector functions in these cells, such as the phagocytosis and degradation of bacteria they encounter. But sensor cells serve to amplify the immune response by the production of inflammatory mediators. Two important categories of inflammatory mediators are the secreted proteins called **cytokines** and **chemokines**, which act in a manner similar to hormones to convey important signals to other immune cells.

ANIMATION 3.5

'Cytokine' is a term for any protein secreted by immune cells that affects the behavior of nearby cells bearing appropriate receptors. There are more than 60 different cytokines; some are produced by many different cell types, and others are produced by only a few specific cell types. Some cytokines influence many types of cells, while others influence only a few, this through the expression

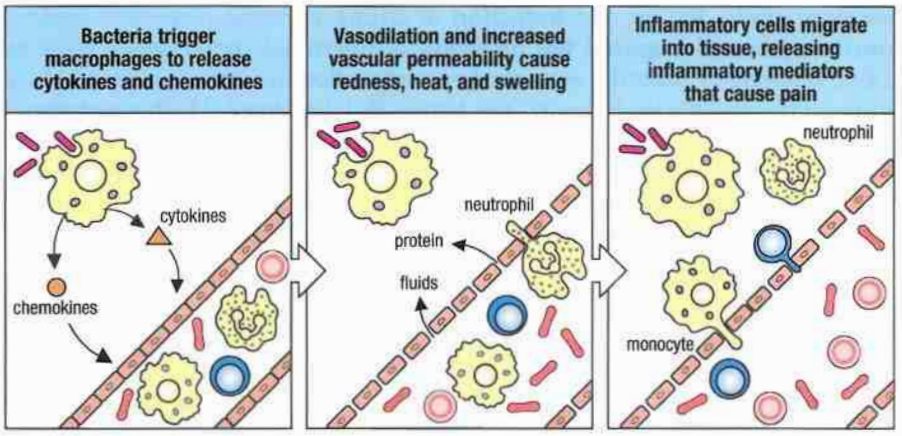

Fig. 1.10 Infection triggers an inflammatory response. Macrophages encountering bacteria or other types of microorganisms in tissues are triggered to release cytokines (left panel) that increase the permeability of blood vessels, allowing fluid and proteins to pass into the tissues (center panel). Macrophages also produce chemokines, which direct the migration of neutrophils to the site of infection. The stickiness of the endothelial cells of the blood vessel wall is also changed, so that circulating cells of the immune system adhere to the wall and are able to crawl through it; first neutrophils and then monocytes are shown entering the tissue from a blood vessel (right panel). The accumulation of fluid and cells at the site of infection causes the redness, swelling, heat, and pain known collectively as inflammation. Neutrophils and macrophages are the principal inflammatory cells. Later in an immune response, activated lymphocytes can also contribute to inflammation.

pattern of each cytokine's specific receptor. The response that a cytokine induces in a target cell is typically related to amplification of an effector mechanism of the target cell, as illustrated in the remaining sections of this chapter.

Instead of presenting all the cytokines together all at once, we introduce each cytokine as it arises during our description of cellular and functional responses. We list the cytokines, their producer and target cells, and their general functions in eAppendix III, found in the ebook and on the Digital Landing Page for this book.

Chemokines are a specialized subgroup of secreted proteins that act as chemoattractants, attracting cells bearing chemokine receptors, such as neutrophils and monocytes, out of the bloodstream and into infected tissue (Fig. 1.10). Beyond this role, chemokines also help organize the various cells in lymphoid tissues into discrete regions where specialized responses can take place. There are about 50 different chemokines. eAppendix IV, found in the ebook and on the Digital Landing Page for this book, lists the chemokines, their target cells, and their general functions. We will discuss chemokines as the need arises during our descriptions of particular cellular immune processes.

The cytokines and chemokines released by activated macrophages act to recruit cells from the blood into infected tissues, a process known as **inflammation**, which helps to destroy the pathogen. Inflammation increases the flow of lymph, which carries microbes or cells bearing their antigens from the infected tissue to nearby lymphoid tissues, where the adaptive immune response is initiated. Once adaptive immunity has been generated, inflammation also recruits these effector components to the site of infection.

Inflammation is described clinically by the Latin words *calor*, *dolor*, *rubor*, and *tumor*, meaning heat, pain, redness, and swelling. Each of these features reflects an effect of cytokines or other inflammatory mediators on the local blood vessels. Heat, redness, and swelling result from the dilation and increased permeability of blood vessels during inflammation, leading to increased local blood flow and leakage of fluid and blood proteins into the tissues. Cytokines and complement fragments have important effects on the **endothelium** that lines blood vessels; the **endothelial cells** themselves also produce cytokines in response to infection. These alter the adhesive properties of the endothelial cells and cause circulating leukocytes to stick to the endothelial cells and migrate between them into the site of infection, to which they are attracted by chemokines. The migration of cells into the tissue and their local actions account for the pain.

The main cell types seen in the initial phase of an inflammatory response are macrophages and neutrophils, the latter being recruited into the inflamed, infected tissue in large numbers. Macrophages and neutrophils are thus also known as **inflammatory cells**. The influx of neutrophils is followed a short time later by the increased entry of monocytes, which rapidly differentiate into

macrophages, thus reinforcing and sustaining the innate immune response. Later, if the inflammation continues, eosinophils also migrate into inflamed tissues and contribute to the destruction of the invading microorganisms.

1-7 Innate lymphoid cells and natural killer cells are effector cells that share similarities with lymphoid lineages of the adaptive immune system.

The **common lymphoid progenitor (CLP)** in the bone marrow gives rise both to antigen-specific lymphocytes of the adaptive immune system and to several innate lineages that lack antigen-specific receptors. Although the B and T lymphocytes of the adaptive immune system were recognized in the 1960s, the **natural killer (NK) cells** (Fig. 1.11) of the innate immune system were not discovered until the 1970s. NK cells are large lymphocyte-like cells with a distinctive granular cytoplasm that were identified because of their ability to recognize and kill certain tumor cells and cells infected with herpesviruses. Initially, the distinction between these cells and T lymphocytes was unclear, but we now recognize that NK cells are a distinct lineage of cells that arise from the CLP in the bone marrow. They lack the antigen-specific receptors of the adaptive immune system cells but express members of various families of innate receptors that can respond to cellular stress and to infections by very specific viruses. NK cells play an important role in the early innate response to viral infections, before the adaptive immune response has developed.

More recently, additional lineages of cells related to NK cells have been identified. Collectively, these cells are called **innate lymphoid cells (ILCs)**. Arising from the CLP, ILCs reside in peripheral tissues, such as the intestine, where they function as the sources of mediators of inflammatory responses. The functions of NK cells and ILCs are discussed in Chapter 3.

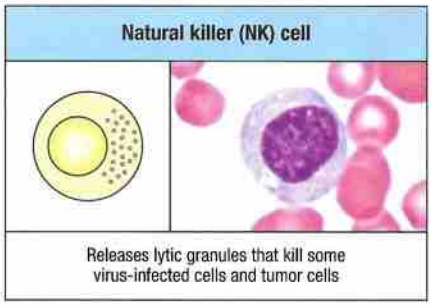

Fig. 1.11 Natural killer (NK) cells. These are large, granular, lymphoid-like cells with important functions in innate immunity (especially against intracellular infections), being able to kill other cells. Unlike lymphocytes, they lack antigen-specific receptors.

Summary.

Strategies of avoidance, resistance, and tolerance represent different ways to deal with pathogens. Anatomic barriers and various chemical barriers, such as complement and antimicrobial proteins, may be considered a primitive form of avoidance, and they are the first line of defense against entry of both commensal organisms and pathogens into host tissues. If these barriers are breached, the vertebrate immune response becomes largely focused on resistance. Inflammatory inducers, which may be either chemical structures unique to microbes (PAMPs) or the chemical signals of tissue damage, act on receptors expressed by sensor cells to inform the immune system of infection. Sensor cells are typically innate immune cells such as macrophages or dendritic cells. Sensor cells can either directly respond with effector activity or produce inflammatory mediators, typically cytokines and chemokines that act on other immune cells, such as the innate NK cells and ILCs. These cells then are recruited into target tissues to provide specific types of immune-response effector activities, such as cell killing or production of cytokines that have direct antiviral activity, all aimed to reduce or eliminate infection by pathogens. Inflammatory mediators released in target tissues can recruit and activate several types of inflammatory cells that are specially suited for eliminating viruses, intracellular bacteria, extracellular pathogens, or parasites.

Principles of adaptive immunity.

We come now to the components of adaptive immunity, the antigen-specific lymphocytes. Unless indicated otherwise, we shall use the term 'lymphocyte' in the remainder of this chapter to refer only to the antigen-specific lymphocytes.

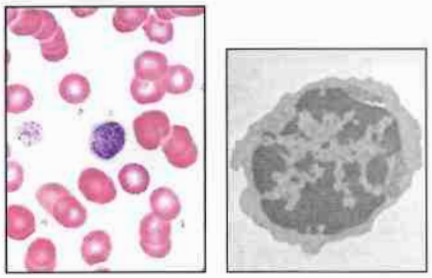

Fig. 1.12 Lymphocytes are mostly small and inactive cells. The left panel shows a light micrograph of a small lymphocyte—in which the nucleus has been stained purple by hematoxylin and eosin dye—surrounded by red blood cells (which have no nuclei). Note the darker purple patches of condensed chromatin of the lymphocyte nucleus, indicating little transcriptional activity and the relative absence of cytoplasm. The right panel shows a transmission electron micrograph of a small lymphocyte. Again, note the evidence of functional inactivity: the condensed chromatin, the scanty cytoplasm, and the absence of rough endoplasmic reticulum.

Lymphocytes allow responses against a vast array of antigens from various pathogens encountered during a person's lifetime and confer the important feature of immunological memory. Lymphocytes make this possible through the highly variable antigen receptors on their surface, by which they recognize and bind antigens. Each lymphocyte matures bearing a unique variant of a prototype antigen receptor, so that the population of lymphocytes expresses a huge repertoire of receptors that are highly diverse in their antigen-binding sites. Among the billion or so lymphocytes circulating in the body at any one time there will always be some that can recognize a given foreign antigen.

A unique feature of the adaptive immune system is that it is capable of generating **immunological memory**, so that having been exposed once to an infectious agent, a person will make an immediate and stronger response against any subsequent exposure to it; that is, the individual will have protective immunity against it. Finding ways of generating long-lasting immunity to pathogens that do not naturally provoke it is one of the greatest challenges facing immunologists today.

1-8 The interaction of antigens with antigen receptors induces lymphocytes to acquire effector and memory activity.

There are two major types of lymphocytes in the vertebrate immune system, the **B lymphocytes (B cells)** and **T lymphocytes (T cells)**. These express distinct types of antigen receptors and have quite different roles in the immune system, as was discovered in the 1960s. Most lymphocytes circulating in the body appear as rather unimpressive small cells with few cytoplasmic organelles and a condensed, inactive-appearing nuclear chromatin (Fig. 1.12). Lymphocytes manifest little functional activity until they encounter a specific antigen that interacts with an antigen receptor on their cell surface. Lymphocytes that have not yet been activated by antigen are known as **naive lymphocytes**; those that have met their antigen, become activated, and have differentiated further into fully functional lymphocytes are known as **effector lymphocytes**.

B cells and T cells are distinguished by the structure of the antigen receptor that they express. The **B-cell antigen receptor**, or **B-cell receptor (BCR)**, is formed by the same genes that encode antibodies, therefore B-cell receptors and antibodies compose the class of proteins known as **immunoglobulin (Ig)** (Fig. 1.13). Thus, the antigen receptor of B lymphocytes is also known as **membrane immunoglobulin (mIg)** or **surface immunoglobulin (sIg)**. The **T-cell antigen receptor**, or **T-cell receptor (TCR)**, is related to the immunoglobulins but is quite distinct in its structure and recognition properties.

After antigen binds to a B-cell receptor, the B cell will proliferate and differentiate into **plasma cells**. These are the effector form of B lymphocytes, and they secrete antibodies that have the same antigen specificity as the plasma cell's B-cell receptor. Thus the antigen that activates a given B cell becomes the target of the antibodies produced by that B cell's progeny.

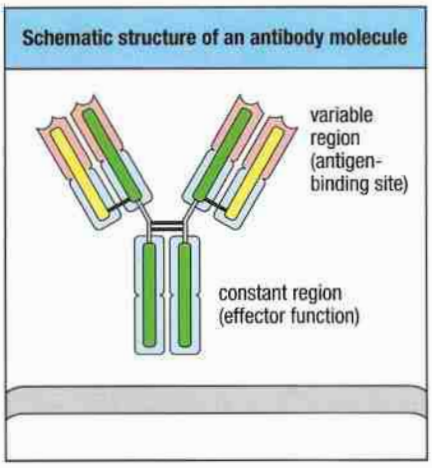

Fig. 1.13 Schematic structure of antigen receptors. Upper panel: an antibody molecule, which is secreted by activated B cells as an antigen-binding effector molecule. A membrane-bound version of this molecule acts as the B-cell antigen receptor (not shown). An antibody is composed of two identical heavy chains (green) and two identical light chains (yellow). Each chain has a constant part (shaded blue) and a variable part (shaded red). Each arm of the antibody molecule is formed by a light chain and a heavy chain, with the variable parts of the two chains coming together to create a variable region that contains the antigen-binding site. The stem is formed from the constant parts of the heavy chains and takes a limited number of forms. This constant region is involved in the elimination of the bound antigen. Lower panel: a T-cell antigen receptor. This is also composed of two chains, an α chain (yellow) and a β chain (green), each of which has a variable and a constant part. As with the antibody molecule, the variable parts of the two chains create a variable region, which forms the antigen-binding site. The T-cell receptor is not produced in a secreted form.

When a T cell first encounters an antigen that its receptor can bind, it proliferates and differentiates into one of several different functional types of **effector T lymphocytes**. When effector T cells subsequently detect antigen, they can manifest three broad classes of activity. **Cytotoxic T cells** kill other cells that are infected with viruses or other intracellular pathogens bearing the antigen. **Helper T cells** provide signals, often in the form of specific cytokines that activate the functions of other cells, such as B-cell production of antibody and macrophage killing of engulfed pathogens. **Regulatory T cells** suppress the activity of other lymphocytes and help to limit the possible damage of immune responses. We discuss the detailed functions of cytotoxic, helper, and regulatory T cells in Chapters 9, 11, 12, and 15.

Some of the B cells and T cells activated by antigen will differentiate into **memory cells**, the lymphocytes that are responsible for the long-lasting immunity that can follow exposure to disease or vaccination. Memory cells will readily differentiate into effector cells on a second exposure to their specific antigen. Immunological memory is described in Chapter 11.

1-9 Antibodies and T-cell receptors are composed of constant and variable regions that provide distinct functions.

Antibodies were studied by traditional biochemical techniques long before recombinant DNA technology allowed the study of the membrane-bound forms of the antigen receptors on B and T cells. These early studies found that antibody molecules are composed of two distinct regions. One is a **constant region**, also called the **fragment crystallizable region**, or **Fc region**, which takes one of only five biochemically distinguishable forms (see Fig. 1.13). The **variable region** of different antibody molecules, by contrast, can be composed of a vast number of different amino acid sequences that allow antibodies to recognize an equally vast variety of antigens. The basic structure of antibody molecules was determined by Gerald Edelman and Rodney Porter, who shared the 1972 Nobel Prize for their work. These biochemical studies led to subsequent X-ray crystallographic determination of the structure of the antibody Fc region.

The antibody molecule is composed of two identical **heavy chain** and two identical **light chain** polypeptides. Heavy and light chains each have variable and constant regions. The variable regions of a heavy chain and a light chain combine to form an **antigen-binding site** that determines the antigen-binding specificity of the antibody. Thus, both heavy and light chains contribute to the antigen-binding specificity of the antibody molecule. Also, each antibody has two identical variable regions, and so has two identical antigen-binding sites. The constant region determines the effector function of the antibody; that is, how the antibody will interact with various immune cells to dispose of antigen once it is bound.

The T-cell receptor shows many similarities to the B-cell receptor and antibody (see Fig. 1.13). It is composed of two chains, the TCR α and β chains, that are roughly equal in size and which span the T-cell membrane. Like antibody, each TCR chain has a variable region and a constant region, and the combination of the α- and β-chain variable regions creates a single site for binding antigen. The structures of both antibodies and T-cell receptors are described in detail in Chapter 4, and functional properties of antibody constant regions are discussed in Chapters 4 and 10.

1-10 Antibodies and T-cell receptors recognize antigens by fundamentally different mechanisms.

In principle, almost any chemical structure can be recognized as an antigen by the adaptive immune system, but the usual antigens encountered in an infection are the proteins, glycoproteins, and polysaccharides of pathogens.

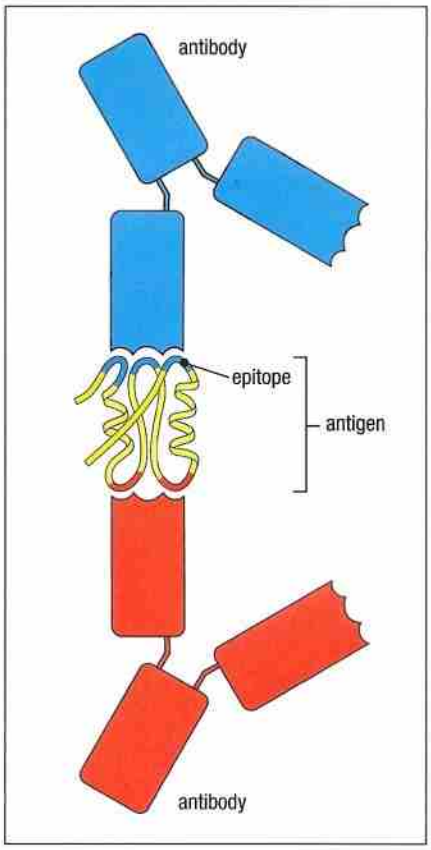

Fig. 1.14 Antigens are the molecules recognized by the immune response, while epitopes are sites within antigens to which antigen receptors bind. Antigens can be complex macromolecules such as proteins, as shown in yellow. Most antigens are larger than the sites on the antibody or antigen receptor to which they bind, and the actual portion of the antigen that is bound is known as the antigenic determinant, or epitope, for that receptor. Large antigens such as proteins can contain more than one epitope (indicated in red and blue) and thus may bind different antibodies (shown here in the same color as the epitopes they bind). Antibodies generally recognize epitopes on the surface of the antigen.

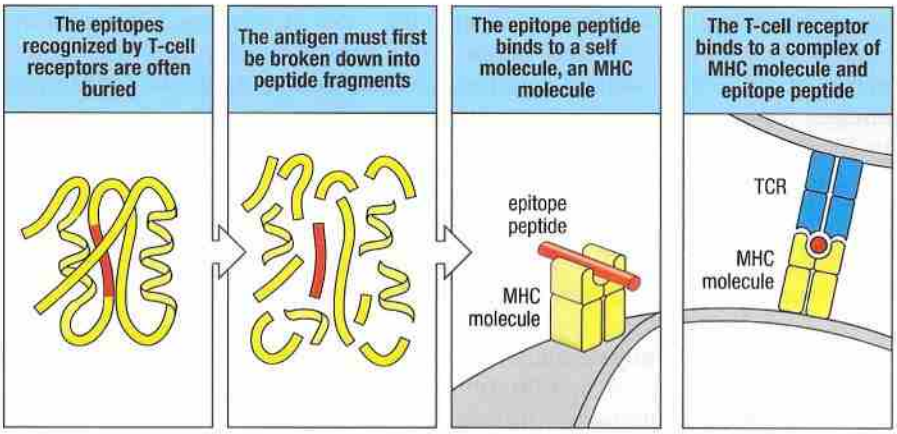
An individual antigen receptor or antibody recognizes a small portion of the antigen's molecular structure, and the part recognized is known as an **antigenic determinant**, or **epitope** (Fig. 1.14). Typically, proteins and glycoproteins have many different epitopes that can be recognized by different antigen receptors.

Antibodies and B-cell receptors directly recognize the epitopes of native antigen in the serum or the extracellular spaces. It is possible for different antibodies to simultaneously recognize an antigen by its different epitopes; such simultaneous recognition increases the efficiency of clearing or neutralizing the antigen.

Whereas antibodies can recognize nearly any type of chemical structure, T-cell receptors usually recognize protein antigens and do so very differently from antibodies. The T-cell receptor recognizes a peptide epitope derived from a partially degraded protein, but only if the peptide is bound to specialized cell-surface glycoproteins called **MHC molecules** (Fig. 1.15). The members of this large family of cell-surface glycoproteins are encoded in a cluster of genes called the **major histocompatibility complex (MHC)**. The antigens recognized by T cells can be derived from proteins arising from intracellular pathogens, such as a virus, or from extracellular pathogens. A further difference from the antibody molecule is that there is no secreted form of the T-cell receptor; the T-cell receptor functions solely to signal to the T cell that it has bound its antigen, and the subsequent immunological effects depend on the actions of the T cells themselves. We will further describe how epitopes from antigens are placed on MHC proteins in Chapter 6 and how T cells carry out their subsequent functions in Chapter 9.

1-11 Antigen-receptor genes are assembled by somatic gene rearrangements of incomplete receptor gene segments.

The innate immune system detects inflammatory stimuli by means of a relatively limited number of sensors, such as the TLR and NOD proteins, numbering fewer than 100 different types of proteins. Antigen-specific receptors of adaptive immunity provide a seemingly infinite range of specificities and yet are encoded by a finite number of genes. The basis for this extraordinary range of specificity was discovered in 1976 by Susumu Tonegawa, for which he was awarded the 1987 Nobel Prize. Immunoglobulin variable regions are inherited as sets of **gene segments**, each encoding a part of the variable region of one of the immunoglobulin polypeptide chains. During B-cell development in the bone marrow, these gene segments are irreversibly joined by a process of DNA recombination to form a stretch of DNA encoding a complete variable region. A similar process of antigen-receptor gene rearrangement takes place for the T-cell receptor genes during development of T cells in the thymus.



The epitopes recognized by T-cell receptors are often buried
The antigen must first be broken down into peptide fragments
The epitope peptide binds to a self molecule, an MHC molecule
The T-cell receptor binds to a complex of MHC molecule and epitope peptide
epitope peptide
MHC molecule
TCR
MHC molecule

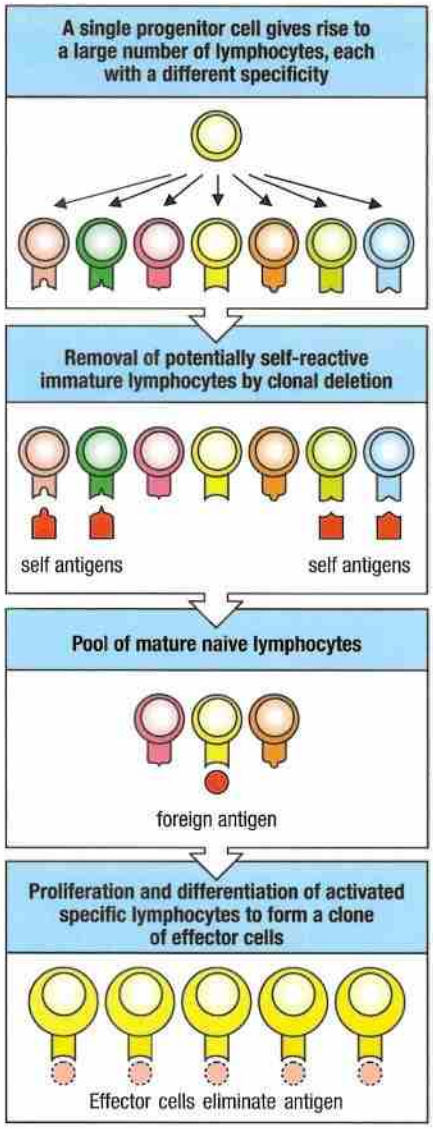
Fig. 1.15 T-cell receptors bind a complex of an antigen fragment and a self molecule. Unlike most antibodies, T-cell receptors can recognize epitopes that are buried within antigens (first panel). These antigens must first be degraded by proteases (second panel) and the epitope peptide delivered to a self molecule, called an MHC molecule (third panel). It is in this form, as a complex of peptide and MHC molecule, that antigens are recognized by T-cell receptors (TCRs; fourth panel).

Just a few hundred different gene segments can combine in different ways to generate thousands of different receptor chains. This **combinatorial diversity** allows a small amount of genetic material to encode a truly staggering diversity of receptors. During this recombination process, the random addition or subtraction of nucleotides at the junctions of the gene segments creates additional diversity known as **junctional diversity**. Diversity is amplified further by the fact that each antigen receptor has two different variable chains, each encoded by distinct sets of gene segments. In Chapter 5 we will describe the gene-rearrangement process that assembles complete antigen receptors from gene segments.

1-12 Lymphocytes activated by antigen give rise to clones of antigen-specific effector cells that mediate adaptive immunity.

There are two critical features of lymphocyte development that distinguish adaptive immunity from innate immunity. First, the process that assembles antigen receptors from incomplete gene segments, described earlier, is carried out in a manner ensuring that each developing lymphocyte expresses only one receptor specificity. Whereas the cells of the innate immune system express many different pattern-recognition receptors and recognize features shared by many pathogens, the antigen-receptor expression of lymphocytes is 'clonal,' so that each mature lymphocyte differs from others in the specificity of its antigen receptor. Second, because the gene-rearrangement process irreversibly changes the lymphocyte's DNA, all its progeny inherit the same receptor specificity. Because this specificity is inherited by a cell's progeny, the proliferation of an individual lymphocyte forms a **clone** of cells with identical antigen receptors.

There are lymphocytes of at least 10^8 different specificities in an individual human at any one time, composing the **lymphocyte receptor repertoire** of the individual. These lymphocytes are continually undergoing a process similar to natural selection: only those lymphocytes that encounter an antigen to which their receptor binds will be activated to proliferate and differentiate into effector cells. This selective mechanism was first proposed in the 1950s by Frank Macfarlane Burnet, who postulated the preexistence in the body of many different potential antibody-producing cells, each displaying on its surface a membrane-bound version of the antibody that served as a receptor for the antigen. On binding antigen, the cell is activated to divide and to produce many identical progeny, a process known as **clonal expansion**; this clone of identical cells can now secrete **clonotypic** antibodies with a specificity identical to that of the surface receptor that first triggered activation and clonal expansion (Fig. 1.16). Burnet called this the **clonal selection theory** of antibody production; its four basic postulates are listed in Fig. 1.17. Clonal selection of lymphocytes is the single most important principle in adaptive immunity.



A single progenitor cell gives rise to a large number of lymphocytes, each with a different specificity
Removal of potentially self-reactive immature lymphocytes by clonal deletion
self antigens
self antigens
Pool of mature naive lymphocytes
foreign antigen
Proliferation and differentiation of activated specific lymphocytes to form a clone of effector cells
Effector cells eliminate antigen

Fig. 1.16 Clonal selection. Each lymphoid progenitor gives rise to a large number of lymphocytes, each bearing a distinct antigen receptor. Lymphocytes with receptors that bind ubiquitous self antigens are eliminated before they become fully mature, ensuring tolerance to such self antigens. When a foreign antigen (red dot) interacts with the receptor on a mature naive lymphocyte, that cell is activated and starts to divide. It gives rise to a clone of identical progeny, all of whose receptors bind the same antigen. Antigen specificity is thus maintained as the progeny proliferate and differentiate into effector cells. Once antigen has been eliminated by these effector cells, the immune response ceases, although some lymphocytes are retained to mediate immunological memory.

Postulates of the clonal selection hypothesis
Each lymphocyte bears a single type of receptor with a unique specificity
Interaction between a foreign molecule and a lymphocyte receptor capable of binding that molecule with high affinity leads to lymphocyte activation
The differentiated effector cells derived from an activated lymphocyte will bear receptors of identical specificity to those of the parental cell from which that lymphocyte was derived
Lymphocytes bearing receptors specific for ubiquitous self molecules are deleted at an early stage in lymphoid cell development and are therefore absent from the repertoire of mature lymphocytes

Fig. 1.17 The four basic principles of clonal selection.

1-13 Lymphocytes with self-reactive receptors are normally eliminated during development or are functionally inactivated.

When Burnet formulated his theory, nothing was known of the antigen receptors or indeed the function of lymphocytes themselves. In the early 1960s, James Gowans discovered that removal of the small lymphocytes from rats resulted in the loss of all known adaptive immune responses, which were restored when the small lymphocytes were replaced. This led to the realization that lymphocytes must be the units of clonal selection, and their biology became the focus of the new field of **cellular immunology**.

Clonal selection of lymphocytes with diverse receptors elegantly explained adaptive immunity, but it raised one significant conceptual problem. With so many different antigen receptors being generated randomly during the lifetime of an individual, there is a possibility that some receptors might react against an individual's own **self antigens**. How are lymphocytes prevented from recognizing native antigens on the tissues of the body and attacking them? Ray Owen had shown in the late 1940s that genetically different twin calves with a common placenta, and thus a shared placental blood circulation, were immunologically unresponsive, or **tolerant**, to one another's tissues. Peter Medawar then showed in 1953 that exposure to foreign tissues during embryonic development caused mice to become immunologically tolerant to these tissues. Burnet proposed that developing lymphocytes that are potentially self-reactive are removed before they can mature, a process known as **clonal deletion**. Medawar and Burnet shared the 1960 Nobel Prize for their work on tolerance. This process was demonstrated experimentally in the late 1980s. Some lymphocytes that receive either too much or too little signal through their antigen receptor during development are eliminated by a form of cell suicide called **apoptosis**—derived from a Greek word meaning the falling of leaves from trees—or **programmed cell death**. Other types of mechanisms of immunological tolerance have been identified since then that rely on the induction of an inactive state, called **anergy**, as well as mechanisms of active suppression of self-reactive lymphocytes. Chapter 8 will describe lymphocyte development and tolerance mechanisms that shape the lymphocyte receptor repertoire. Chapters 14 and 15 will discuss how immune-tolerance mechanisms can sometimes fail.

1-14 Lymphocytes mature in the bone marrow or the thymus and then congregate in lymphoid tissues throughout the body.

Lymphocytes circulate in the blood and the lymph and are also found in large numbers in **lymphoid tissues** or **lymphoid organs**, the latter being organized aggregates of lymphocytes in a framework of nonlymphoid cells. Lymphoid organs can be divided broadly into the **central (or primary) lymphoid organs**, where lymphocytes are generated, and the **peripheral (or secondary) lymphoid organs**, where mature naive lymphocytes are maintained and adaptive immune responses are initiated. The central lymphoid organs are the bone marrow and the **thymus**, an organ in the upper chest. The peripheral lymphoid organs comprise the **lymph nodes**, the **spleen**, and the mucosal lymphoid tissues of the gut, the nasal and respiratory tract, the urogenital tract, and other mucosa. The locations of the main lymphoid tissues are shown schematically in Fig. 1.18; we describe the individual peripheral lymphoid organs in more detail later in the chapter. Lymph nodes are interconnected by a system of lymphatic vessels, which drain extracellular fluid from tissues, carry it through the lymph nodes, and deposit it back into the blood.

The progenitors that give rise to B and T lymphocytes originate in the bone marrow. B cells complete their development within the bone marrow.

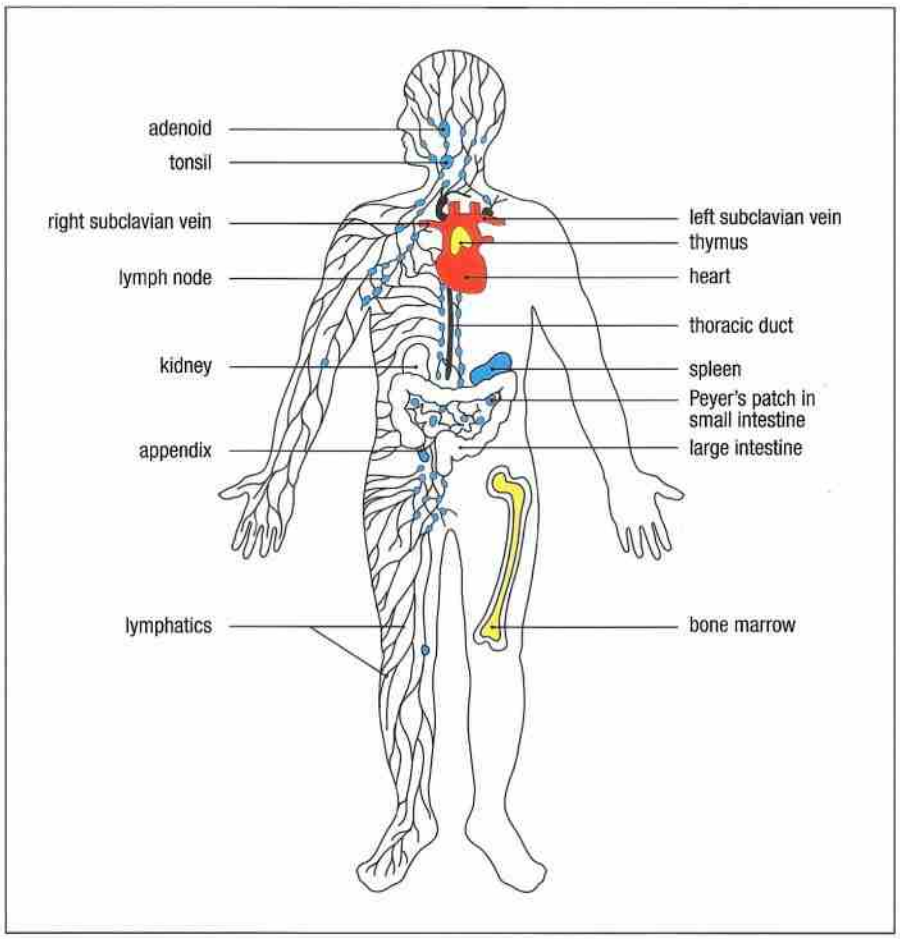


Fig. 1.18 The distribution of lymphoid tissues in the body. Lymphocytes arise from stem cells in bone marrow and differentiate in the central lymphoid organs (yellow)—B cells in the bone marrow and T cells in the thymus. They migrate from these tissues and are carried in the bloodstream to the peripheral lymphoid organs (blue). These include lymph nodes, spleen, and lymphoid tissues associated with mucosa, such as the gut-associated tonsils, Peyer's patches, and appendix. The peripheral lymphoid organs are the sites of lymphocyte activation by antigen, and lymphocytes recirculate between the blood and these organs until they encounter their specific antigen. Lymphatics drain extracellular fluid from the peripheral tissues, through the lymph nodes, and into the thoracic duct, which empties into the left subclavian vein. This fluid, known as lymph, carries antigen taken up by dendritic cells and macrophages to the lymph nodes, and it recirculates lymphocytes from the lymph nodes back into the blood. Lymphoid tissue is also associated with other mucosa such as the bronchial linings (not shown).

Although the 'B' in B lymphocytes originally stood for the **bursa of Fabricius**, a lymphoid organ in young chicks in which lymphocytes mature, it is a useful mnemonic for bone marrow. The immature precursors of T lymphocytes migrate to the thymus, from which they get their name, and complete their development there. Once they have completed maturation, both types of lymphocytes enter the bloodstream as mature naive lymphocytes and continually circulate through the peripheral lymphoid tissues.

1-15 Adaptive immune responses are initiated by antigen and antigen-presenting cells in peripheral lymphoid tissues.

ANIMATION 1.1

Adaptive immune responses are initiated when B or T lymphocytes encounter antigens for which their receptors have specific reactivity, provided that there are appropriate inflammatory signals to support activation. For T cells, this activation occurs via encounters with dendritic cells that have picked up antigens at sites of infection and migrated to peripheral (also called secondary) lymphoid organs. Activation of the dendritic cells' PRRs by PAMPs at the site of infection stimulates the dendritic cells in the tissues to engulf the pathogen and degrade it intracellularly. They also take up extracellular material, including virus particles and bacteria, by receptor-independent macropinocytosis. These processes lead to the display of peptide antigens on the MHC molecules of the dendritic cells, a display that activates the antigen receptors of lymphocytes. Activation of PRRs also triggers the dendritic cells to express cell-surface proteins called **co-stimulatory molecules**, which support the ability of the T lymphocyte to proliferate and differentiate into

Fig. 1.19 Dendritic cells initiate adaptive immune responses. Immature dendritic cells residing in a tissue take up pathogens and their antigens by macropinocytosis and by receptor-mediated endocytosis. They are stimulated by recognition of the presence of pathogens to migrate through the lymphatics to regional lymph nodes, where they arrive as fully mature nonphagocytic dendritic cells that express both antigen and the co-stimulatory molecules necessary to activate a naive T cell that recognizes the antigen. Thus the dendritic cells stimulate lymphocyte proliferation and differentiation.

its final, fully functional form (Fig. 1.19). For these reasons dendritic cells are also called **antigen-presenting cells (APCs)**, and as such, they form a crucial link between the innate immune response and the adaptive immune response (Fig. 1.20). In certain situations, macrophages and B cells can also act as antigen-presenting cells, but dendritic cells are the cells that are specialized in initiating the adaptive immune response. Free antigens can also stimulate the antigen receptors of B cells, but most B cells respond better to antigens on the surface of cells, such as pathogens, and in addition require 'help' from activated helper T cells for optimal antibody responses. The activation of naive T lymphocytes is therefore an essential first stage in virtually all adaptive immune responses. Chapter 6 returns to dendritic cells to discuss how antigens are processed for presentation to T cells. Chapters 7 and 9 discuss co-stimulation and lymphocyte activation. Chapter 10 describes how T cells help in activating B cells.

1-16 Lymphocytes encounter and respond to antigen in the peripheral lymphoid organs.

Antigen and lymphocytes eventually encounter each other in the peripheral lymphoid organs—the lymph nodes, spleen, and mucosal lymphoid tissues (see Fig. 1.18). Mature naive lymphocytes are continually recirculating through these tissues, to which pathogen antigens are carried from sites of infection, primarily by dendritic cells. The peripheral lymphoid organs are specialized to trap antigen-bearing dendritic cells and to facilitate the initiation of adaptive immune responses. Peripheral lymphoid organs are composed of aggregations of lymphocytes in a framework of nonleukocyte stromal cells. The stromal cells provide both the basic structural organization of the tissue and survival signals to help sustain the life of the lymphocytes. Besides lymphocytes, peripheral lymphoid organs also contain resident macrophages and dendritic cells.

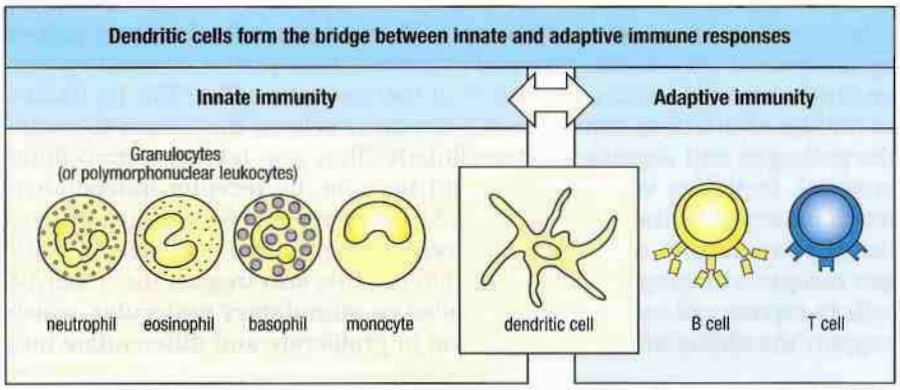

Fig. 1.20 Dendritic cells form a key link between the innate immune system and the adaptive immune system. Like the other cells of innate immunity, dendritic cells recognize pathogens via invariant cell-surface receptors for pathogen molecules and are activated by these stimuli early in an infection. Dendritic cells in tissues are phagocytic; they are specialized to ingest a wide range of pathogens and to display their antigens at the dendritic cell surface in a form that can be recognized by T cells.

When an infection occurs in a tissue such as the skin, free antigen and antigen-bearing dendritic cells travel from the site of infection through the afferent lymphatic vessels into the **draining lymph nodes** (Fig. 1.21)—peripheral lymphoid organs in which the free antigen and antigen-bearing dendritic cells activate antigen-specific lymphocytes. The activated lymphocytes then undergo a period of proliferation and differentiation, after which most leave the lymph nodes as effector cells via the efferent lymphatic vessel. This eventually returns them to the bloodstream (see Fig. 1.18), which then carries them to the tissues where they will act. This whole process takes about 4–6 days from the time that the antigen is recognized, which means that an adaptive immune response to an antigen that has not been encountered before does not become effective until about a week after infection (see Fig. 1.7). Naive lymphocytes that do not recognize their antigen also leave through the efferent lymphatic vessel and are returned to the blood, from which they continue to recirculate through lymphoid tissues until they recognize antigen or die.

The lymph nodes are highly organized lymphoid organs located at the points of convergence of vessels of the lymphatic system, which is the extensive system that collects extracellular fluid from the tissues and returns it to the blood (see Fig. 1.18). This extracellular fluid is produced continually by filtration from the blood and is called lymph. Lymph flows away from the peripheral tissues under the pressure exerted by its continual production and is carried by **lymphatic vessels**, or **lymphatics**. One-way valves in the lymphatic vessels prevent a reverse flow, and the movements of one part of the body in relation to another are important in driving the lymph along.

As noted above, **afferent lymphatic vessels** drain fluid from the tissues and carry pathogens and antigen-bearing cells from infected tissues to the lymph nodes (Fig. 1.22). Free antigens simply diffuse through the extracellular fluid to the lymph node, while the dendritic cells actively migrate into the lymph node, attracted by chemokines. The same chemokines also attract lymphocytes from the blood, and these enter lymph nodes by squeezing through the walls of specialized blood vessels called **high endothelial venules (HEVs)**, named for their thicker, more rounded appearance relative to flatter endothelial cells in other locations. In the lymph nodes, B lymphocytes are localized in **follicles**, which make up the outer **cortex** of the lymph node, with T cells more diffusely distributed in the surrounding **paracortical areas**, also referred to as the deep cortex or **T-cell zones** (see Fig. 1.22). Lymphocytes migrating from the blood into lymph nodes enter the paracortical areas first, and because they are attracted by the same chemokines, antigen-presenting dendritic cells and macrophages also become localized there. Free antigen diffusing through the lymph node can become trapped on these dendritic cells and macrophages. This juxtaposition of antigen, antigen-presenting cells, and naive T cells in the T-cell zone creates an ideal environment in which naive T cells can bind their specific antigen and thus become activated.

As noted earlier, activation of B cells usually requires not only antigen, which binds to the B-cell receptor, but also the cooperation of activated helper T cells, a type of effector T cell. The location of B cells and T cells within the lymph node is dynamically regulated by their state of activation. When they become activated, T cells and B cells both move to the border of the follicle and T-cell zone, where T cells can first provide their helper function to B cells. Some of the B-cell follicles include **germinal centers**, where activated B cells are undergoing intense proliferation and differentiation into plasma cells. These mechanisms are described in detail in Chapter 10.

In humans, the spleen is a fist-sized organ situated just behind the stomach (see Fig. 1.18). It has no direct connection with the lymphatic system; instead, it collects antigen from the blood and is involved in immune responses to blood-borne pathogens. Lymphocytes enter and leave the spleen via blood vessels. The spleen also collects and disposes of senescent red blood cells.

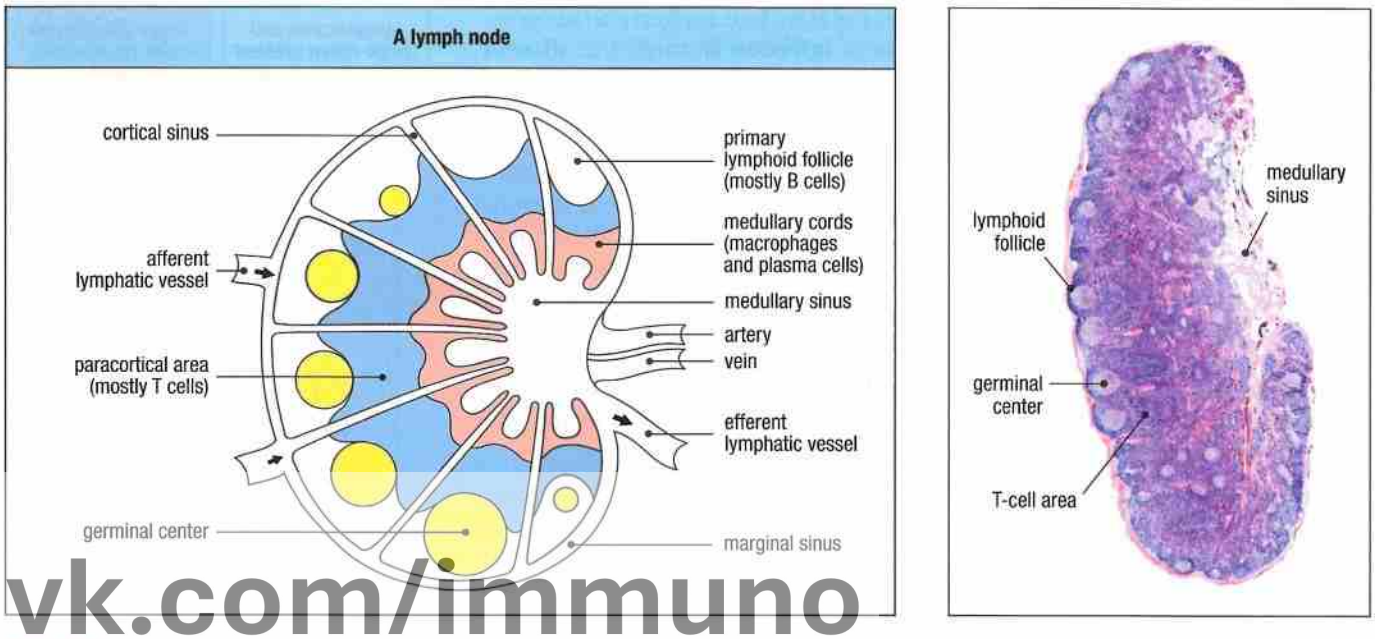
infected peripheral tissue
Antigens from sites of infection reach lymph nodes via lymphatics

Fig. 1.21 Circulating lymphocytes encounter antigen in peripheral lymphoid organs. Naive lymphocytes recirculate constantly through peripheral lymphoid organs, here illustrated as a popliteal lymph node—a lymph node situated behind the knee. In the case of an infection in the foot, this will be the draining lymph node, where lymphocytes may encounter their specific antigens and become activated. Both activated and nonactivated lymphocytes are returned to the bloodstream via the lymphatic system.



vk.com/immuno

Fig. 1.22 Organization of a lymph node. As shown at left in the diagram of a lymph node in longitudinal section, a lymph node consists of an outermost cortex (the yellow and blue areas) and an inner medulla (dark pink). The cortex is composed of an outer cortex of B cells organized into lymphoid follicles and of adjacent, or paracortical, areas made up mainly of T cells and dendritic cells. When an immune response is under way, some of the follicles contain central areas of intense B-cell proliferation called germinal centers. Lymph draining from the extracellular spaces of the body carries antigens in phagocytic dendritic cells and phagocytic macrophages from the tissues to the lymph node via the afferent lymphatics. These migrate directly from the sinuses into the cellular parts of the node. Lymph leaves via the efferent lymphatic in the medulla. The medulla consists of strings of macrophages and antibody-secreting plasma cells known as the medullary cords. Naive lymphocytes enter the node from the bloodstream through specialized postcapillary venules (not shown) and leave with the lymph through the efferent lymphatic. The light micrograph at right shows a longitudinal section through a lymph node that has follicles containing germinal centers. Original magnification ×40.

Its organization is shown schematically in Fig. 1.23. The bulk of the spleen is composed of **red pulp**, which is the site of red blood cell disposal. The lymphocytes surround the arterioles running through the spleen, forming isolated areas of **white pulp**. The sheath of lymphocytes around an arteriole is called the **periarteriolar lymphoid sheath (PALS)** and contains mainly T cells. Lymphoid follicles occur at intervals along it, and these contain mainly B cells. An area called the **marginal zone** surrounds the follicle; it has few T cells, is rich in macrophages, and has a resident, noncirculating population of B cells known as **marginal zone B cells**. These B cells are poised to rapidly produce antibodies that have low affinity to bacterial capsular polysaccharides. These antibodies, which are discussed in Chapter 8, provide some degree of protection before the adaptive immune response is fully activated. Blood-borne microbes, soluble antigens, and antigen:antibody complexes are filtered from the blood by macrophages and immature dendritic cells within the marginal zone. Like the migration of immature dendritic cells from peripheral tissues to the T-cell areas of lymph nodes, dendritic cells in the marginal zones in the spleen migrate to the T-cell areas after taking up antigen and becoming activated; here they are able to present the antigens they carry to T cells.

1-17 Mucosal surfaces have specialized immune structures that orchestrate responses to environmental microbial encounters.

Most pathogens enter the body through mucosal surfaces, which are also exposed to a vast load of other potential antigens from the air, food, and the natural microbial flora of the body. Mucosal surfaces are protected by an extensive system of lymphoid tissues known generally as the **mucosal immune system** or **mucosa-associated lymphoid tissue (MALT)**. Collectively, the

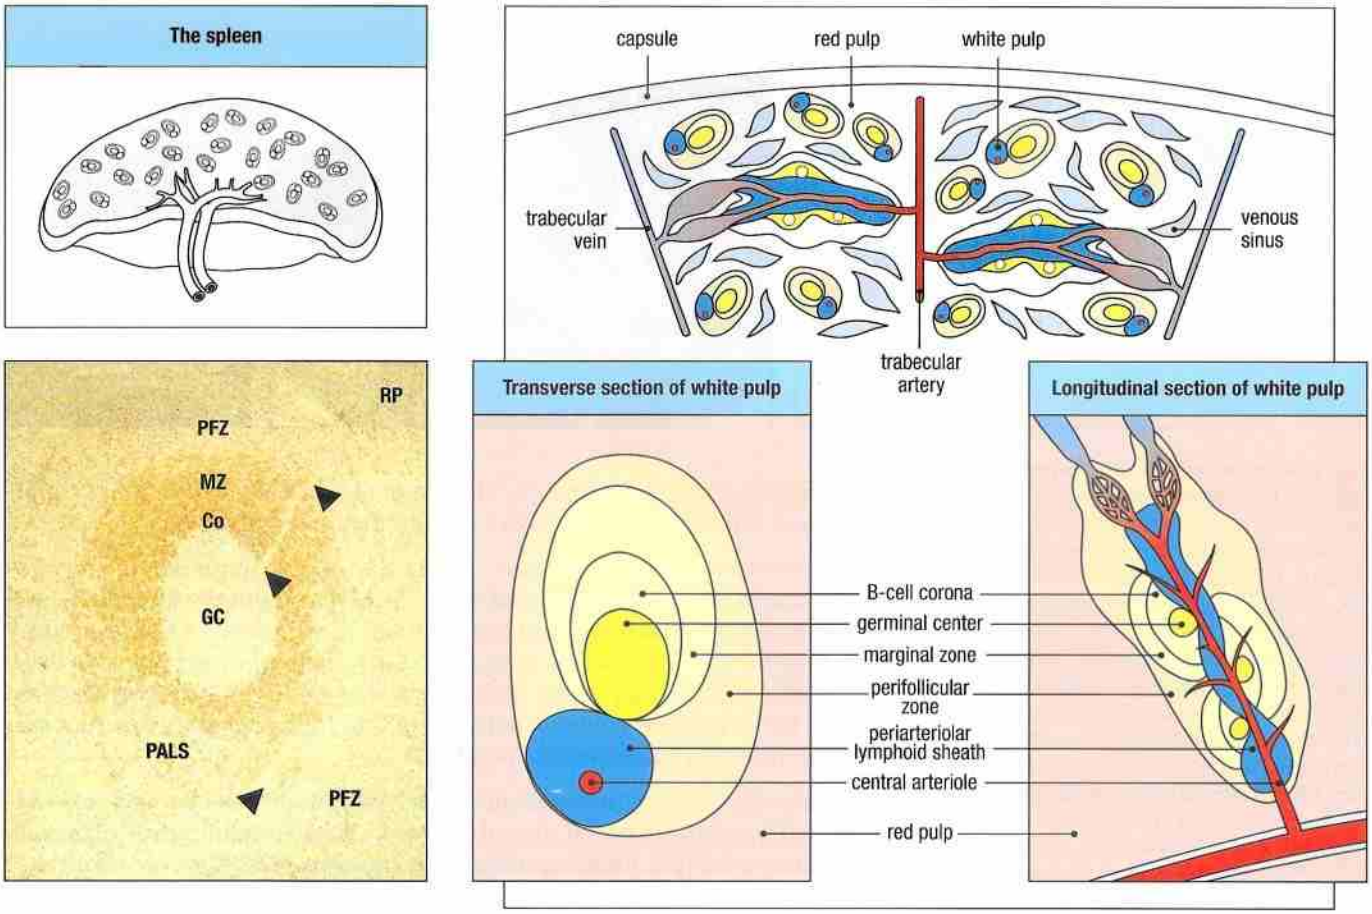


Fig. 1.23 Organization of the lymphoid tissues of the spleen. The schematic at top left shows that the spleen consists of red pulp (pink areas), which is a site of red blood cell destruction, interspersed with the lymphoid white pulp. An enlargement of a small section of a human spleen (top right) shows the arrangement of discrete areas of white pulp (yellow and blue) around central arterioles. Most of the white pulp is shown in transverse section, with two portions in longitudinal section. The two schematics below this diagram show enlargements of a transverse section (bottom center) and longitudinal section (bottom right) of white pulp. Surrounding the central arteriole is the periarteriolar lymphoid sheath (PALS), made up of T cells. Lymphocytes and antigen-loaded dendritic cells come together here. The follicles consist mainly of B cells; in secondary follicles, a germinal center is surrounded by a B-cell corona. The follicles are surrounded by a so-called marginal zone of lymphocytes. In each area of white pulp, blood carrying both lymphocytes and antigen flows from a trabecular artery into a central arteriole. From this arteriole smaller blood vessels fan out, eventually terminating in a specialized zone in the human spleen called the perifollicular zone (PFZ), which surrounds each marginal zone. Cells and antigen then pass into the white pulp through open blood-filled spaces in the perifollicular zone. The light micrograph at bottom left shows a transverse section of white pulp of human spleen immunostained for mature B cells. Both follicle and PALS are surrounded by the perifollicular zone. The follicular arteriole emerges in the PALS (arrowhead at bottom), traverses the follicle, goes through the marginal zone, and opens into the perifollicular zone (upper arrowheads). Co, follicular B-cell corona; GC, germinal center; MZ, marginal zone; RP, red pulp; arrowheads, central arteriole.

mucosal immune system is estimated to contain as many lymphocytes as all the rest of the body, and these lymphocytes form a specialized set of cells obeying somewhat different rules of recirculation from those of lymphocytes in the other peripheral lymphoid organs. The **gut-associated lymphoid tissue (GALT)** includes the **tonsils**, **adenoids**, **appendix**, and specialized structures in the small intestine called **Peyer's patches**, and they collect antigen from the epithelial surfaces of the gastrointestinal tract. In Peyer's patches, which are the most important and highly organized of these tissues, the antigen is collected by specialized epithelial cells called **microfold cells**, or **M cells** (Fig. 1.24). The lymphocytes form a follicle consisting of a large central dome of B lymphocytes surrounded by smaller numbers of T lymphocytes. Dendritic cells resident within the Peyer's patch present the antigen to T lymphocytes. Lymphocytes enter Peyer's patches from the blood and leave through efferent lymphatics. Effector lymphocytes generated in Peyer's patches travel through

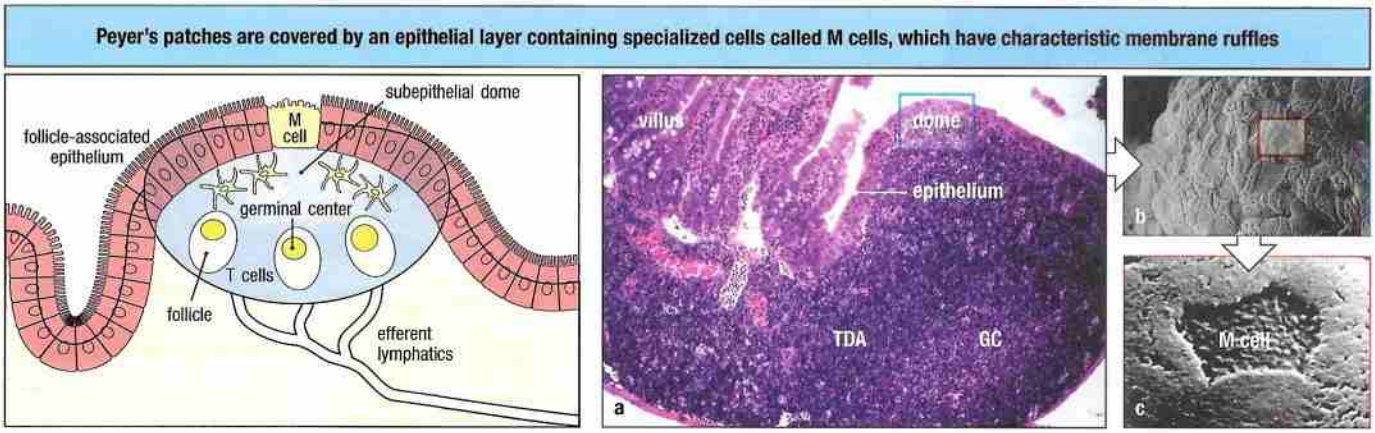

Fig. 1.24 Organization of a Peyer's patch in the gut mucosa. As the diagram on the left shows, a Peyer's patch contains numerous B-cell follicles with germinal centers. The areas between follicles are occupied by T cells and are therefore called the T cell–dependent areas. The layer between the surface epithelium and the follicles is known as the subepithelial dome and is rich in dendritic cells, T cells, and B cells. Peyer's patches have no afferent lymphatics, and the antigen enters directly from the gut across a specialized epithelium made up of so-called microfold (M) cells. Although this tissue looks very different from other lymphoid organs, the basic divisions are maintained. As in the lymph nodes, lymphocytes enter Peyer's patches from the blood across the walls of high endothelial venules (not shown), and leave via the efferent lymphatic. Panel a: The light micrograph shows a section through a Peyer's patch in the gut wall of a mouse. The Peyer's patch can be seen lying beneath the epithelial tissues. GC, germinal center; TDA, T cell–dependent area. Panel b: A scanning electron micrograph of the follicle-associated epithelium boxed in panel a shows the M cells, which lack the microvilli and the mucus layer present on normal epithelial cells. Each M cell appears as a sunken area on the epithelial surface. Panel c: A higher-magnification view of the boxed area in panel b shows the characteristic ruffled surface of an M cell. M cells are the portal of entry for many pathogens and other particles. Panel a, hematoxylin and eosin stain, magnification ×100; panel b, magnification ×5000; panel c, magnification ×23,000.

the lymphatic system and into the bloodstream, from where they are disseminated back into mucosal tissues to carry out their effector actions.

Similar but more diffuse aggregates of lymphocytes are present in the respiratory tract and other mucosa: **nasal-associated lymphoid tissue (NALT)** and **bronchus-associated lymphoid tissue (BALT)** are present in the respiratory tract. Like the Peyer's patches, these mucosal lymphoid tissues are also overlaid by M cells, through which inhaled microbes and antigens that become trapped in the mucous covering of the respiratory tract can pass. The mucosal immune system is discussed in Chapter 12.

Although very different in appearance, the lymph nodes, spleen, and mucosa-associated lymphoid tissue all share the same basic architecture. They all operate on the same principle, trapping antigens and antigen-presenting cells from sites of infection in order to present antigen to migratory small lymphocytes, thus inducing adaptive immune responses. The peripheral lymphoid organs also provide sustaining signals to lymphocytes that do not encounter their specific antigen immediately, so that they survive and continue to recirculate.

Because they are involved in initiating adaptive immune responses, the peripheral lymphoid organs are not static structures but vary quite markedly, depending on whether or not infection is present. The diffuse mucosal lymphoid tissues may appear in response to infection and then disappear, whereas the architecture of the organized tissues changes in a more defined way during an infection. For example, the B-cell follicles of the lymph nodes expand as B lymphocytes proliferate to form germinal centers (see Fig. 1.22), and the entire lymph node enlarges, a phenomenon familiarly known as swollen glands.

Finally, specialized populations of lymphocytes and innate lymphoid cells can be found distributed throughout particular sites in the body rather than being found in organized lymphoid tissues. Such sites include the liver and the **lamina propria** of the gut, as well as the base of the epithelial lining of the gut, reproductive epithelia, and, in mice but not in humans, the epidermis. These lymphocyte populations seem to have an important role in protecting these tissues from infection and are described further in Chapters 8 and 12.

1-18 Lymphocytes activated by antigen proliferate in the peripheral lymphoid organs, generating effector cells and immunological memory.

The great diversity of the lymphocyte receptor repertoire means that there will usually be some lymphocytes bearing a receptor for any given foreign antigen. Recent experiments suggest this number to be perhaps a few hundred per mouse, certainly not enough to mount a response against a pathogen. To generate sufficient antigen-specific effector lymphocytes to fight an infection,

a lymphocyte with an appropriate receptor specificity is activated first to proliferate. Only when a large clone of identical cells has been produced do these finally differentiate into effector cells, a process that requires 4–6 days. This means the adaptive immune response to a pathogen occurs nearly a week after the initial infection has occurred and been detected by the innate immune system.

On recognizing its specific antigen on an activated antigen-presenting cell, a naive lymphocyte stops migrating, the volume of its nucleus and cytoplasm increases, and new mRNA molecules and new proteins are synthesized. Within a few hours, the cell looks completely different and is known as a **lymphoblast**. Dividing lymphoblasts are able to duplicate themselves two to four times every 24 hours over the course of 3–5 days, so that a single naive lymphocyte can produce a clone of around 1000 daughter cells of identical specificity. These then differentiate into effector cells. In the case of B cells, the differentiated effector cells are the plasma cells, which secrete antibody. In the case of T cells, the effector cells are either cytotoxic T cells, which are able to destroy infected cells, or helper T cells, which activate other cells of the immune system (see Section 1-8).

Effector lymphocytes do not recirculate like naive lymphocytes. Some effector T cells detect sites of infection and migrate into them from the blood; others stay in the lymphoid tissues to activate B cells. Some antibody-secreting plasma cells remain in the peripheral lymphoid organs, but most plasma cells generated in the lymph nodes and spleen will migrate to the bone marrow and take up residence there, secreting large amounts of antibodies into the blood system. Effector cells generated in the mucosal immune system generally stay within the mucosal tissues. Most lymphocytes generated by clonal expansion in an immune response will eventually die. However, a significant number of activated antigen-specific B cells and T cells persist after antigen has been eliminated. These cells are known as **memory cells** and form the basis of immunological memory. They can be reactivated much more quickly than naive lymphocytes, which ensures a more rapid and effective response on a second encounter with a pathogen and thereby usually provides lasting protective immunity.

The characteristics of immunological memory are readily observed by comparing an individual's antibody response to a first or **primary immunization** with the response to a **secondary (or booster) immunization** with the same antigen. As shown in Fig. 1.25, the secondary antibody response occurs after

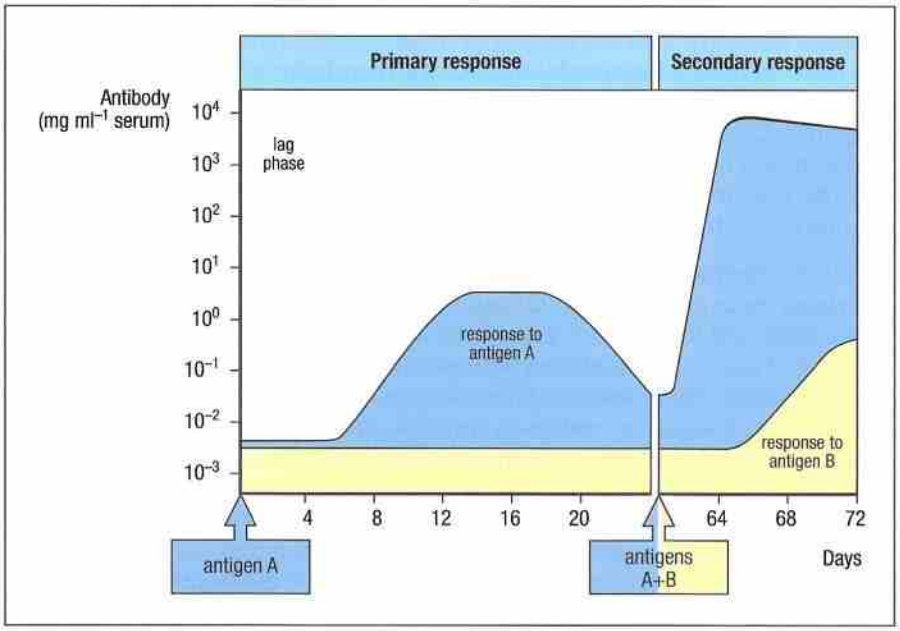

Fig. 1.25 The course of a typical antibody response. The first encounter with an antigen produces a primary response. Antigen A introduced at time zero encounters little specific antibody in the serum. After a lag phase (light blue), antibody against antigen A (dark blue) appears; its concentration rises to a plateau and then gradually declines, as is typical of a primary response. When the serum is tested for antibody against another antigen, B (yellow), there is little preset. When the animal is later challenged with a mixture of antigens A and B, a very rapid and intense antibody secondary response to A occurs, illustrating immunological memory. This is the main reason for giving booster injections after an initial vaccination. Note that the response to B resembles the primary response to A, as this is the first encounter with antigen B.

a shorter lag phase and achieves a markedly higher level than in the primary response. During the secondary response, antibodies can also acquire higher affinity, or strength of binding, for the antigen because of a process called **affinity maturation**, which takes place in the specialized germinal centers within B-cell follicles (see Section 1-16). Importantly, helper T cells are required for the process of affinity maturation, but T-cell receptors do not undergo affinity maturation. Compared with naive T cells, memory T cells show a lower threshold for activation, but as a result of changes in the responsiveness of the cell and not because of changes in the receptor. We describe the mechanisms of antibody affinity maturation in Chapter 10.

The cellular basis of immunological memory is the clonal expansion and clonal differentiation of cells that have a specific attraction for the eliciting antigen, and the memory is therefore entirely antigen-specific. It is immunological memory that enables successful vaccination and prevents reinfection with pathogens that have been repelled successfully by an adaptive immune response. In Chapter 11, we will return to immunological memory, which is perhaps the most important biological consequence of adaptive immunity.

Summary.

While the innate immune system relies on invariant pattern-recognition receptors to detect common microbial structures or the damage they cause, the adaptive immune system relies on a repertoire of antigen receptors to recognize structures that are specific to individual pathogens. This feature provides adaptive immunity with greater sensitivity and specificity. The clonal expansion of antigen-reactive lymphocytes also confers the property of immunological memory, which enhances protection against reinfection by the same pathogen.

Adaptive immunity relies on two major types of lymphocytes. B cells mature in the bone marrow and are the source of circulating antibodies. T cells mature in the thymus and recognize peptides from pathogens presented by MHC molecules on infected cells or antigen-presenting cells. An adaptive response involves the selection and amplification of clones of lymphocytes bearing receptors that recognize the foreign antigen. This clonal selection provides the theoretical framework for understanding all the key features of an adaptive immune response.

Each lymphocyte carries cell-surface receptors of a single antigen specificity. These receptors are generated by the random recombination of variable receptor gene segments and the pairing of distinct variable protein chains: heavy and light chains in immunoglobulins or the two chains of T-cell receptors. The large antigen-receptor repertoire of lymphocytes can recognize virtually any antigen. Adaptive immunity is initiated when an innate immune response fails to eliminate a new infection, and activated antigen-presenting cells—typically dendritic cells that bear antigens from pathogens and co-stimulatory receptors—migrate to the draining lymphoid tissues.

Immune responses are initiated in several peripheral lymphoid organs. The spleen serves as a filter for blood-borne infections. Lymph nodes draining various tissues and the mucosa-associated and gut-associated lymphoid tissues (MALT and GALT) are organized into specific zones where T and B cells can be activated efficiently by antigen-presenting cells or helper T cells. When a recirculating lymphocyte encounters its corresponding antigen in these peripheral lymphoid organs, it proliferates, and its clonal progeny differentiate into effector T and B lymphocytes that can eliminate the infectious agent. A subset of these proliferating lymphocytes differentiates into memory cells, ready to respond rapidly to the same pathogen if it is encountered again. The details of these processes of recognition, development, and differentiation form the main material of the central three parts of this book.

The effector mechanisms of immunity.

For activated innate and adaptive immune cells to destroy pathogens, they must employ an appropriate effector mechanism suited to each infecting agent. The different types of pathogens noted in Fig. 1.26 have different lifestyles and require different responses for both their recognition and their destruction. Perhaps it is not surprising, then, that defenses against different pathogen types are organized into **effector modules** suited for these different lifestyles. For example, defense against extracellular pathogens can involve both phagocytic cells and B cells, which recognize extracellular antigens and become plasma cells that secrete antibody into the extracellular environment. Defense against intracellular pathogens involves T cells that can detect peptides generated inside the infected cell. Some effector T cells directly kill cells infected with intracellular pathogens such as viruses. These examples illustrate components of two distinct effector modules, one specialized for elimination of extracellular pathogens, and a second specialized for elimination of intracellular pathogens. In general, an effector module is a collection of cell-mediated and humoral mechanisms that involve components of both the innate and adaptive immune systems; these mechanisms act together to achieve elimination of a particular category of pathogen. One important component of each effector module is the effector T cell response. Depending on the nature of the pathogen, activated T cells differentiate into three major subsets of helper T cells, each of which produces different patterns of cytokines. These three subsets, discussed later, generally specialize in promoting defenses against pathogens having three major lifestyles: they can defend against intracellular infection, destroy extracellular bacteria and fungi, or provide barrier immunity directed at parasites. T cells also promote defense against extracellular pathogens by helping B cells make antibody.

Most of the other effector mechanisms used by an adaptive immune response to dispose of pathogens are the same as those of innate immunity and involve cells such as macrophages and neutrophils and proteins such as complement. Indeed, it seems likely that the vertebrate adaptive immune response evolved by the addition of specific recognition properties to innate defense mechanisms already existing in invertebrates. This is supported by recent findings that the innate lymphoid cells—the ILCs—show similar patterns of differentiation into different cytokine-producing subsets as those of T cells.

We begin this section by outlining the effector actions of antibodies, which depend almost entirely on recruiting cells and molecules of the innate immune system.

The immune system protects against four classes of pathogens

Type of pathogen	Examples	Diseases
Viruses (intracellular)	Variola Influenza Varicella	Smallpox Flu Chickenpox
Intracellular bacteria, protozoa, parasites	*Mycobacterium leprae* *Leishmania donovani* *Plasmodium falciparum* *Toxoplasma gondii*	Leprosy Leishmaniasis Malaria Toxoplasmosis
Extracellular bacteria, parasites, fungi	*Streptococcus pneumoniae* *Clostridium tetani* *Trypanosoma brucei* *Pneumocystis jirovecii*	Pneumonia Tetanus Sleeping sickness *Pneumocystis* pneumonia
Parasitic worms (extracellular)	*Ascaris* *Schistosoma*	Ascariasis Schistosomiasis

Fig. 1.26 The major types of pathogens confronting the immune system, and some of the diseases they cause.

1-19 Innate immune responses can select from several effector modules to protect against different types of pathogens.

As we mentioned in Section 1-7, the innate immune system contains several types of cells—NK cells and ILCs—that have similarities to lymphocytes, particularly T cells. NK cells lack the antigen-specific receptors of T cells but can exhibit the cytotoxic capacity of T cells and produce some of the cytokines that effector T cells produce. ILCs develop from the same progenitor cells in the bone marrow as NK cells, and they also lack antigen-specific receptors. Very recent discoveries indicate that ILCs actually comprise several closely related lineages that differ in the specific cytokines that they will produce when activated. Remarkably, there is a striking similarity between the patterns of cytokines produced by ILC subsets and by helper T-cell subsets, as mentioned above. It appears that subsets of ILCs are the innate homologs of their helper T-cell counterparts, and NK cells are the innate homolog of cytotoxic T cells.

As mentioned in Section 1-6, there are a large number of cytokines with different functions (see eAppendix III, found in the ebook and on the Digital Landing Page for this book). A convenient way to organize the effects of cytokines is by the effector module that each cytokine promotes. Some cytokines tend to promote immunity to intracellular pathogens. One such cytokine is **interferon-γ (IFN-γ)**, which acts both by activating phagocytes to more efficiently kill intracellular pathogens and by inducing target tissues to resist intracellular pathogens. This effector module is called **type 1 immunity**. IFN-γ is produced by some but not all subsets of innate and adaptive lymphocytes, and the ILC subset making IFN-γ is called **ILC1**. Other ILC subsets produce cytokines favoring effector modules called **type 2 immunity** and **type 3 immunity**, which coordinate defense against parasitic and extracellular pathogens, respectively. The modular nature of immune effector functions will be encountered frequently throughout this book. One principle seems to be that activated sensor cells from either the innate or the adaptive immune system can activate different subsets of innate or adaptive lymphocytes that are specialized for amplifying particular effector modules that are directed against different categories of pathogens (Fig. 1.27).

Effector module	Cell types, functions, and mechanisms
Cytotoxicity	NK cells, CD8 T cells
	Elimination of virally infected and metabolically stressed cells
Intracellular immunity (Type 1)	ILC1, T_H1 cells
	Elimination of intracellular pathogens; activation of macrophages
Mucosal and barrier immunity (Type 2)	ILC2, T_H2 cells
	Elimination and expulsion of parasites; recruitment of eosinophils, basophils, and mast cells
Extracellular immunity (Type 3)	ILC3, T_H17 cells
	Elimination of extracellular bacteria and fungi; recruitment and activation of neutrophils

Fig. 1.27 Innate and adaptive lymphocytes share a variety of functions. The different effector modules are served by both innate and adaptive immune mechanisms. For each of the four major types of innate lymphocytes, there is a corresponding type of T cell with generally similar functional characteristics. Each set of innate lymphocyte and T cell exerts an effector activity that is broadly directed at a distinct category of pathogen.

1-20 Antibodies protect against extracellular pathogens and their toxic products.

Antibodies are found in plasma—the fluid component of blood—and in extracellular fluids. Because body fluids were once known as humors, immunity mediated by antibodies and other proteins in the plasma is known as **humoral immunity**.

Antibodies are Y-shaped molecules with two identical antigen-binding sites and one constant, or Fc, region. As mentioned in Section 1-9, there are five forms of the constant region of an antibody, known as the antibody **classes** or **isotypes**. The constant region determines an antibody's functional properties—how it will engage with the effector mechanisms that dispose of antigen once it is recognized. Each class carries out its particular function by engaging a distinct set of effector mechanisms. We describe the antibody classes and their actions in Chapters 4 and 10.

The first and most direct way in which antibodies can protect against pathogens or their products is by binding to them and thereby blocking their access to cells that they might infect or destroy (Fig. 1.28, left panels). This function is known as **neutralization** and is important for protection against viruses, which are prevented from entering cells and replicating, and against bacterial toxins. Neutralization is the form of immunity elicited by most vaccines against bacterial toxins.

For bacteria, however, binding by antibodies is not sufficient to stop their replication. In this case, a second function of antibodies is to enable a phagocytic cell such as a macrophage or a neutrophil to ingest and destroy the bacterium. Many bacteria evade the innate immune system because they have an outer coat that is not recognized by the pattern-recognition receptors of phagocytes. However, antigens in the coat can be recognized by antibodies, and phagocytes have receptors, called **Fc receptors**, that bind the constant region and facilitate phagocytosis of the bacterium (see Fig. 1.28, center panels). The coating of pathogens and foreign particles in this way is known as **opsonization**.

The third function of antibodies is **complement activation**. In Section 1-2 we briefly mentioned Bordet's discovery of complement as a serum factor that 'complements' the activities of antibodies. Complement can be activated by microbial surfaces even without the help of antibodies, which leads to the covalent deposition of certain complement proteins onto the bacterial surface. But when an antibody binds first to the bacterial surface, its constant region provides a platform that is much more efficient in complement activation than microbial activation of complement alone. Thus, once antibodies are produced, complement activation against a pathogen can be substantially increased.

Certain complement components that are deposited on the bacterial surface can directly lyse the membranes of some bacteria, and this is important in a few bacterial infections (see Fig. 1.28, right panels). The major function of complement, however, is to enable phagocytes to engulf and destroy bacteria that the phagocytes would not otherwise recognize. Most phagocytes express receptors that bind certain complement proteins; called complement receptors, these receptors bind to the complement proteins deposited onto the bacterial surface and thus facilitate bacterial phagocytosis. Certain other complement proteins also enhance the phagocytes' bactericidal capacity. The end result is that all pathogens and free molecules bound by antibody are eventually delivered to phagocytes for ingestion, degradation, and removal from the body (see Fig. 1.28, bottom panels). The complement system and the phagocytes that antibodies recruit are not themselves antigen-specific; they depend on antibody molecules to mark the particles as foreign.

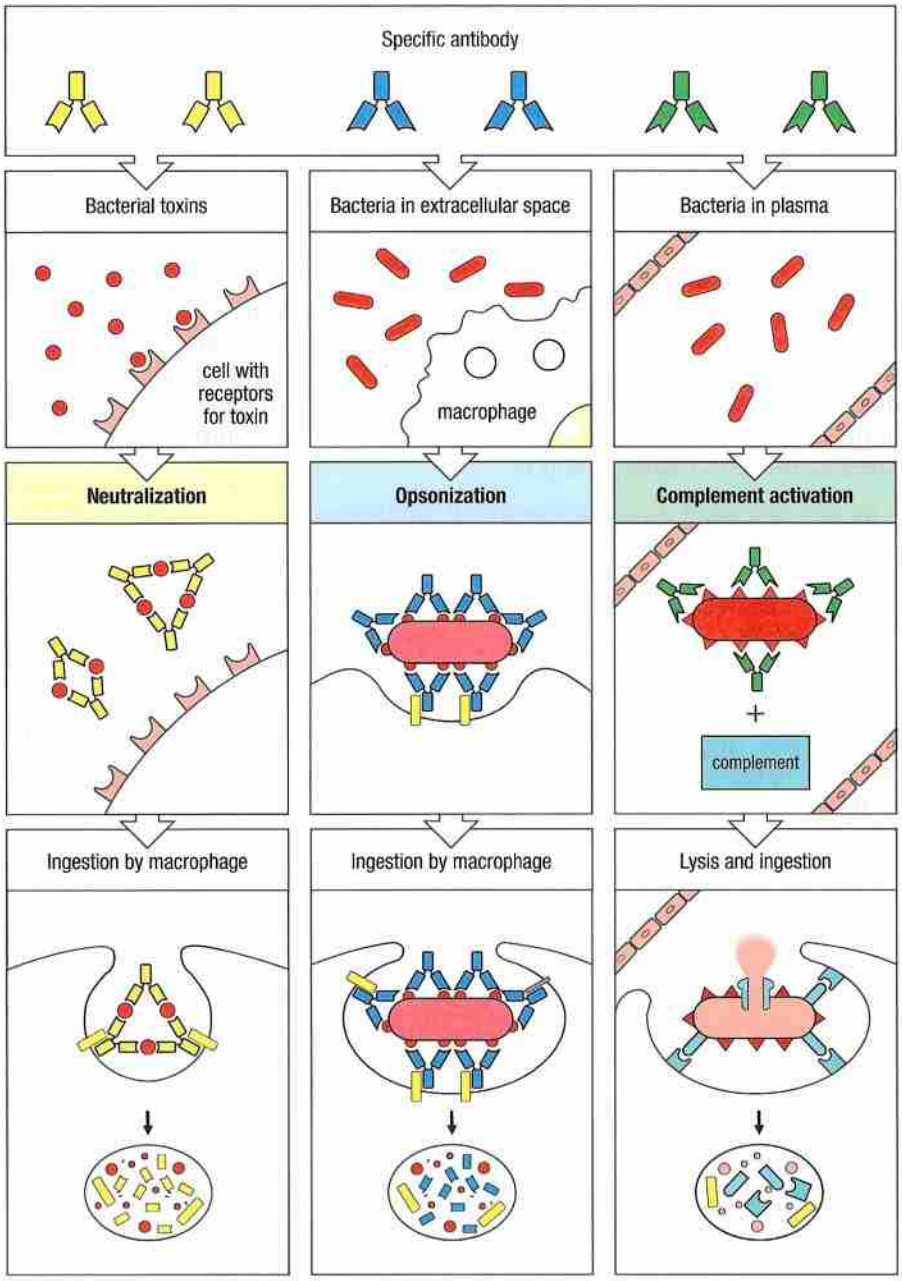

Fig. 1.28 Antibodies can participate in host defense in three main ways. The left panels show antibodies binding to and neutralizing a bacterial toxin, thus preventing it from interacting with host cells and causing pathology. Unbound toxin can react with receptors on the host cell, whereas the toxin:antibody complex cannot. Antibodies also neutralize complete virus particles and bacterial cells by binding to them and, as for toxins, preventing these microbes from interacting with host cells. For these intact microbes, neutralization by bound antibodies prevents host-cell infection and/or damage by the microbes. The antigen:antibody complex is eventually scavenged and degraded by macrophages.

Antibodies coating an antigen render it recognizable as foreign by phagocytes (macrophages and neutrophils), which then ingest and destroy it; this is called opsonization. The center panels show opsonization and phagocytosis of a bacterial cell. Antibody first binds to antigens (red) on the bacterial cell through the variable regions. Then the antibody's Fc region binds to Fc receptors (yellow) expressed by macrophages and other phagocytes, facilitating phagocytosis.

The right panels show activation of the complement system by antibodies coating a bacterial cell. Bound antibodies form a platform that activates the first protein in the complement system, which deposits complement proteins (blue) on the surface of the bacterium. This can lead in some cases to formation of a pore that lyses the bacterium directly. More generally, complement proteins on the bacterium can be recognized by complement receptors on phagocytes; this stimulates the phagocytes to ingest and destroy the bacterium. Thus, antibodies target pathogens and their toxic products for disposal by phagocytes.

1-21 T cells orchestrate cell-mediated immunity and regulate B-cell responses to most antigens.

Some bacteria and parasites, and all viruses, replicate inside cells, where they cannot be detected by antibodies, which access only the blood and extracellular space. The destruction of intracellular invaders is the function of the T lymphocytes, which are responsible for the **cell-mediated immune responses** of adaptive immunity. But T lymphocytes participate in responses to a wide variety of pathogens, including extracellular organisms, and so must exert a wide variety of effector activities.

T lymphocytes, of which there are several types, develop in the thymus. They are characterized by the type of T-cell receptors they express and by the expression of certain markers. The two main classes of T cells express either a cell-surface protein called **CD8** or another called **CD4**. These are not just random markers, but are important for a T cell's function, because they help to determine the interactions between the T cell and other cells. Recall from Section 1-10 that T cells detect peptides derived from foreign antigens that are displayed by MHC molecules on a cell's surface. CD8 and CD4 function in antigen recognition by recognizing different regions of MHC molecules and by being involved in the signaling of the T-cell receptor that is engaged with its antigen. Thus, CD4 and CD8 are known as **co-receptors** and they provide a functional difference between CD8 and CD4 T cells.

Importantly, there are two main types of MHC molecules, called **MHC class I** and **MHC class II**. These have slightly different structures, but both have an elongated groove on the outer surface that can bind a peptide (Fig. 1.29). The peptide becomes trapped in this groove during the synthesis and assembly of the MHC molecule inside the cell, and the peptide:MHC complex is then transported to the cell surface and displayed to T cells (Fig. 1.30). Because CD8 recognizes a region of the MHC class I protein while CD4 recognizes a region of the MHC class II protein, the two co-receptors functionally distinguish T cells. Therefore, CD8 T cells selectively recognize peptides that are presented by MHC class I molecules, while CD4 T cells selectively recognize peptides that are presented by MHC class II molecules.

The most direct action of T cells is cytotoxicity. Cytotoxic T cells are effector T cells that act against cells infected with viruses. Antigens derived from the virus multiplying inside the infected cell are displayed on the cell's surface, where they are recognized by the antigen receptors of cytotoxic T cells. These T cells can then control the infection by directly killing the infected cell before viral replication is complete and new viruses are released (Fig. 1.31). Cytotoxic T cells carry CD8, and so recognize antigen presented by MHC class I molecules. Because MHC class I molecules are expressed on most cells of the body, they serve as an important mechanism to defend against viral infections.

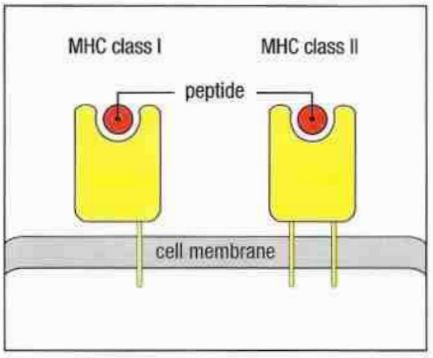

Fig. 1.29 MHC molecules on the cell surface display peptide fragments of antigens. MHC molecules are membrane proteins whose outer extracellular domains form a cleft in which a peptide fragment is bound. These fragments are derived from proteins degraded inside the cell and include both self and foreign protein antigens. The peptides are bound by the newly synthesized MHC molecule before it reaches the cell surface. There are two kinds of MHC molecules, MHC class I and MHC class II; they have related but distinct structures and functions. Although not shown here for simplicity, both MHC class I and MHC class II molecules are trimers of two protein chains and the bound self or nonself peptide.

Fig. 1.30 MHC class I molecules present antigen derived from proteins in the cytosol. In cells infected with viruses, viral proteins are synthesized in the cytosol. Peptide fragments of viral proteins are transported into the endoplasmic reticulum (ER), where they are bound by MHC class I molecules, which then deliver the peptides to the cell surface.

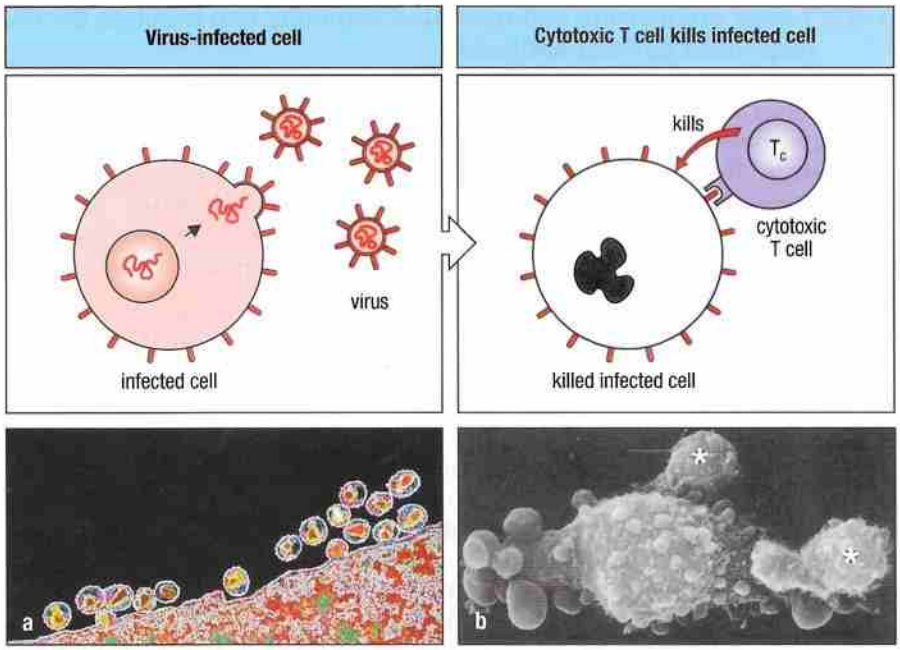

Fig. 1.31 Mechanism of host defense against intracellular infection by viruses. Cells infected by viruses are recognized by specialized T cells called cytotoxic T cells, which kill the infected cells directly. The killing mechanism involves the activation of enzymes known as caspases, which contain cysteine in their active site and cleave target proteins at aspartic acid. The caspases in turn activate a cytosolic nuclease that cleaves host and viral DNA in the infected cell. Panel a is a colored transmission electron micrograph of human immunodeficiency viruses (HIV) budding from the surface of an infected T-cell. Panel b is a scanning electron micrograph of a target cell being killed by two cytotoxic T lymphocytes (asterisks).

MHC class I molecules bearing viral peptides are recognized by CD8-bearing cytotoxic T cells, which then kill the infected cell (Fig. 1.32).

CD4 T cells recognize antigen presented by MHC class II molecules, which are expressed by the predominant antigen-presenting cells of the immune system: dendritic cells, macrophages, and B cells (Fig. 1.33). Thus CD4 T cells tend to recognize antigens taken up by phagocytosis from the extracellular environment. CD4 T cells are the helper T cells mentioned earlier in the chapter. They develop into a variety of different effector subsets, called $\mathbf{T_H1}$ (for T helper type 1), $\mathbf{T_H2}$, $\mathbf{T_H17}$, and so on, and they produce cytokines in patterns similar to those of the subsets of ILCs mentioned earlier that activate effector modules protective against different pathogens. These subsets act primarily at sites of infection or injury in peripheral tissues. In the lymphoid tissues, a subset of CD4 T cells, called the **T follicular helper (T_{FH})** cell, interacts with B cells to regulate antibody production during the immune response. The various T helper subsets are described in Chapter 9.

For example, the T_H1 subset of CD4 T cells helps to control certain bacteria that take up residence in membrane-enclosed vesicles inside macrophages. They produce the same cytokine as ILC1 cells, IFN-γ, which activates macrophages to increase their intracellular killing power and destroy these bacteria. Important infections that are controlled by this function are tuberculosis and leprosy, which are caused by the bacteria *Mycobacterium tuberculosis* and *M. leprae*, respectively. Mycobacteria survive intracellularly because they prevent the vesicles they occupy from fusing with lysosomes, which contain a variety of degradative enzymes and antimicrobial substances (Fig. 1.34). However, on its surface, the infected macrophage presents mycobacteria-derived antigens that can be recognized by activated

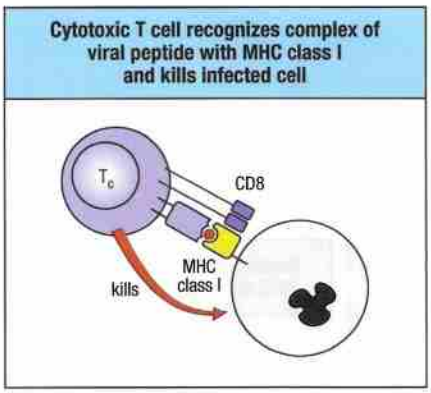

Fig. 1.32 Cytotoxic CD8 T cells recognize antigen presented by MHC class I molecules and kill the cell. The peptide:MHC class I complex on virus-infected cells is detected by antigen-specific cytotoxic T cells. Cytotoxic T cells are preprogrammed to kill the cells they recognize.

antigen-specific T_H1 cells, which in turn secrete particular cytokines that induce the macrophage to overcome the block on vesicle fusion. T_H2 and T_H17 subsets produce cytokines that are specialized for promoting responses against parasites or extracellular bacteria and fungi, respectively. CD4 T cells, and their specialized subsets, play a pervasive role in adaptive immunity, and we will be returning to them many times in this book, including in Chapters 8, 9, 11, and 12.

1-22 Inherited and acquired defects in the immune system result in increased susceptibility to infection.

We tend to take for granted the ability of our immune systems to free our bodies of infection and prevent its recurrence. In some people, however, parts of the immune system fail. In the most severe of these **immunodeficiency diseases**, adaptive immunity is completely absent, and death occurs in infancy from overwhelming infection unless heroic measures are taken. Other less catastrophic failures lead to recurrent infections with particular types of pathogens, depending on the particular deficiency. Much has been learned about the functions of the different components of the human immune system through the study of these immunodeficiencies, many of which are caused by inherited genetic defects. Because understanding the features of immunodeficiencies requires a detailed knowledge of normal immune mechanisms, we have postponed discussion of most of these diseases until Chapter 13, where they can be considered together.

In the 1980s, a devastating form of immunodeficiency appeared, the **acquired immune deficiency syndrome**, or **AIDS**, which is caused by an infectious agent, the human immunodeficiency viruses HIV-1 and HIV-2. This disease destroys T cells, dendritic cells, and macrophages bearing CD4, leading to infections caused by intracellular bacteria and other pathogens normally controlled by such cells. These infections are the major cause of death from this increasingly prevalent immunodeficiency disease, which is discussed fully in Chapter 13 together with the inherited immunodeficiencies.

Fig. 1.33 CD4 T cells recognize antigen presented by MHC class II molecules. On recognition of their specific antigen on infected macrophages, T_H1 cells activate the macrophage, leading to the destruction of the intracellular bacteria (top panel). When T follicular helper (T_{FH}) cells recognize antigen on B cells (bottom panel), they activate these cells to proliferate and differentiate into antibody-producing plasma cells (not shown).

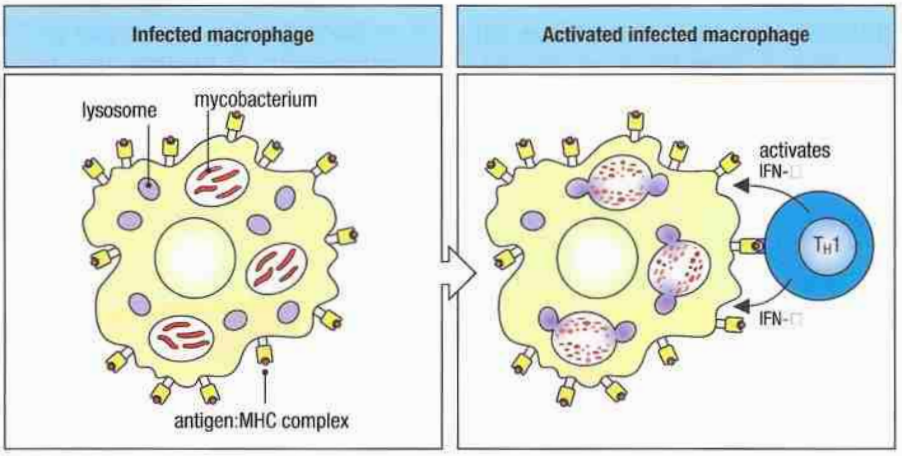

Fig. 1.34 Mechanism of host defense against intracellular infection by mycobacteria. Mycobacteria are engulfed by macrophages but resist being destroyed by preventing the intracellular vesicles in which they reside from fusing with lysosomes containing bactericidal agents. Thus the bacteria are protected from being killed. In resting macrophages, mycobacteria persist and replicate in these vesicles. When the phagocyte is recognized and activated by a T_H1 cell, however, the phagocytic vesicles fuse with lysosomes, and the bacteria can be killed. Macrophage activation is controlled by T_H1 cells, both to avoid tissue damage and to save energy.

Acquired Immune Deficiency Syndrome (AIDS)

1-23 Understanding adaptive immune responses is important for the control of allergies, autoimmune disease, and the rejection of transplanted organs.

The main function of our immune system is to protect the human host from infectious agents. However, many medically important diseases are associated with a normal immune response directed against an inappropriate antigen, often in the absence of infectious disease. Immune responses directed at noninfectious antigens occur in **allergy**, in which the antigen is an innocuous foreign substance; in **autoimmune disease**, in which the response is to a self antigen; and in **graft rejection**, in which the antigen is borne by a transplanted foreign cell (discussed in Chapter 15). The major antigens provoking graft rejection are, in fact, the MHC molecules, as each of these is present in many different versions in the human population—that is, they are highly **polymorphic**—and most unrelated people differ in the set of MHC molecules they express, a property commonly known as their 'tissue type.' The MHC was originally recognized by the work of Peter Gorer in the 1930s as a gene locus in mice, the **H-2 locus**, that controlled the acceptance or rejection of transplanted tumors. Genes in this locus were later studied by George Snell, who examined their role in tissue transplantation by developing mouse strains differing only at these histocompatibility loci. The human MHC molecules were first discovered during the Second World War, when attempts were made to use skin grafts from donors to repair badly burned pilots and bomb victims. The patients rejected the grafts, which were recognized by their immune systems as being 'foreign.' What we call a successful immune response or a failure, and whether the response is considered harmful or beneficial to the host, depends not on the response itself but rather on the nature of the antigen and the circumstances in which the response occurs (Fig. 1.35). Snell was awarded the 1980 Nobel Prize (together with Baruj Benacerraf and Jean Dausset) for his work on the MHC.

Allergic diseases, which include asthma, are an increasingly common cause of disability in the developed world. Autoimmunity is also now recognized as the cause of many important diseases. An autoimmune response directed against pancreatic β cells is the leading cause of diabetes in the young. In allergies and autoimmune diseases, the powerful protective mechanisms of the adaptive immune response cause serious damage to the individual.

Immune responses to harmless antigens, to body tissues, or to organ grafts are, like all other immune responses, highly specific. At present, the usual way to treat these responses is with immunosuppressive drugs, which inhibit all immune responses, desirable and undesirable alike. If it were possible

Antigen	Effect of response to antigen	
	Normal response	Deficient response
Infectious agent	Protective immunity	Recurrent infection
Innocuous substance	Allergy	No response
Grafted organ	Rejection	Acceptance
Self organ	Autoimmunity	Self tolerance
Tumor	Tumor immunity	Cancer

Fig. 1.35 Immune responses can be beneficial or harmful, depending on the nature of the antigen. Beneficial responses are shown in white boxes, harmful responses in red-shaded boxes. Where the response is beneficial, its absence is harmful.

to suppress only those lymphocyte clones responsible for the unwanted response, the disease could be cured or the grafted organ protected without impeding protective immune responses. At present, antigen-specific immunoregulation is outside the reach of clinical treatment. But as we shall see in Chapter 16, many new drugs have been developed recently that offer more selective immune suppression to control autoimmune and other unwanted immune responses. Among these, therapies using highly specific **monoclonal antibodies** were made possible by Georges Köhler and César Milstein, who shared the 1984 Nobel Prize along with Niels K. Jerne. Köhler and Milstein received the prize for their "discovery of the principle for production of monoclonal antibodies." We shall discuss the current state of understanding of allergies, autoimmune disease, graft rejection, and immunosuppressive drugs and monoclonal antibodies in Chapters 14–16, and we shall see in Chapter 15 how the mechanisms of immune regulation are beginning to emerge from a better understanding of the functional subsets of lymphocytes and the cytokines that control them.

1-24 Vaccination is the most effective means of controlling infectious diseases.

The deliberate stimulation of an immune response by immunization, or vaccination, has achieved many successes in the two centuries since Jenner's pioneering experiment. Mass immunization programs have led to the virtual eradication of several diseases that used to be associated with significant morbidity (illness) and mortality (Fig. 1.36). Immunization is considered so safe and so important that most states in the United States require children to be immunized against up to seven common childhood diseases. Impressive as these accomplishments are, there are still many diseases for which we lack effective vaccines. And even though vaccines for diseases such as measles can be used effectively in developed countries, technical and economic problems can prevent their widespread use in developing countries, where mortality from these diseases is still high.

The tools of modern immunology and molecular biology are being applied to develop new vaccines and improve old ones, and we discuss these advances in Chapter 16. The prospect of controlling these important diseases is tremendously exciting. The guarantee of good health is a critical step toward population control and economic development. At a cost of pennies per person, great hardship and suffering can be alleviated.

Many serious pathogens have resisted efforts to develop vaccines against them, often because they can evade or subvert the protective mechanisms of an adaptive immune response. We examine some of the evasive strategies used by successful pathogens in Chapter 13. The conquest of many of the world's leading diseases, including malaria and diarrheal diseases (the leading killers of children) as well as the more recent threat from AIDS, depends on a better understanding of the pathogens that cause them and their interactions with the cells of the immune system.

1-25 Emerging pathogens present new challenges for the immune system.

Pathogenic microbes have been besieging humans for centuries, if not millennia. Reports of the bubonic plague, caused by the bacterium *Yersinia pestis*, date back to the Philistines in 1320 BCE. Influenza virus has been causing human disease for centuries, with the earliest report of an influenza-like illness by Hippocrates, the Greek physician, in ~410 BCE. Current estimates indicate that *Mycobacterium tuberculosis*, the causative agent of tuberculosis,

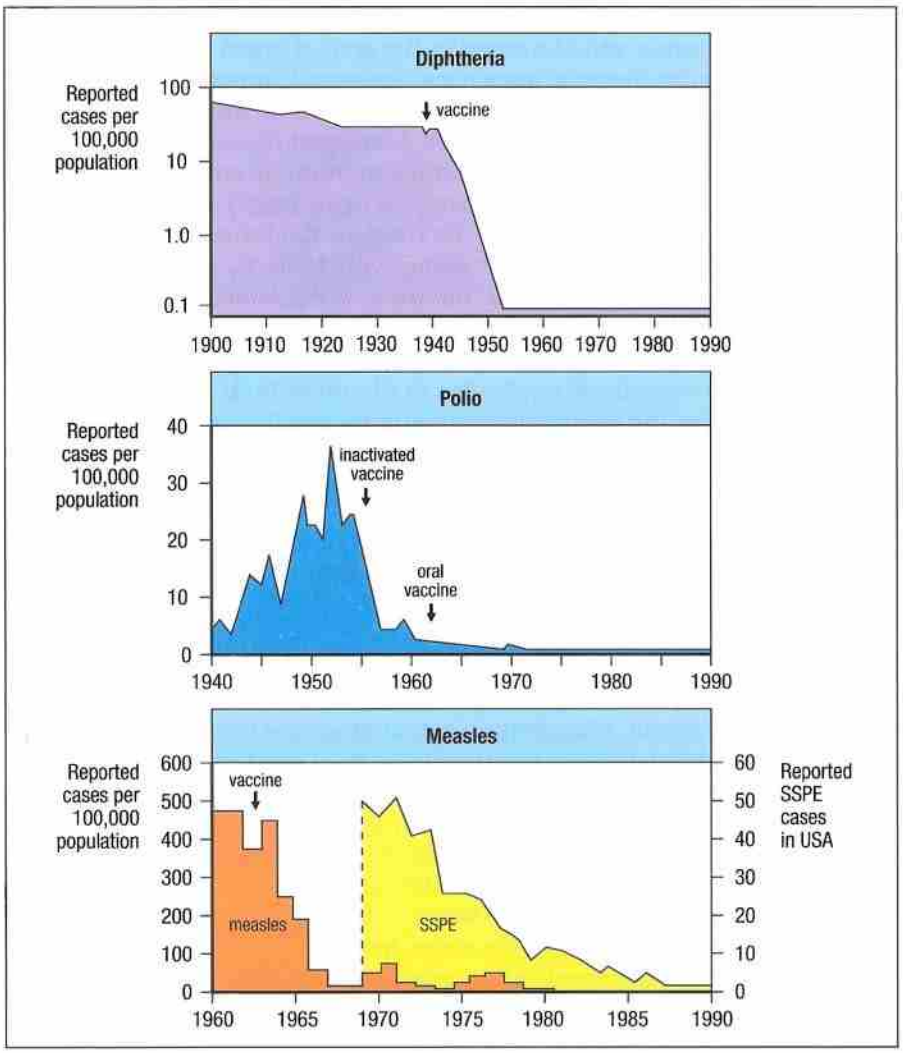

Fig. 1.36 Successful vaccination campaigns. Diphtheria, polio, and measles and their consequences have been virtually eliminated in the United States, as shown in these three graphs. SSPE stands for subacute sclerosing panencephalitis, a brain disease that is a late consequence of measles infection in few individuals. When measles was prevented, SSPE disappeared 15–20 years later. However, because these diseases have not been eradicated worldwide, immunization must be maintained in a very high percentage of the population to prevent their reappearance.

has existed for more than 70,000 years. However, as recent history has shown us, new pathogenic organisms occasionally arise and wreak devastation on the human population. Frequently, these emerging pathogens are viruses with relatively small genomes and high mutation rates, ideal conditions for the development of human-to-human transmission capabilities.

The early 21st century witnessed the emergence of several novel coronaviruses that cause respiratory infections with a high rate of transmission. These viruses are believed to have crossed into humans from bats, their natural reservoir. Two of these viruses caused epidemics with a high fatality rate, SARS-CoV in 2002–2003 and MERS-CoV in 2012, but ultimately were responsible for fewer than 1000 deaths each. A third coronavirus, SARS-CoV-2, emerged in late 2019 and rapidly spread across the globe, causing a worldwide pandemic that disrupted societies and economies and by June 2020 was responsible for more than 4000 deaths a day. Studies of the immune response to SARS-CoV-2 are proceeding at a remarkable pace, and by early 2021 multiple effective vaccines had been developed and introduced to the public.

Summary.

The responses to infection can be organized into several effector modules that target the various types of pathogen lifestyles. Innate sensor cells that detect infection generate mediators that activate innate lymphoid cells (ILCs)

and T cells, which amplify the immune response and also activate various effector modules. ILCs include subsets that produce different cytokines and activate distinct effector modules. T cells fall into two major classes that are based on the expression of the co-receptors CD8 and CD4. CD8 and CD4 T cells recognize antigen presented by MHC class I or MHC class II proteins, respectively. These subsets of T cells, like their ILC counterparts, also promote the actions of distinct effector modules. NK cells and CD8 T cells can exert cytotoxic activity to target intracellular infections such as viruses. Other subsets of innate lymphoid and helper T cells can secrete mediators that activate other effector functions, ones that target intracellular bacteria, extracellular bacteria and fungi, and parasites. T cells also provide signals that help regulate B cells and stimulate them to produce antibodies. Specific antibodies mediate the clearance and elimination of soluble toxins and extracellular pathogens. They interact not only with the toxins or the antigens on microbes but also with the Fc region of specific receptors that are expressed by many types of phagocytes. Phagocytes also express receptors for complement proteins that are deposited on microbial surfaces, particularly in the presence of antibody.

Failures of immunity can be caused by genetic defects or by infections that target important components of the immune system. Misdirected immune responses can damage host tissues, as in autoimmune diseases or allergy, or lead to the failure of transplanted organs. While vaccination is still the greatest tool of immunology to fight diseases, modern approaches have added new tools, such as monoclonal antibodies, that have become progressively more important in the clinic since their initial use in the mid-1980s.

Summary to Chapter 1.

The immune system defends the host against infection. Innate immunity serves as a first line of defense but lacks the ability to recognize certain pathogens and to provide the specific protective immunity that prevents reinfection. Adaptive immunity is based on clonal selection from a repertoire of lymphocytes bearing highly diverse antigen-specific receptors that enable the immune system to recognize any foreign antigen. In the adaptive immune response, antigen-specific lymphocytes proliferate and differentiate into clones of effector lymphocytes that eliminate the pathogen. Figure 1.7 summarizes the phases of the immune response and their approximate timings. Host defense requires different recognition systems and a wide variety of effector mechanisms to seek out and destroy the wide variety of pathogens in their various habitats within the body and at its external and internal surfaces. Not only can the adaptive immune response eliminate a pathogen, but, in the process, it also generates increased numbers of differentiated memory lymphocytes through clonal selection, and this allows a more rapid and effective response upon reinfection. The regulation of immune responses, whether to suppress them when unwanted or to stimulate them in the prevention of infectious disease, is the major medical goal of research in immunology.

Innate Immunity: The First Lines of Defense

2

As stated in Chapter 1, most microbial invaders can be detected and destroyed within minutes or hours by the body's defense mechanisms of **innate immunity**, which do not rely on expansion of antigen-specific lymphocytes. The innate immune system uses a limited number of secreted proteins and cell-associated receptors to detect infection and to distinguish between pathogens and host tissues. These are called innate receptors because they are inborn; they are encoded by genes directly inherited from an individual's parents and do not need to be generated by the gene rearrangements used to assemble antigen receptors of lymphocytes described in Section 1-11. The importance of innate immunity is illustrated by several immunodeficiencies that result when it is impaired, increasing susceptibility to infection even in the presence of an intact adaptive immune system, as we will discuss in Chapter 13.

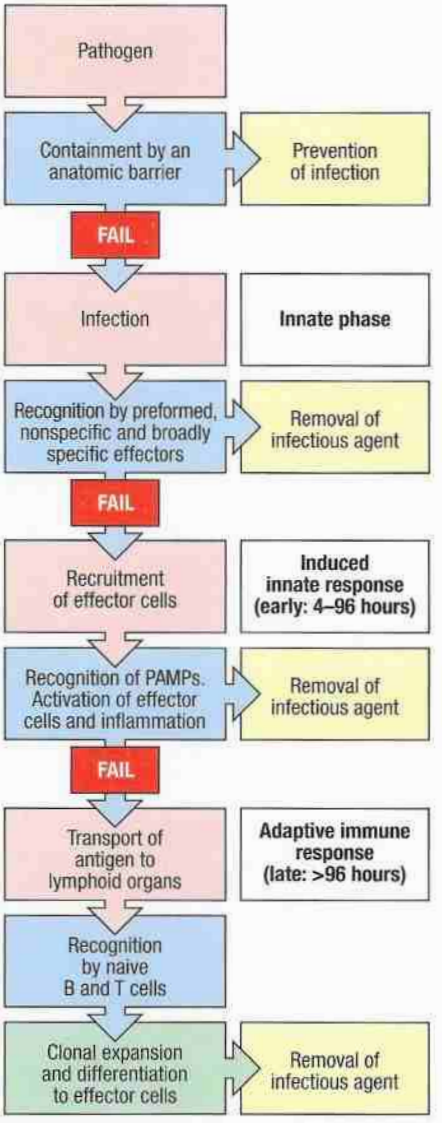
As we saw in Fig. 1.5, an infection starts when a pathogen breaches one of the host's anatomic barriers. Some innate immune mechanisms start acting immediately (Fig. 2.1). These immediate defenses include several classes of preformed soluble molecules that are present in extracellular fluid, blood, and epithelial secretions and which can either kill the pathogen or weaken its effect. **Antimicrobial enzymes** such as lysozyme begin to digest bacterial cell walls; **antimicrobial peptides** such as the defensins lyse bacterial cell membranes directly; and a system of plasma proteins known as the **complement system** targets pathogens both for lysis and for phagocytosis by cells of the innate immune system, such as macrophages. If these fail, innate immune cells become activated by pattern-recognition receptors (PRRs) that detect molecules called pathogen-associated molecular patterns (PAMPs) that are typical of microbes (see Section 1-5). The activated innate cells can engage various effector mechanisms to eliminate the infection. By themselves, neither the soluble nor the cellular components of innate immunity generate long-term protective immunological memory. If an infectious organism breaches these first two lines of defense, mechanisms will be engaged to induce an adaptive immune response—the third phase of the response to a pathogen. This leads to the expansion of antigen-specific lymphocytes that target the pathogen specifically and to the formation of memory cells that provide long-lasting specific immunity.

This chapter considers the first phase of the innate immune response. We first describe the anatomic barriers that protect the host against infection and examine the immediate innate defenses provided by various secreted soluble

IN THIS CHAPTER

Anatomic barriers and initial chemical defenses.

The complement system and innate immunity.



Pathogen
Containment by an anatomic barrier
Prevention of infection
FAIL
Infection
Innate phase
Recognition by preformed, nonspecific and broadly specific effectors
Removal of infectious agent
FAIL
Recruitment of effector cells
Induced innate response (early: 4–96 hours)
Recognition of PAMPs. Activation of effector cells and inflammation
Removal of infectious agent
FAIL
Transport of antigen to lymphoid organs
Adaptive immune response (late: >96 hours)
Recognition by naive B and T cells
Clonal expansion and differentiation to effector cells
Removal of infectious agent

Fig. 2.1 The response to an initial infection occurs in three phases. These are the innate phase, the induced innate response, and the adaptive immune response. The first two phases rely on the recognition of pathogens by germline-encoded receptors of the innate immune system, whereas adaptive immunity uses variable antigen-specific receptors that are produced as a result of gene segment rearrangements. Adaptive immunity occurs late, because the rare B cells and T cells specific for the invading pathogen must first undergo clonal expansion before they differentiate into effector cells that migrate to the site of infection and clear the infection. The effector mechanisms that remove the infectious agent are similar or identical in each phase.

proteins. The anatomic barriers are fixed defenses against infection and consist of the epithelia that line the internal and external surfaces of the body, along with the phagocytes residing beneath all epithelial surfaces. These phagocytes act directly by engulfing and digesting invading microorganisms. Epithelia are also protected by many kinds of chemical defenses, including antimicrobial enzymes and peptides. Next we describe the complement system, which directly kills some microorganisms and interacts with others to promote their removal by phagocytic cells. The complement system together with other soluble circulating defensive proteins is sometimes referred to as **humoral** innate immunity, from the old word 'humor' for body fluids. If these early defenses fail, the phagocytes at the site of infection help recruit new cells and circulating effector molecules, a process called inflammation, which we will discuss in Chapter 3.

Anatomic barriers and initial chemical defenses.

Microorganisms that cause disease in humans and animals enter the body at different sites and produce disease symptoms by a variety of mechanisms. Microorganisms that cause disease and produce damage, or pathology, to tissues are referred to as **pathogenic microorganisms**, or simply **pathogens**. As innate immunity eliminates most microorganisms that may occasionally cross an anatomic barrier, pathogens are microorganisms that have evolved ways of overcoming the body's innate defenses more effectively than have other microorganisms. Once infection is established, both innate and adaptive immune responses are typically required to eliminate pathogens from the body. Even in these cases, the innate immune system performs a valuable function by reducing pathogen numbers during the time needed for the adaptive immune system to gear up for action. In the first part of this chapter, we briefly describe the different types of pathogens and their invasive strategies and then examine the immediate innate defenses that, in most cases, prevent microorganisms from establishing an infection.

2-1 Infectious diseases are caused by diverse living agents that replicate in their hosts.

The agents that cause disease fall into five groups: viruses, bacteria, fungi, protozoa, and helminths (worms). Protozoa and worms are usually grouped together as parasites and are the subject of the discipline of parasitology, whereas viruses, bacteria, and fungi are the subject of microbiology. Figure 2.2 lists some examples of the different classes of microorganisms and parasites, and the diseases they cause. The characteristic features of each pathogen are its mode of transmission, its mechanism of replication, its mechanism of **pathogenesis**—the means by which it causes disease—and the response it elicits from the host. The distinct pathogen habitats and life cycles mean that a range of different innate and adaptive immune mechanisms have to be deployed for pathogen destruction.

Infectious agents can grow in all body compartments, as shown schematically in Fig. 2.3. We saw in Chapter 1 that two major compartments can be defined: extracellular and intracellular. Both innate and adaptive immune responses have different ways of dealing with pathogens found in these two compartments. Many bacterial pathogens live and replicate in extracellular spaces, either within tissues or on the surface of the epithelia that line body cavities. Extracellular bacteria are usually susceptible to killing by phagocytes, an important arm of the innate immune system, but some pathogens, such as *Staphylococcus* and *Streptococcus* species, achieve a very basic form of

Routes of infection for pathogens				
Route of entry	**Mode of transmission**	**Pathogen**	**Disease**	**Type of pathogen**
Mucosal surfaces				
Mouth and respiratory tract	Inhalation or ingestion of infective material (e.g., saliva droplets)	Measles virus	Measles	Paramyxovirus
		Influenza virus	Influenza	Orthomyxovirus
		Varicella-zoster	Chickenpox	Herpesvirus
		Epstein–Barr virus	Mononucleosis	Herpesvirus
		Streptococcus pyogenes	Tonsilitis	Gram-positive bacterium
		Haemophilus influenzae	Pneumonia, meningitis	Gram-negative bacterium
		Neisseria meningitidis	Meningococcal meningitis	Gram-negative bacterium
	Spores	*Bacillus anthracis*	Inhalation anthrax	Gram-positive bacterium
Gastrointestinal tract	Contaminated water or food	Rotavirus	Diarrhea	Rotavirus
		Hepatitis A	Jaundice	Picornavirus
		Salmonella enterica ssp. *enteritidis*, *Salmonella enterica* ssp. *typhimurium*	Food poisoning	Gram-negative bacterium
		Vibrio cholerae	Cholera	Gram-negative bacterium
		Salmonella enterica ssp. *typhi*	Typhoid fever	Gram-negative bacterium
		Trichuris trichiura	Trichuriasis	Helminth
Reproductive tract and other routes	Sexual transmission/ infected blood	Hepatitis B virus	Hepatitis B	Hepadnavirus
		Human immunodeficiency virus (HIV)	Acquired immune deficiency syndrome (AIDS)	Retrovirus
	Sexual transmission	*Neisseria gonorrhoeae*	Gonorrhea	Gram-negative bacterium
		Treponema pallidum	Syphilis	Bacterium (spirochete)
Opportunistic infections	Resident microbiota	*Candida albicans*	Candidiasis, thrush	Fungus
	Resident lung microbiota	*Pneumocystis jirovecii*	Pneumonia	Fungus
External epithelia				
External surface	Physical contact	*Trichophyton*	Athlete's foot	Fungus
Wounds and abrasions	Minor skin abrasions	*Bacillus anthracis*	Cutaneous anthrax	Gram-positive bacterium
	Puncture wounds	*Clostridium tetani*	Tetanus	Gram-positive bacterium
	Handling infected animals	*Francisella tularensis*	Tularemia	Gram-negative bacterium
Insect bites	Mosquito bites (*Aedes aegypti*)	Flavivirus	Yellow fever	Virus
	Deer tick bites	*Borrelia burgdorferi*	Lyme disease	Bacterium (spirochete)
	Mosquito bites (*Anopheles*)	*Plasmodium* spp.	Malaria	Protozoan

Fig. 2.2 A variety of microorganisms can cause disease. Pathogenic organisms are of five main types: viruses, bacteria, fungi, protozoa, and helminths (worms). Some well-known pathogens are listed.

	Extracellular		Intracellular	
	Interstitial spaces, blood, lymph	Epithelial surfaces	Cytoplasmic	Vesicular
Site of infection				Organisms	Viruses Bacteria Protozoa Fungi Worms	*Neisseria gonorrhoeae* *Streptococcus pneumoniae* *Vibrio cholerae* *Helicobacter pylori* *Candida albicans* Worms	Viruses *Chlamydia* spp. *Rickettsia* spp. Protozoa	*Mycobacterium* spp. *Yersinia pestis* *Legionella pneumophila* *Cryptococcus neoformans* *Leishmania* spp.
Protective immunity	Complement Phagocytosis Antibodies	Antimicrobial peptides Antibodies, especially IgA	NK cells Cytotoxic T cells	T cell–dependent and NK cell–dependent macrophage activation

Fig. 2.3 Pathogens can be found in various compartments of the body, where they must be combated by different host-defense mechanisms. Virtually all pathogens have an extracellular phase in which they are vulnerable to the circulating molecules and cells of innate immunity and to the antibodies of the adaptive immune response. All these clear the microorganism mainly by promoting its uptake and destruction by the phagocytes of the immune system. Intracellular phases of pathogens such as viruses are not accessible to these mechanisms; instead, the infected cell is attacked by the NK cells of innate immunity or by the cytotoxic T cells of adaptive immunity. Activation of macrophages as a result of NK-cell or T-cell activity can induce the macrophage to kill pathogens that are living inside macrophage vesicles.

immune evasion by having a protective polysaccharide capsule that resists engulfment. This can be overcome to some extent by the help of another component of innate immunity (complement), which deposits specific molecules on the surface of the bacteria (opsonization), rendering them more susceptible to phagocytosis. In the adaptive immune response, bacteria are rendered more susceptible to phagocytosis by a combination of antibodies and complement.

Infectious diseases differ in their symptoms and outcome depending on where the causal pathogen replicates within the body—the intracellular or the extracellular compartment—and what damage it does to the tissues (Fig. 2.4). Pathogens that live intracellularly frequently cause disease by damaging or killing the cells they infect. Obligate intracellular pathogens, such as viruses, must invade host cells to replicate. Facultative intracellular pathogens, such as mycobacteria, can replicate either intracellularly or outside the cell. Two strategies of innate immunity defend against intracellular pathogens. One strategy aims to destroy pathogens before they infect cells and includes soluble defenses such as antimicrobial peptides, as well as phagocytic cells that can engulf and destroy pathogens before they become intracellular. Alternatively, the innate immune system can recognize and kill cells infected by some pathogens. This is the role of the natural killer cells (NK cells), which act to limit certain viral infections before cytotoxic T cells of the adaptive immune system become functional. Intracellular pathogens can be subdivided further into those that replicate freely in the cell, such as viruses and certain bacteria (for example, *Chlamydia*, *Rickettsia*, and *Listeria*), and those that replicate inside intracellular vesicles, such as mycobacteria. Pathogens that live inside macrophage vesicles may become more susceptible to being killed after activation of the macrophage as a result of NK-cell or T-cell actions (see Fig. 2.3).

Many of the most dangerous extracellular bacterial pathogens cause disease by releasing protein toxins; these secreted toxins are called **exotoxins** (see Fig. 2.4). The innate immune system has little defense against such toxins, and highly specific antibodies produced by the adaptive immune system are required to neutralize their action (see Fig. 1.28). The damage caused by a particular infectious agent also depends on where it grows; *Streptococcus*

	Direct mechanisms of tissue damage by pathogens			Indirect mechanisms of tissue damage by pathogens		
	Exotoxin production	Endotoxin	Direct cytopathic effect	Immune complexes	Anti-host antibody	Cell-mediated immunity
Pathogenic mechanism						Infectious agent	*Streptococcus pyogenes* *Staphylococcus aureus* *Corynebacterium diphtheriae* *Clostridium tetani* *Vibrio cholerae*	*Escherichia coli* *Haemophilus influenzae* *Salmonella enterica* ssp. *typhi* *Shigella* *Pseudomonas aeruginosa* *Yersinia pestis*	Variola Varicella-zoster Hepatitis B virus Polio virus Measles virus Influenza virus Herpes simplex virus Human herpes virus 8 (HHV8)	Hepatitis B virus *Plasmodium* *Streptococcus pyogenes* *Treponema pallidum* Most acute infections	*Streptococcus pyogenes* *Mycoplasma pneumoniae*	Lymphocytic choriomeningitis virus Herpes simplex virus *Mycobacterium tuberculosis* *Mycobacterium leprae* *Borrelia burgdorferi* *Schistosoma mansoni*
Disease	Tonsilitis, scarlet fever Boils, toxic shock syndrome, food poisoning Diphtheria Tetanus Cholera	Gram-negative sepsis Meningitis, pneumonia Typhoid fever Bacillary dysentery Wound infection Plague	Smallpox Chickenpox, shingles Hepatitis Poliomyelitis Measles, subacute sclerosing panencephalitis Influenza Cold sores Kaposi's sarcoma	Kidney disease Vascular deposits Glomerulonephritis Kidney damage in secondary syphilis Transient renal deposits	Rheumatic fever Hemolytic anemia	Aseptic meningitis Herpes stromal keratitis Tuberculosis Tuberculoid leprosy Lyme arthritis Schistosomiasis

Fig. 2.4 Pathogens can damage tissues in a variety of different ways. The mechanisms of damage, representative infectious agents, and the common names of the diseases associated with each are shown. Exotoxins are released by microorganisms and act at the surface of host cells, for example, by binding to receptors. Endotoxins, which are intrinsic components of microbial structure, trigger phagocytes to release cytokines that produce local or systemic symptoms. Many pathogens are cytopathic, directly damaging the cells they infect. Finally, an adaptive immune response to the pathogen can generate antigen:antibody complexes that activate neutrophils and macrophages, antibodies that can cross-react with host tissues, or T cells that kill infected cells. All of these have some potential to damage the host's tissues. In addition, neutrophils, the most abundant cells early in infection, release many proteins and small-molecule inflammatory mediators that both control infection and cause tissue damage.

pneumoniae in the lung causes pneumonia, for example, whereas in the blood it causes a potentially fatal systemic illness, pneumococcal sepsis. In contrast, nonsecreted constituents of bacterial structure that trigger phagocytes to release cytokines with local and systemic effects are called **endotoxins**. An endotoxin of major medical importance is the **lipopolysaccharide (LPS)** of the outer cell membrane of **Gram-negative bacteria**, such as *Salmonella*. Many of the clinical symptoms of infection by such bacteria—including fever, pain, rash, hemorrhage, septic shock—are due largely to LPS.

Most pathogenic microorganisms can overcome innate immune responses and continue to grow, making us ill. An adaptive immune response is required to eliminate them and to prevent subsequent reinfections. Certain pathogens are never entirely eliminated by the immune system and persist in the body for years. But most pathogens are not universally lethal. Those that have lived for thousands of years in the human population are highly evolved to exploit their human hosts; they cannot alter their pathogenicity without upsetting the compromise they have achieved with the human immune system. Rapidly killing every host it infects is no better for the long-term survival of a pathogen than being wiped out by the immune response before the microbe has had time to infect someone else. In short, we have adapted to live with many microbes, and they with us. Nevertheless, highly pathogenic strains of avian influenza,

the episode in 2002–2003 of SARS (severe acute respiratory syndrome), a severe pneumonia in humans that is caused by the coronavirus SARS-CoV from bats, and the SARS-CoV-2 pandemic of 2020 all remind us that new and deadly infections can transfer from animal reservoirs to humans. Even though infection with SARS-CoV-2 has a case fatality rate substantially lower than that seen in SARS, the 2020 pandemic has had an enormous negative impact on the global economy. Such transmission appears responsible for the Ebola virus epidemic in West Africa in 2014–2015. These are known as **zoonotic** infections—and we must be on the alert at all times for the emergence of new pathogens and new threats to health. The human immunodeficiency virus that causes AIDS (discussed in Chapter 13) serves as a warning that we remain constantly vulnerable.

Acquired Immune Deficiency Syndrome (AIDS)

2-2 Epithelial surfaces of the body provide the first barrier against infection.

Our body surfaces are composed of epithelia with diverse functions. They can provide a protective physical barrier between the internal milieu and the external world that contains pathogens. Epithelia compose the skin and the linings of the body's tubular structures—the respiratory, urogenital, and gastrointestinal tracts. Epithelia in these locations are specialized for their particular functions and possess unique innate defense strategies against the microbes they typically encounter (Fig. 2.5 and Fig. 2.6). The necessity to carry out various functions in these locations, such as absorption of nutrients or oxygen for example, means that these epithelia are not perfect barriers to infection.

Epithelia can be a layer of single cells or multiple layers of cells with varying geometry. Epithelial cells are held together by tight junctions, which effectively form a seal against the external environment. The body's internal epithelia are known as **mucosal epithelia** because they secrete a viscous fluid called **mucus**, which contains many glycoproteins called **mucins**. Mucus has a number of protective functions. The mucus layer establishes a viscous physical barrier that impedes microbial access to various epithelial surfaces. In the respiratory tract, microorganisms can be expelled in the outward flow of

	Skin	Gut	Lungs	Eyes/nose/oral cavity
	Stratified epithelium	Single cell layer of columnar epithelium	Upper airway: pseudostratified columnar epithelium Lower airway: single cell layer of columnar epithelium	Pseudostratified columnar epithelium
Mechanical	Epithelial cells joined by tight junctions			
	Longitudinal flow of air or fluid	Longitudinal flow of air or fluid	Movement of mucus by cilia	Tears Nasal cilia
Chemical	Fatty acids	Low pH	Pulmonary surfactant	Enzymes in tears and saliva (lysozyme)
		Enzymes (pepsin)		
	β-defensins Lamellar bodies Cathelicidin	α-defensins (cryptdins) RegIII (lecticidins) Cathelicidin	α-defensins Cathelicidin	Histatins β-defensins
Microbiological	Normal microbiota			

Fig. 2.5 Many barriers prevent pathogens from crossing epithelia and colonizing tissues. Surface epithelia provide mechanical, chemical, and microbiological barriers to infection. The epithelium of the skin is stratified, having multiple layers. Epithelia in the various locations in the intestine have a single cell layer. The epithelia of the upper airway have a single cell layer, but the cell nuclei are staggered in a way that suggests multiple layers.

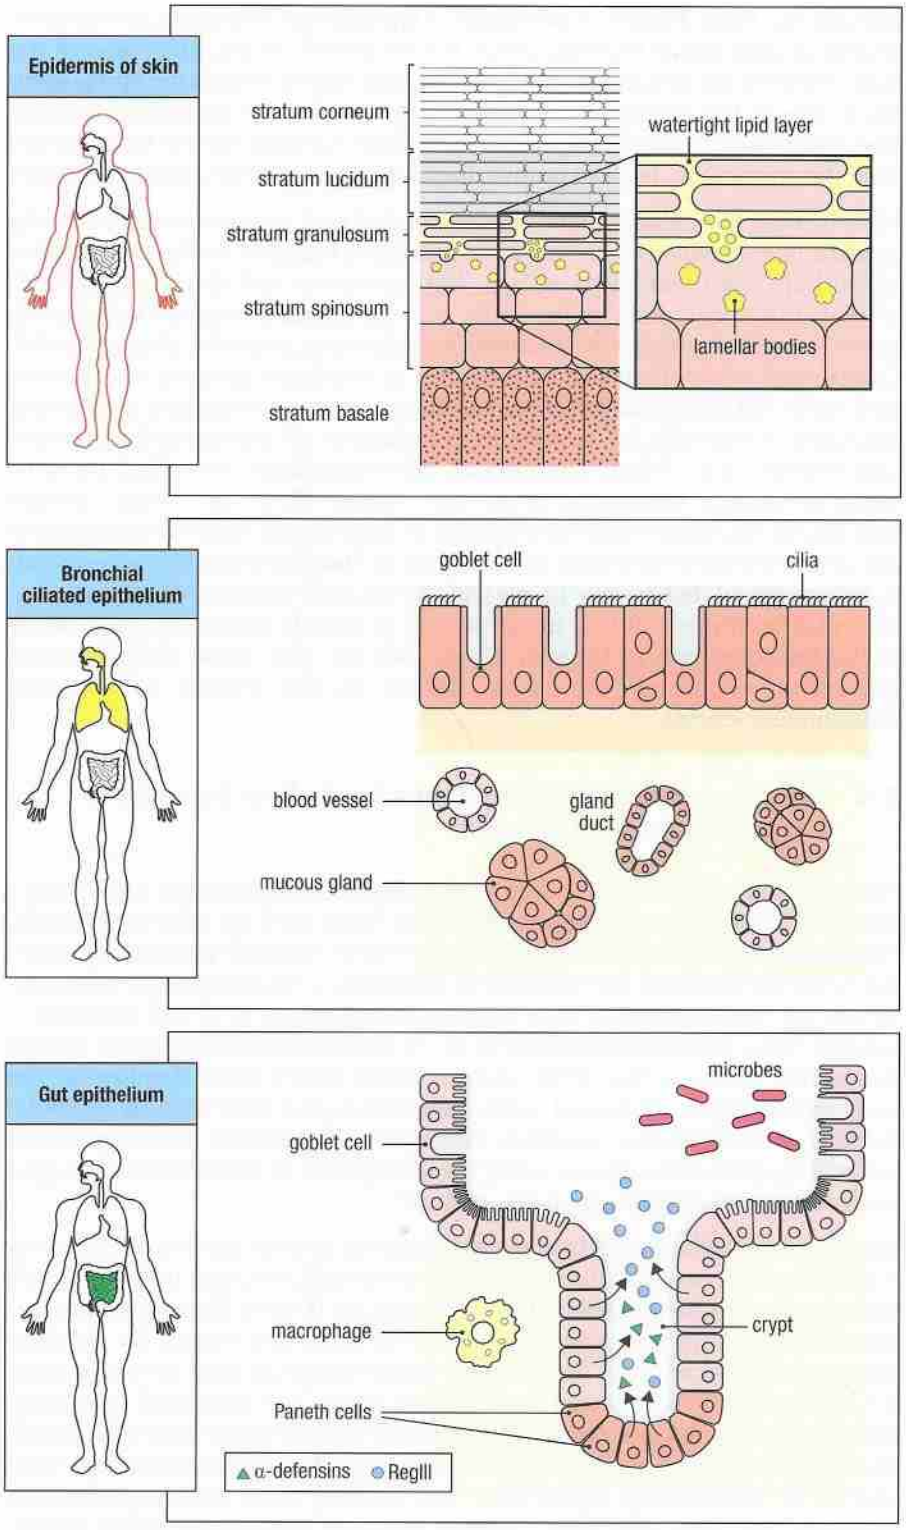

Fig. 2.6 Epithelia form specialized physical and chemical barriers that provide innate defenses in different locations. Top panel: The epidermis has multiple layers of keratinocytes in different stages of differentiation arising from the basal layer of stem cells. Differentiated keratinocytes in the stratum spinosum produce β-defensins and cathelicidins, which are incorporated into secretory organelles called lamellar bodies (yellow) and secreted into the intercellular space to form a waterproof lipid layer (the stratum corneum) containing antimicrobial activity. Center panel: In the lung, the airways are lined with ciliated epithelium. Beating of the cilia moves a continuous stream of mucus (green) secreted by goblet cells outward, trapping and ejecting potential pathogens. Type II pneumocytes in the lung alveoli (not shown) also produce and secrete antimicrobial defensins. Bottom panel: In the intestine, epithelial cells and Paneth cells—specialized cells deep in the epithelial crypts—produce several kinds of antimicrobial proteins: α-defensins (cryptdins) and the antimicrobial RegIII proteins.

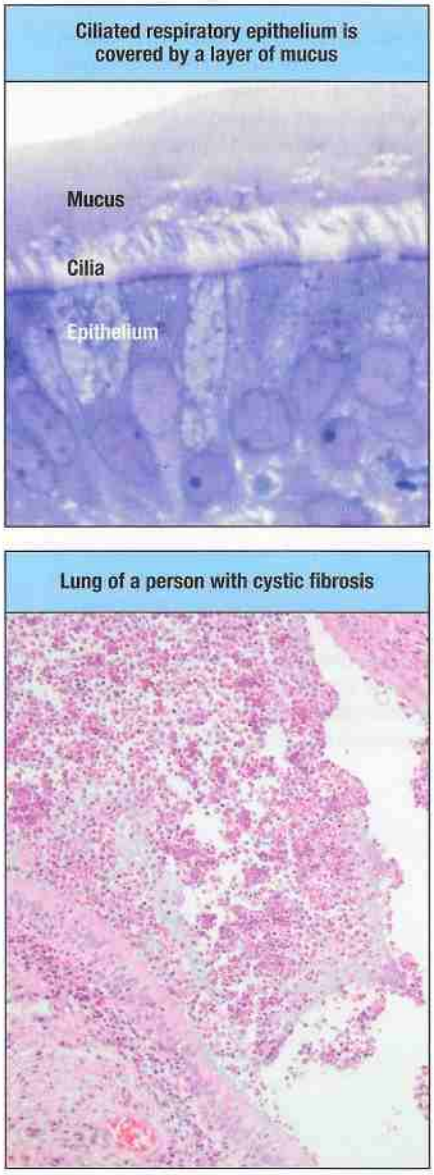
mucus driven by the beating of cilia on the mucosal epithelium (Fig. 2.7). The importance of mucus flow in clearing infection is illustrated by people with the inherited disease **cystic fibrosis**, in which the mucus becomes abnormally thick and dehydrated because of defects in a gene, *CFTR*, encoding a chloride channel in the epithelium. Such individuals frequently develop lung infections caused by bacteria that colonize the epithelial surface but do not cross it (see Fig. 2.7). Mucus also plays an important role in the gut. Peristalsis is an important mechanism for keeping both food and infectious agents moving



Ciliated respiratory epithelium is covered by a layer of mucus
Mucus
Cilia
Epithelium
Lung of a person with cystic fibrosis

Fig. 2.7 Ciliated respiratory epithelium propels the overlying mucus layer for clearance of environmental microbes. Top panel: The ciliated respiratory epithelium in the airways of the lung is covered by a layer of mucus. The cilia propel the mucus outward and help prevent colonization of the airways by bacteria. Bottom panel: Section of a lung from an individual with cystic fibrosis. The dehydrated mucus layer impairs the ability of cilia to propel it, leading to frequent bacterial colonization and resulting inflammation of the airway.

through the body. Failure of peristalsis is typically accompanied by the overgrowth of pathogenic bacteria within the lumen of the gut. The colon of the large intestine has two layers of mucus. The inner layer, nearest the epithelium, has a denser, less porous composition that excludes the passage of bacteria from the colonic lumen to the epithelial surface. An outer mucus layer, farther from the epithelium, is more porous, forming the habitat for colonic bacteria.

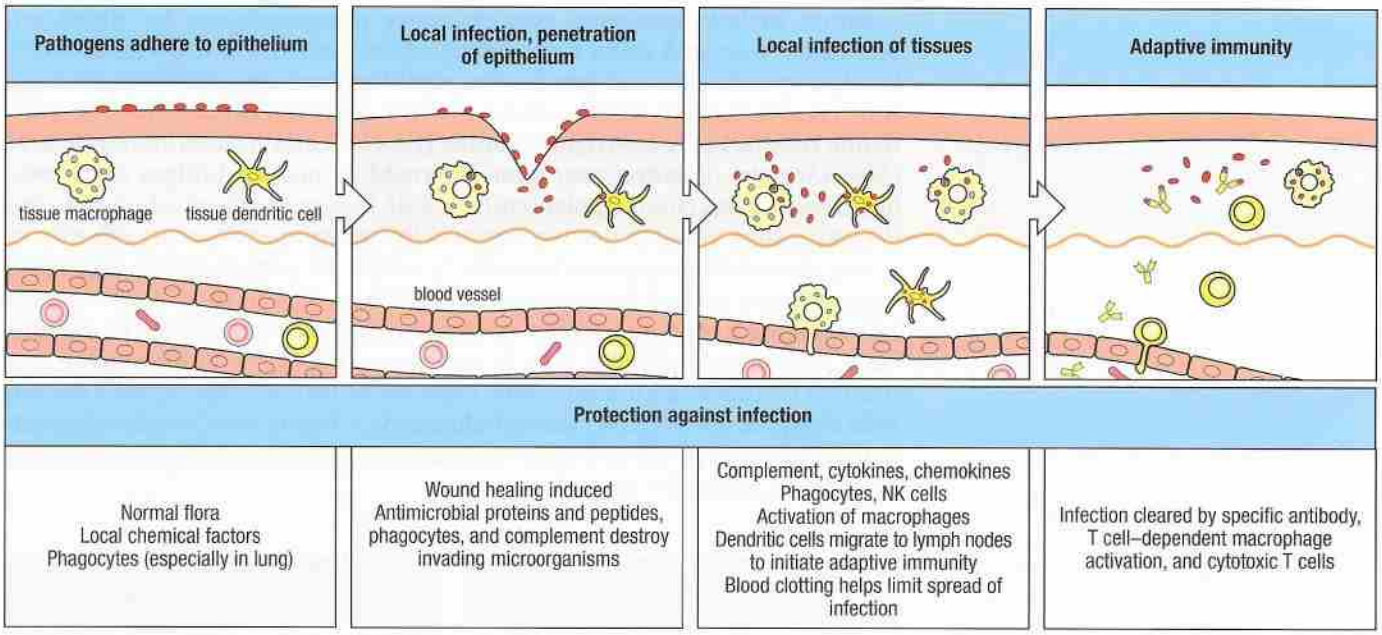
Most healthy epithelial surfaces are associated with populations of normally nonpathogenic bacteria, known as **commensal bacteria** or the **microbiota**, which help keep pathogens at bay. The microbiota can also make antimicrobial substances, such as the lactic acid produced by vaginal lactobacilli, some strains of which also produce antimicrobial peptides (bacteriocins). Commensal microorganisms in the outer mucus layer generate short-chain fatty acids (SCFAs) and other metabolites that can strengthen the barrier functions of epithelia by stimulating production of antimicrobial peptides (see Section 2-4). When commensal microorganisms are killed by antibiotic treatment, pathogens frequently replace them and cause disease (see Fig. 12.13). Under some circumstances commensal microbes themselves can cause disease if their growth is not kept in check or if the immune system is compromised. In Chapter 12, we will discuss how commensal microorganisms play an important role in the setting of normal immunity, particularly in the intestine; and in Chapter 15, we will see how these normally nonpathogenic organisms can cause disease in the context of inherited immunodeficiencies.

2-3 Infectious agents must overcome innate host defenses to establish a focus of infection.

Our bodies are constantly exposed to microorganisms present in our environment, including infectious agents that have been shed by other individuals. Contact with these microorganisms may occur through external or internal epithelial surfaces. To establish an infection, a microorganism must first invade the body by binding to or crossing an epithelium (Fig. 2.8). Infection is a major cause of mortality and morbidity in cases of epithelial damage caused by wounds, burns, or loss of the integrity of the body's internal epithelia. The body rapidly repairs damaged epithelial surfaces, but even without epithelial damage, pathogens may establish infection by specifically adhering to and colonizing epithelial surfaces, using the attachment to avoid being dislodged by the flow of air or fluid across the surface.

Disease occurs when a microorganism succeeds in evading or overwhelming innate host defenses to establish a local site of infection, and then replicates there to allow its further transmission within our bodies. The epithelium lining the respiratory tract provides a route of entry into tissues for airborne microorganisms, and the lining of the gastrointestinal tract does the same for microorganisms ingested in food and water. The intestinal pathogens *Salmonella enterica* ssp. *typhi*, which causes typhoid fever, and *Vibrio cholerae*, which causes cholera, are spread through fecally contaminated food and water, respectively. Insect bites and wounds allow microorganisms to penetrate the skin, and direct contact between individuals offers opportunities for infection through the skin, the gut, and the reproductive tract (see Fig. 2.2).

In spite of this exposure, infectious disease is fortunately quite infrequent. Most of the microorganisms that succeed in crossing an epithelial surface are efficiently removed by innate immune mechanisms that function in the underlying tissues, preventing infection from becoming established. It is difficult to know how many infections are repelled in this way, because they cause no symptoms and pass undetected.



Pathogens adhere to epithelium
Local infection, penetration of epithelium
Local infection of tissues
Adaptive immunity
tissue macrophage
tissue dendritic cell
blood vessel
Protection against infection
Normal flora
Local chemical factors
Phagocytes (especially in lung)
Wound healing induced
Antimicrobial proteins and peptides, phagocytes, and complement destroy invading microorganisms
Complement, cytokines, chemokines
Phagocytes, NK cells
Activation of macrophages
Dendritic cells migrate to lymph nodes to initiate adaptive immunity
Blood clotting helps limit spread of infection
Infection cleared by specific antibody, T cell–dependent macrophage activation, and cytotoxic T cells

Fig. 2.8 An infection and the response to it can be divided into a series of stages. These are illustrated here for an infectious microorganism entering through a wound in the skin. The infectious agent must first adhere to the epithelial cells and then cross the epithelium. A local immune response may prevent the infection from becoming established. If not, it helps to contain the infection and also delivers the infectious agent, carried in lymph and inside dendritic cells, to local lymph nodes. This initiates the adaptive immune response and eventual clearance of the infection.

In general, pathogenic microorganisms are distinguished from the mass of microorganisms in the environment by having special adaptations that evade the immune system. In some cases, such as the fungal disease athlete's foot, the initial infection remains local and does not cause significant pathology. In other cases, such as tetanus, the bacterium (*Clostridium tetani* in this case) secretes a powerful neurotoxin, and the infection causes serious illness as it spreads through the lymphatics or the bloodstream, invades and destroys tissues, and disrupts the body's workings.

The spread of a pathogen is often initially countered by an **inflammatory response** that recruits more effector cells and molecules of the innate immune system out of the blood and into the tissues, while inducing clotting in small blood vessels further downstream so that the microbe cannot spread through the circulation (see Fig. 2.8). The cellular responses of innate immunity act over several days. During this time, the adaptive immune response may also begin if antigens derived from the pathogen are delivered to local lymphoid tissues by dendritic cells (see Section 1-15). While an innate immune response may eliminate some infections, an adaptive immune response can target particular strains and variants of pathogens and protect the host against reinfection by using either effector T cells or antibodies to generate immunological memory.

2-4 Epithelial cells and phagocytes produce several kinds of antimicrobial molecules.

Our surface epithelia are more than mere physical barriers to infection; they also produce a wide variety of chemical substances that are microbicidal or that inhibit microbial growth. For example, the acid pH of the stomach and the digestive enzymes, bile salts, fatty acids, and lysolipids present in the upper gastrointestinal tract create a substantial chemical barrier to infection (see Fig. 2.5). One important group of antimicrobial proteins comprises enzymes that attack chemical features specific to bacterial cell walls. Such antimicrobial

enzymes include **lysozyme** and **secretory phospholipase A_2**, which are secreted in tears and saliva and by phagocytes. Lysozyme is a glycosidase that breaks a specific chemical bond in the **peptidoglycan** layer of the bacterial cell wall. Peptidoglycan is composed of a network of polymers that consist of alternating residues of *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc); the peptidoglycan layer is formed by peptide bridges that cross-link these polysaccharide polymers (Fig. 2.9). Lysozyme selectively cleaves the β-(1,4) linkage between the two sugars of the polymer and is more effective in acting against Gram-positive bacteria, in which the peptidoglycan cell wall is exposed, than against Gram-negative bacteria, which have an outer layer of LPS covering the peptidoglycan layer. Lysozyme is also produced by **Paneth cells**, specialized epithelial cells in the base of the crypts in the small intestine that secrete many antimicrobial proteins into the gut (see Fig. 2.6). Paneth cells also produce secretory phospholipase A_2, a highly basic enzyme that can enter the bacterial cell wall to access and hydrolyze phospholipids in the cell membrane, killing the bacteria.

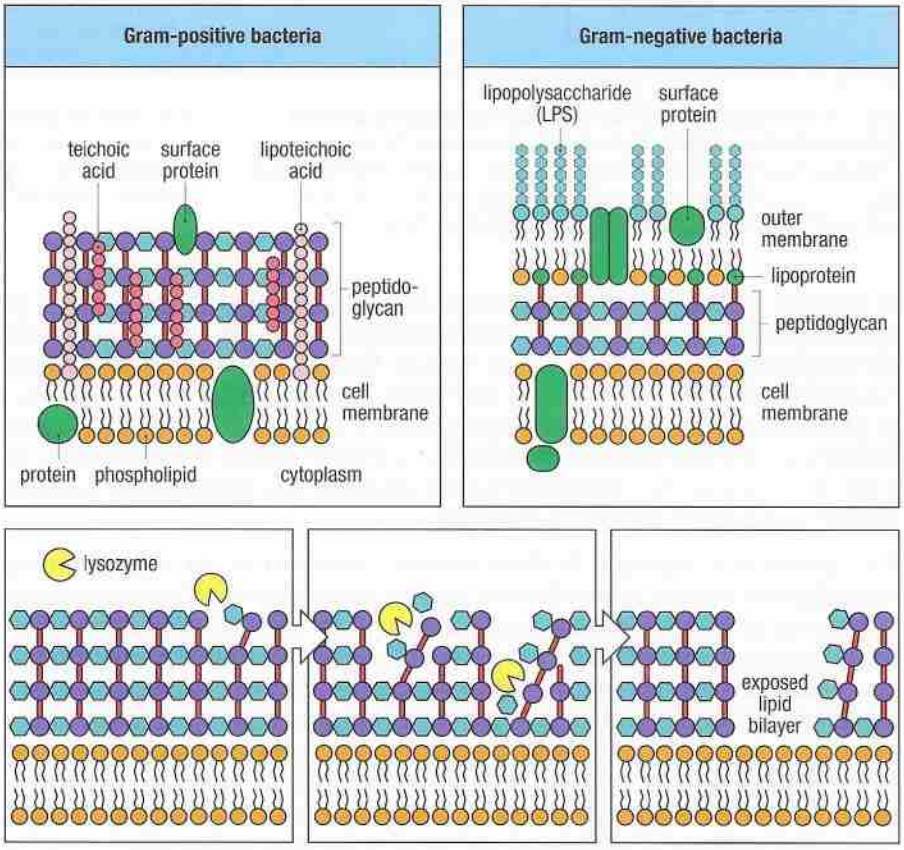


Fig. 2.9 Lysozyme digests the cell walls of Gram-positive and Gram-negative bacteria. Upper panels: The peptidoglycan layer of bacterial cell walls is a dense, three-dimensional network of polymers of alternating residues of β-(1,4)–linked *N*-acetylglucosamine (GlcNAc; large turquoise hexagons) and *N*-acetylmuramic acid (MurNAc; purple circles) that are cross-linked by peptide bridges (red bars). In Gram-positive bacteria (upper left panel), peptidoglycan forms the outer layer in which other molecules are embedded such as teichoic acid and the lipoteichoic acids that link the peptidoglycan layer to the bacterial cell membrane itself. In Gram-negative bacteria (upper right panel), a thin inner wall of peptidoglycan is covered by an outer lipid membrane that contains proteins and lipopolysaccharide (LPS). Lipopolysaccharide is composed of a lipid, lipid A (turquoise circles), to which is attached a polysaccharide core (small turquoise hexagons). Lysozyme (lower panels) cleaves β-(1,4) linkages between GlcNAc and MurNAc, creating a defect in the peptidoglycan layer and exposing the underlying cell membrane to other antimicrobial agents. Lysozyme is more effective against Gram-positive bacteria because of the relatively greater accessibility of the peptidoglycan.

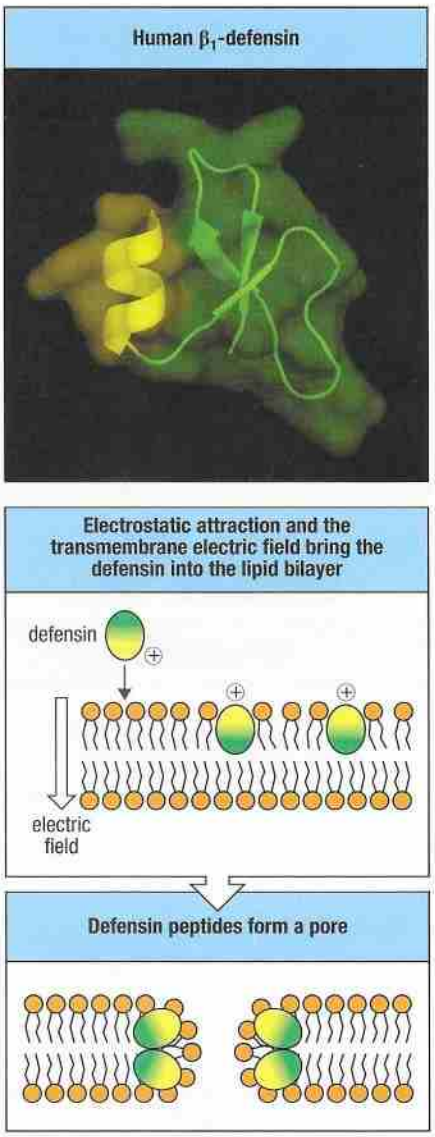

Human β_1-defensin

defensin
electric field
Defensin peptides form a pore

Fig. 2.10 Defensins are amphipathic peptides that disrupt the cell membranes of microbes. The structure of human β_1-defensin is shown in the top panel. It is composed of a short segment of α helix (yellow) resting against three strands of antiparallel β sheet (green), generating an amphipathic peptide with charged and hydrophobic residues residing in separate regions. This general feature is shared by defensins from plants and insects and allows the defensins to interact with the charged surface of the cell membrane and become inserted in the lipid bilayer (center panel). Although the details are still unclear, a transition in the arrangement of the defensins in the membrane leads to the formation of pores and a loss of membrane integrity (bottom panel).

A second group of antimicrobial agents secreted by epithelial cells and phagocytes is the antimicrobial peptides. These represent one of the most ancient forms of defense against infection. These peptides can be produced by phagocytic immune cells, such as neutrophils, where they may be retained within phagocytic granules. They are also produced by epithelial cells, such as in the lung, where they can be secreted onto mucosal surfaces. Three important classes of antimicrobial peptides in mammals are **defensins**, **cathelicidins**, and **histatins**.

Defensins are an ancient, evolutionarily conserved class of antimicrobial peptides made by many eukaryotic organisms, including mammals, insects, and plants (Fig. 2.10). They are short cationic peptides of around 30–40 amino acids that usually have three disulfide bonds stabilizing a common **amphipathic** structure—a positively charged region separated from a hydrophobic region. Defensins act within minutes to disrupt the cell membranes of bacteria and fungi, as well as the membrane envelopes of some viruses. The mechanism is thought to involve insertion of the hydrophobic region into the membrane bilayer and the formation of a pore that makes the membrane leaky (see Fig. 2.10). Most multicellular organisms make many different defensins—the plant *Arabidopsis thaliana* produces 13 and the fruit fly *Drosophila melanogaster* at least 15. Human Paneth cells make as many as 21 different defensins, many of which are encoded by a cluster of genes on chromosome 8.

Three subfamilies of defensins—α-, β-, and θ-defensins—are distinguished on the basis of amino acid sequence. Each family has members with distinct activities, some being active against Gram-positive bacteria and some against Gram-negative bacteria, while others are specific for fungal pathogens. All the antimicrobial peptides, including the defensins, are generated by proteolytic processing from inactive **propeptides** (Fig. 2.11). In humans, developing neutrophils produce **α-defensins** through the processing of an initial propeptide of about 90 amino acids by cellular proteases to remove an anionic propiece, generating a mature cationic defensin that is stored in so-called **primary granules**. The primary granules of neutrophils are specialized membrane-enclosed vesicles, rather similar to lysosomes, that contain a number of other antimicrobial agents as well as defensins. We will explain in Chapter 3 how these primary granules are induced to fuse with phagocytic vesicles (phagosomes) after the cell has engulfed a pathogen, helping to kill the microbe. The Paneth cells of the gut constitutively produce α-defensins, called **cryptdins**, which are processed by proteases such as the metalloprotease matrilysin in mice or trypsin in humans, before being secreted into the gut lumen. The **β-defensins** lack the long propiece of α-defensins and are generally produced specifically in response to the presence of microbial products. β-Defensins (and some α-defensins) are made by epithelia outside the gut, primarily in the respiratory and urogenital tracts, skin, and tongue. β-Defensins made by keratinocytes in the epidermis and by type II pneumocytes in the lungs are packaged into **lamellar bodies** (see Fig. 2.6), lipid-rich secretory organelles that release their contents into the extracellular space to form a watertight lipid sheet in the epidermis and the pulmonary surfactant layer in the lung. The θ-defensins arose in the primates, but the single human θ-defensin gene has been inactivated by a mutation.

The antimicrobial peptides belonging to the cathelicidin family lack the disulfide bonds that stabilize the defensins. Humans and mice have one

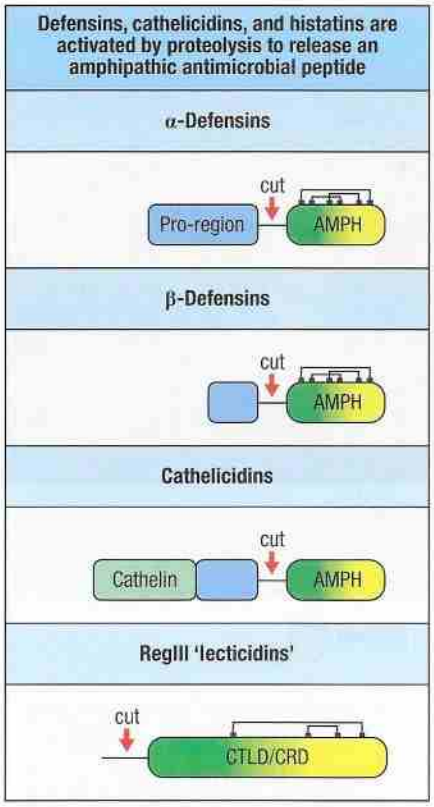

Fig. 2.11 Defensins, cathelicidins, and RegIII proteins are activated by proteolysis. When α- and β-defensins are first synthesized, they contain a signal peptide (not shown); a pro-region (blue), which is shorter in the β-defensins; and an amphipathic domain (AMPH; green–yellow); the pro-region represses the membrane-inserting properties of the amphipathic domain. After defensins are released from the cell or into phagosomes, they undergo cleavage by proteases, which releases the amphipathic domain in active form. Newly synthesized cathelicidins contain a signal peptide (not shown), a cathelin domain, a short pro-region, and an amphipathic domain; they, too, are activated by proteolytic cleavage. RegIII proteins contain a C-type lectin domain (CTLD), also known as a carbohydrate-recognition domain (CRD). After release of the signal peptide, further proteolytic cleavage of a RegIII protein also regulates its antimicrobial activity.

cathelicidin gene, but some other mammals, including cattle and sheep, have several. Cathelicidins are made constitutively by neutrophils and macrophages, and in response to infection by keratinocytes in the skin and epithelial cells in the lungs and intestine. They are made as inactive propeptides composed of two linked domains and are processed before secretion (see Fig. 2.11). In neutrophils, the inactive cathelicidin propeptides are stored in another type of specialized cytoplasmic granules called **secondary granules**. Cathelicidin is activated by proteolytic cleavage only when primary and secondary granules are induced to fuse with phagosomes, where it is cleaved by **neutrophil elastase** that has been stored in primary granules. Cleavage separates the two domains, and the cleavage products either remain in the phagosome or are released from the neutrophil by exocytosis. The carboxyl-terminal peptide is a cationic amphipathic peptide that disrupts membranes and is toxic to a wide range of microorganisms. The amino-terminal peptide is similar in structure to a protein called **cathelin**, an inhibitor of cathepsin L (a lysosomal enzyme involved in antigen processing and protein degradation), but its role in immune defense is unclear. In keratinocytes, cathelicidins, like β-defensins, are stored and processed in the lamellar bodies.

A class of antimicrobial peptides called histatins are constitutively produced in the oral cavity by the parotid, sublingual, and submandibular glands. These short, histidine-rich, cationic peptides are active against pathogenic fungi such as *Cryptococcus neoformans* and *Candida albicans*. More recently, histatins were found to promote the rapid wound healing that is typical in the oral cavity, but the mechanism of this effect is unclear.

Another type of bactericidal proteins made by epithelia is carbohydrate-binding proteins, or **lectins**. Most **C-type lectins** require calcium for the binding activity of their carbohydrate-recognition domain (CRD), which provides a variable interface for binding carbohydrate structures. C-type lectins of the RegIII family include several bactericidal proteins expressed by intestinal epithelium in humans and mice. However, carbohydrate recognition by RegIII proteins is not calcium dependent, but instead is inhibited by calcium. In mice, **RegIIIγ** is produced by Paneth cells and secreted into the gut, where it binds to peptidoglycans in bacterial cell walls and exerts direct bactericidal activity. Like other bactericidal peptides, RegIIIγ is produced in inactive form but is cleaved by the protease trypsin, which removes a short amino-terminal fragment to activate the bactericidal potential of RegIIIγ within the intestinal lumen (see Fig. 2.11). Human RegIIIα (also called **HIP/PAP** for hepatocarcinoma intestine pancreas/pancreatitis-associated protein) kills bacteria directly by forming a hexameric pore in the bacterial membrane (Fig. 2.12). RegIII family

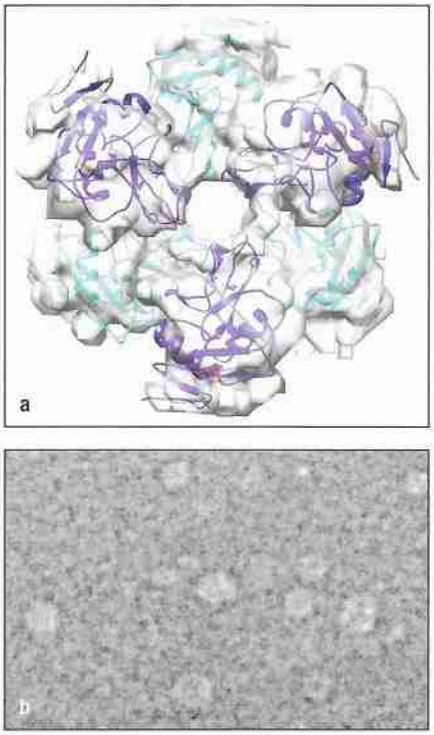

Fig. 2.12 Pore formation by human RegIIIα. Panel a: A model of the RegIIIα pore was generated by docking the human pro-RegIIIα structure (PDB ID: 1UV0), shown as individual purple and turquoise ribbon diagrams, into the cryo-electron microscopic map of the RegIIIα filament. LPS blocks the pore-forming activity of RegIIIα, explaining its selective bactericidal activity against Gram-positive but not Gram-negative bacteria. Panel b: Electron microscopic images of RegIIIα pores assembled in the presence of lipid bilayers.

proteins preferentially kill Gram-positive bacteria, in which the peptidoglycan is exposed on the outer surface (see Fig. 2.9). In fact, the LPS of Gram-negative bacteria inhibits the pore-forming ability of RegIIIα, further enforcing the selectivity of RegIII proteins for Gram-positive bacteria.

Finally, we briefly mention the peptides S100A8 and S100A9, which heterodimerize to form **calprotectin**, which we will discuss in Section 11-11 in the context of production by T cells. Calprotectin acts to sequester magnesium and iron required by microorganisms and exerts an antimicrobial effect at sites of its production. This activity requires binding of calcium to one of calprotectin's two metal-binding sites, which allows its second site to bind other metal ions. Calprotectin is produced in high amounts by neutrophils, and by T cells, but it is also made by intestinal epithelia, and so is part of the innate barrier defense system.

Summary.

The mammalian immune response to invading organisms proceeds in three phases, beginning with immediate innate defenses, then the induced innate defenses, and finally adaptive immunity. The first phase of host defense consists of those mechanisms that are present and ready to resist an invader at any time. Epithelial surfaces provide a physical barrier against pathogen entry, but they also have other, more specialized strategies. Mucosal surfaces have a protective barrier of mucus. Through particular cell-surface interactions, highly differentiated epithelia protect against both microbial colonization and invasion. Defense mechanisms of epithelia include the prevention of pathogen adherence, secretion of antimicrobial enzymes and bactericidal peptides, and the flow caused by the actions of cilia. Antimicrobial peptides and the bactericidal lectins of the RegIII family are made as inactive proproteins that require a proteolytic step to complete their activation, whereupon they become capable of killing microbes by forming pores in the microbial cell membranes. The actions of antimicrobial enzymes and peptides described in this part of the chapter often involve binding to unique glycan/carbohydrate structures on the microbe. Thus, these soluble molecular defenses are both pattern-recognition receptors and effector molecules at the same time, representing the simplest form of innate immunity.

The complement system and innate immunity.

When a pathogen breaches the host's epithelial barriers and initial antimicrobial defenses, it next encounters a major component of innate immunity known as the complement system, or **complement**. Complement is a collection of soluble proteins present in blood and other body fluids. It was discovered in the 1890s by Jules Bordet as a heat-labile substance in normal plasma whose activity could 'complement' the bactericidal activity of immune sera. Part of the process is **opsonization**, which refers to coating a pathogen with antibodies and/or complement proteins so that it can be more readily taken up and destroyed by phagocytic cells. Although complement was first discovered as an effector arm of the antibody response, we now understand that it originally evolved as part of the innate immune system and that it still provides protection early in infection, in the absence of antibodies, through more ancient pathways of complement activation.

The complement system is composed of more than 30 different plasma proteins, which are produced mainly by the liver. In the absence of infection, these proteins circulate in an inactive form. In the presence of pathogens or of antibody bound to pathogens, the complement system becomes 'activated.'

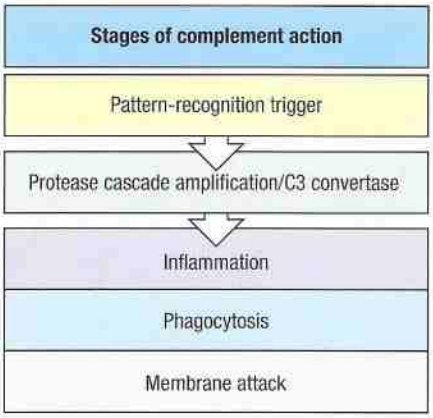

Fig. 2.13 The complement system proceeds in distinct phases in the elimination of microbes. Proteins that can distinguish self from microbial surfaces (yellow) activate a proteolytic amplification cascade that ends in the formation of the critical enzymatic activity (green) of C3 convertase, a family of proteases. This activity is the gateway to the three effector arms of complement, which produce inflammation (purple), enhance phagocytosis of the microbe (blue), and lyse microbial membranes (pink). We will use this color scheme in the figures throughout this chapter to illustrate which activity each complement protein serves.

Particular **complement proteins** interact with each other to form several different pathways of complement activation, all of which have the final outcome of killing the pathogen, either directly or by facilitating its phagocytosis, and inducing inflammatory responses that help to fight infection. There are three pathways of **complement activation**. As the antibody-triggered pathway of complement activation was discovered first, this became known as the classical pathway of complement activation. The next to be discovered, the so-called alternative pathway, can be activated by the presence of the pathogen alone; and the most recently discovered is the lectin pathway, which is activated by lectin-type proteins that recognize and bind to carbohydrates on pathogen surfaces.

We learned in Section 2-4 that proteolysis can be used as a means of activating antimicrobial proteins. In the complement system, activation by proteolysis is inherent, with many of the complement proteins being proteases that successively cleave and activate one another. The proteases of the complement system are synthesized as inactive pro-enzymes, or **zymogens**, which become enzymatically active only after proteolytic cleavage, usually by another complement protein. The complement pathways are triggered by proteins that act as pattern-recognition receptors to detect the presence of pathogens. This detection activates an initial zymogen, triggering a cascade of proteolysis in which complement zymogens are activated sequentially, each becoming an active protease that cleaves and activates many molecules of the next zymogen in the pathway, amplifying the signal as the cascade proceeds. This results in activation of three distinct effector pathways—**inflammation**, **phagocytosis**, and **membrane attack**—that help eliminate the pathogen. In this way, the detection of even a small number of pathogens produces a rapid response that is greatly amplified at each step. This overall scheme for complement is shown in Fig. 2.13.

Nomenclature for complement proteins can seem confusing, so we will start by explaining their names. The first proteins discovered belong to the classical pathway, and they are designated by the letter C followed by a number. The native complement proteins—such as the inactive zymogens—have a simple number designation; for example, C1 and C2. Unfortunately, they were named in the order of their discovery rather than the sequence of reactions. The reaction sequence in the classical pathway, for example, is C1, C4, C2, C3, C5, C6, C7, C8, and C9 (note that not all of these are proteases). Products of cleavage reactions are designated by adding a lowercase letter as a suffix. For example, cleavage of C3 produces a small protein fragment called C3a and the remaining larger fragment, C3b. By convention, the larger fragment for other factors is designated by the suffix b. There is an exception to this convention. For **C2**, the larger fragment was originally named **C2a** in the literature by its discoverers. Although there have been discussions regarding changes to this nomenclature, there has not been uniform agreement and so we will preserve the original usage of C2a as the large active fragment of C2. Another exception is the naming of C1q, C1r, and C1s: these are not cleavage products of C1 but are distinct proteins that together compose C1. The proteins of the alternative pathway were discovered later and are designated by different capital letters; for example, factor B and factor D. The factor B cleavage products are also designated by the addition of lowercase a and b; thus, the large fragment of B is called Bb and the small fragment is called Ba. Activated complement components were often designated in the past by a horizontal line, for example, $\overline{C2a}$, but we will not use this convention. All the components of the complement system are listed in Fig. 2.14.

Besides acting in innate immunity, complement also influences adaptive immunity. Opsonization of pathogens by complement facilitates their uptake by phagocytic antigen-presenting cells that express complement receptors;

this enhances the presentation of pathogen antigens to T cells, which we discuss in more detail in Chapter 6. B cells express receptors for complement proteins that enhance their responses to complement-coated antigens, as we describe later in Chapter 10. In addition, several of the complement fragments can act to influence cytokine production by antigen-presenting cells, thereby influencing the direction and extent of the subsequent adaptive immune response, as we describe in Chapter 11.

2-5 The complement system recognizes features of microbial surfaces and marks them for destruction by coating them with C3b.

Figure 2.15 gives a highly simplified preview of the initiation mechanisms and outcomes of complement activation. The three pathways of complement activation are initiated in different ways. The **lectin pathway** is initiated by soluble carbohydrate-binding proteins—mannose-binding lectin (MBL) and ficolins—that bind to particular carbohydrate structures on microbial surfaces. Specific proteases, called MBL-associated serine proteases (MASPs), that associate with these recognition proteins trigger the cleavage of complement proteins and activation of the pathway. The **classical pathway** is initiated when complement component 1 (C1), which comprises a recognition protein (C1q) associated with proteases (C1r and C1s), either recognizes a microbial surface directly or binds to antibodies already bound to a pathogen. Finally, the **alternative pathway** can be initiated by spontaneous hydrolysis and activation of complement component 3 (C3), which can then bind directly to microbial surfaces.

These three pathways converge at the central and most important step in complement activation. When any of the pathways interacts with a pathogen surface, the enzymatic activity of a **C3 convertase** is generated. There are various types of C3 convertase, depending on the complement pathway activated, but each is a multi-subunit protein with protease activity that cleaves C3. The C3 convertase is bound covalently to the pathogen surface, where it cleaves C3 to generate large amounts of **C3b**, the main effector molecule of the complement system, and **C3a**, a small peptide that binds to specific receptors and helps induce inflammation. Cleavage of C3 is the critical step in complement activation and leads directly or indirectly to all the effector activities of the complement system (see Fig. 2.15). C3b binds covalently to the microbial surface and acts as an opsonin, enabling phagocytes that carry receptors for complement to take up and destroy the C3b-coated microbe. Later in the chapter, we will describe the different complement receptors that bind C3b and are involved in this function of complement and explain how C3b is degraded by a serum protease into inactive smaller fragments called **C3f** and **C3dg** and C3d. C3b can also bind to the C3 convertases produced by the classical and lectin pathways and form another multi-subunit enzyme, the **C5 convertase**, which cleaves C5, liberating the highly inflammatory peptide **C5a** and generating **C5b**. C5b initiates the 'late' events of complement activation, also called the terminal pathway, in which additional complement proteins interact with C5b to form a **membrane-attack complex (MAC)** on the pathogen surface, creating a pore in the cell membrane that leads to cell lysis (see Fig. 2.15, bottom right).

The key feature of C3b is its ability to form a covalent bond with microbial surfaces, which allows the innate recognition of microbes to be translated into effector responses. Covalent bond formation is due to a highly reactive thioester bond that is hidden inside the folded C3 protein and cannot react until C3 is cleaved. When C3 convertase cleaves C3 and releases the C3a fragment, large conformational changes occur in C3b that allow the thioester bond to react with a hydroxyl or amino group on the nearby microbial surface

Functional protein classes in the complement system

ANIMATION 2.1

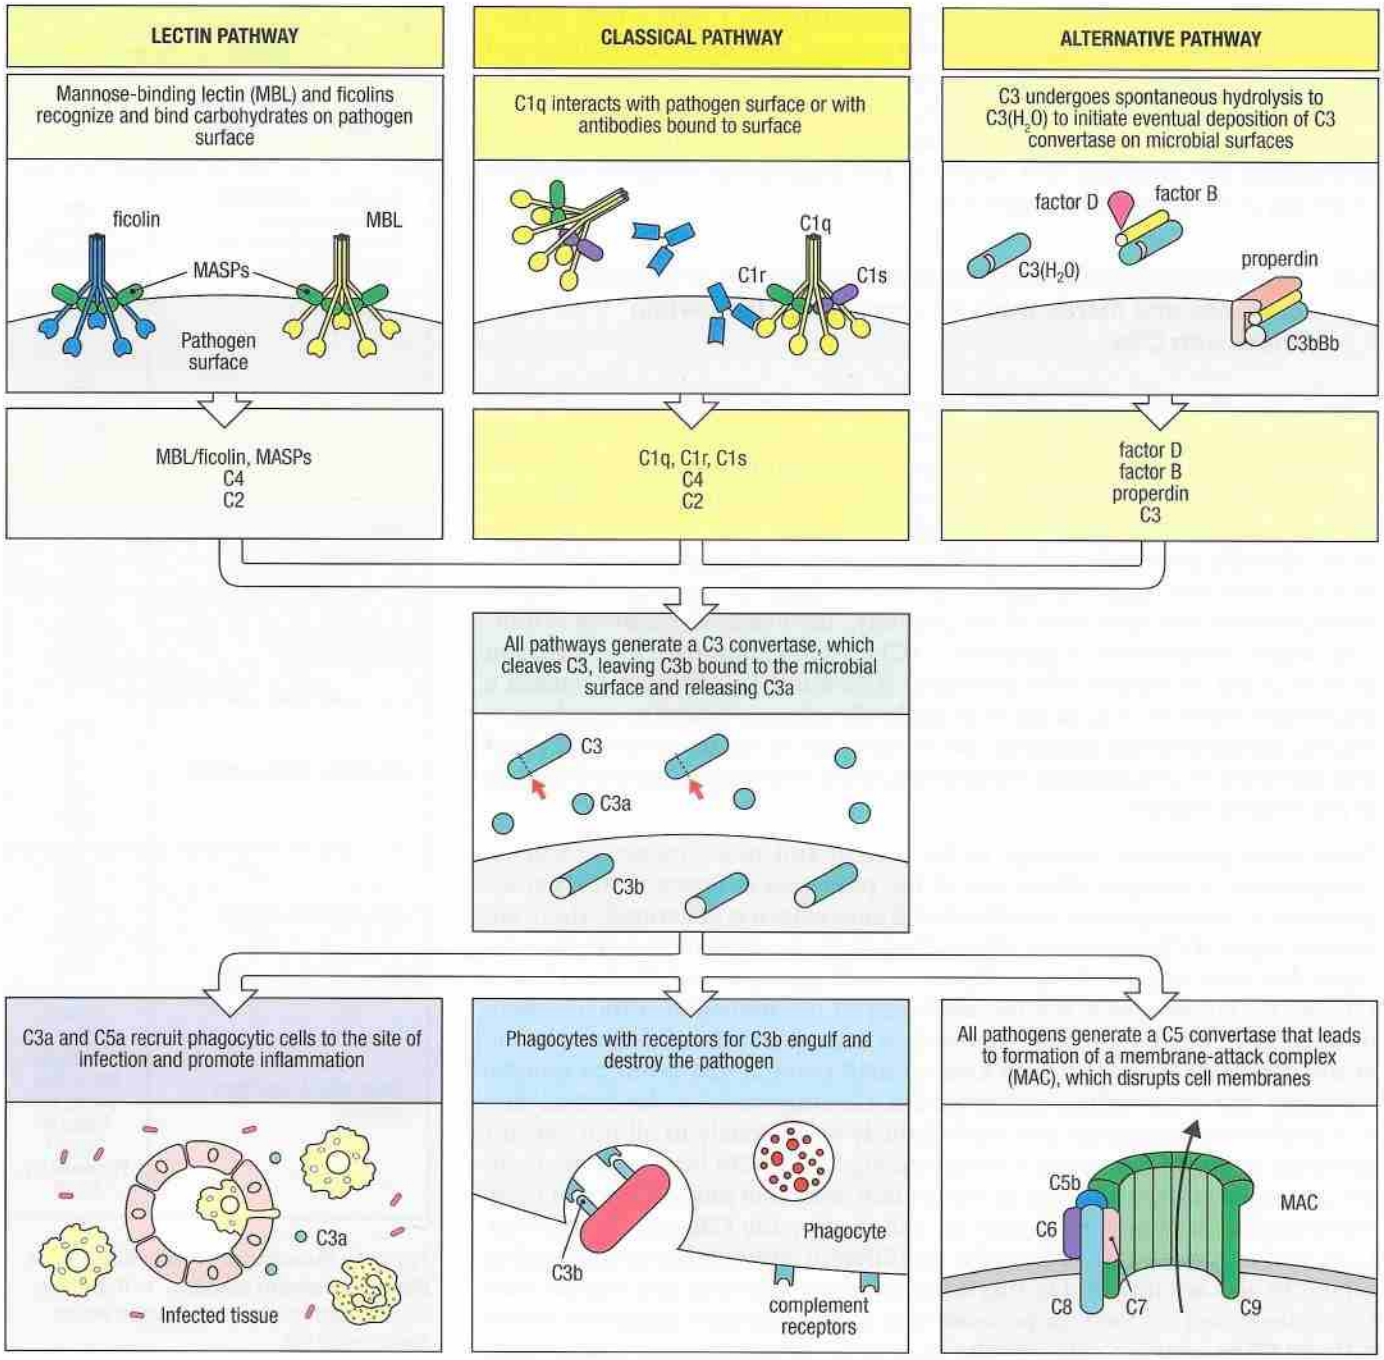

Fig. 2.15 Complement is a system of soluble pattern-recognition receptors and effector molecules that detect and destroy microorganisms. The pathogen-recognition mechanisms of the three complement-activation pathways are shown in the top row, along with the complement components used in the proteolytic cascades leading to formation of a C3 convertase. This enzyme activity cleaves complement component 3 (C3) into a small soluble protein, C3a, and a larger component, C3b, which becomes covalently bound to the pathogen surface (middle row). The components are listed by biochemical function in Fig. 2.14 and are described in detail in later figures. The lectin pathway of complement activation (top left) is triggered by the binding of mannose-binding lectin (MBL) or ficolins to carbohydrate residues in microbial cell walls and capsules. The classical pathway (top center) is triggered by binding of C1 either to the pathogen surface or to antibody bound to the pathogen. In the alternative pathway (top right), soluble C3 undergoes spontaneous hydrolysis in the fluid phase, generating $C3(H_2O)$, which, in concert with factors B, D, and properdin, propagates the cascade. All pathways thus converge on the formation of C3b bound to a pathogen and lead to all of the effector activities of complement, which are shown in the bottom row. C3b bound to a pathogen acts as an opsonin, enabling phagocytes that express receptors for C3b to ingest the complement-coated microbe more easily (bottom center). C3b can also bind to C3 convertases to produce another enzyme, a C5 convertase (detail not shown here), which cleaves C5 to C5a and C5b. C5b triggers the late events of the complement pathway in which the terminal components of complement—C6 to C9—assemble into a membrane-attack complex (MAC) that can damage the membrane of certain pathogens (bottom right). C3a and C5a act as chemoattractants that recruit immune-system cells to the site of infection and cause inflammation (bottom left).

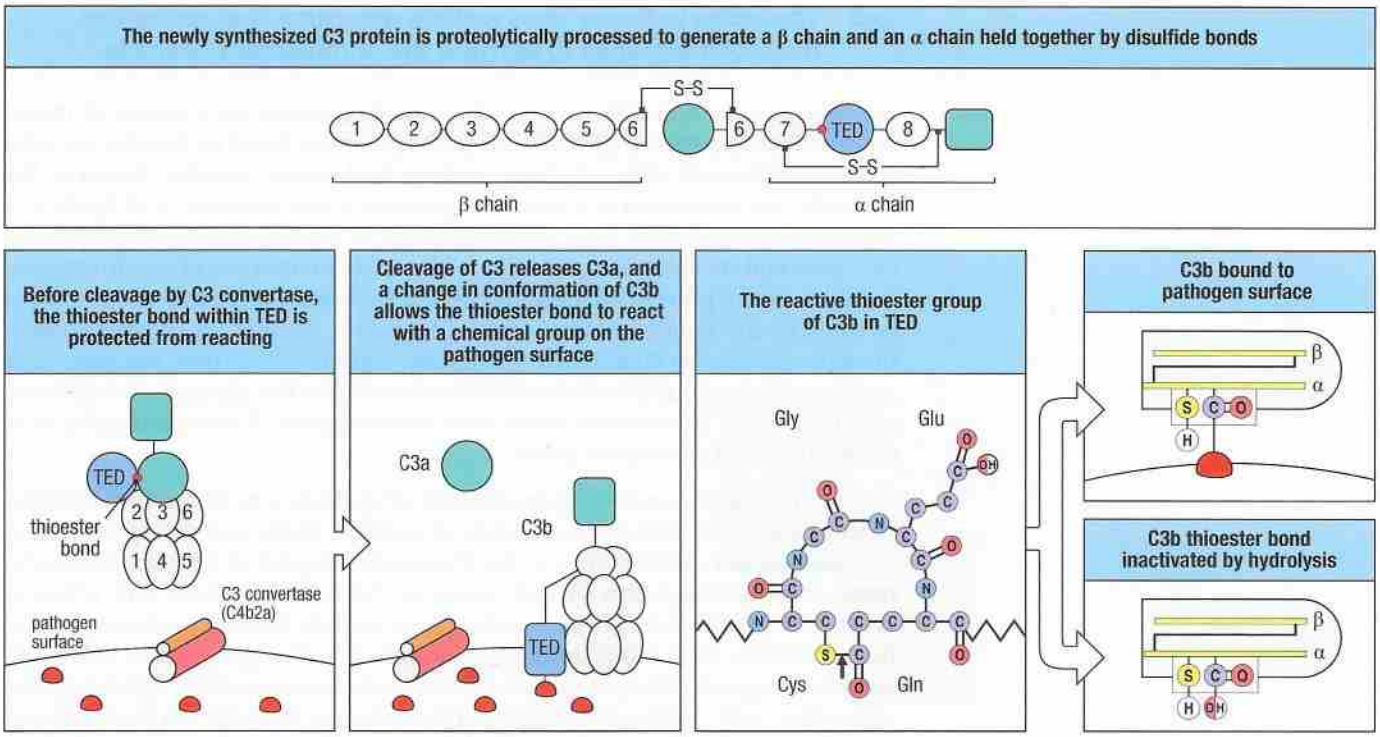

Fig. 2.16 C3 convertase activates C3 for covalent bonding to microbial surfaces by cleaving it into C3a and C3b and exposing a highly reactive thioester bond in C3b. Top panel: C3 in blood plasma consists of an α chain and a β chain (formed by proteolytic processing from the native C3 polypeptide) held together by a disulfide bond. The thioester-containing domain (TED) of the α chain contains a potentially highly reactive thioester bond (red spot). Bottom left panels: Cleavage by C3 convertase (the lectin and classical pathway convertase C4b2a is shown here) and release of C3a from the amino terminus of the α chain causes a conformational change in C3b that exposes the thioester bond. This can now react with hydroxyl or amino groups on molecules on microbial surfaces, covalently bonding C3b to the surface. Bottom right panels: Schematic view of the thioester reaction. If a bond is not made with a microbial surface, the thioester is rapidly hydrolyzed (that is, cleaved by water), rendering C3b inactive.

(Fig. 2.16). If no bond is made, the thioester is rapidly hydrolyzed, inactivating C3b, which is one way that alternative pathway activity is confined to a target area in healthy individuals. As we will see below, some of the individual components of C3 and C5 convertases differ between the various complement pathways; the components that are different are listed in Fig. 2.17.

Pathways leading to such potent inflammatory and destructive effects—and which have a series of built-in amplification steps—are potentially dangerous and must be tightly regulated. One important safeguard is that the key activated complement components are rapidly inactivated unless they bind to the pathogen surface on which their activation was initiated. There are also several points in the pathway at which regulatory proteins act to prevent the activation of complement on the surfaces of healthy host cells, thereby protecting them from accidental damage, as we shall see later in the chapter. Complement can, however, be activated by dying cells, such as those at sites of ischemic injury, and by cells undergoing apoptosis, or programmed cell death. In these cases, the complement coating helps phagocytes dispose of the dead and dying cells neatly, thus limiting the risk of cell contents being released and triggering an autoimmune response (discussed in Chapter 15).

Having introduced some of the main complement components, we are ready for a more detailed account of the three pathways. To help indicate the types of functions carried out by each of the complement components in the tables throughout the rest of the chapter, we will use the color code introduced in Fig. 2.13 and Fig. 2.14: yellow for recognition and activation, green for amplification, purple for inflammation, blue for phagocytosis, and pink for membrane attack.

2-6 The lectin pathway uses soluble receptors that recognize microbial surfaces to activate the complement cascade.

Microorganisms typically bear on their surface repeating patterns of molecular structures, known generally as pathogen-associated molecular patterns (PAMPs). The cell walls of Gram-positive and Gram-negative bacteria, for example, are composed of a matrix of proteins, carbohydrates, and lipids in a repetitive array (see Fig. 2.9). The lipoteichoic acids of Gram-positive bacterial cell walls and the lipopolysaccharide of the outer membrane of Gram-negative bacteria are not present on animal cells and are important in the recognition of bacteria by the innate immune system. Similarly, the glycans of yeast surface proteins commonly terminate in mannose residues rather than the sialic acid residues (*N*-acetylneuraminic acid) that terminate the glycans of vertebrate cells (Fig. 2.18). The lectin pathway uses these features of microbial surfaces to detect and respond to pathogens.

The lectin pathway can be triggered by any of four different pattern-recognition receptors that circulate in blood and extracellular fluids and recognize carbohydrates on microbial surfaces. The first such receptor to be discovered was **mannose-binding lectin (MBL)**, which is shown in Fig. 2.19, and which is synthesized in the liver. MBL is an oligomeric protein built up from a monomer that contains an amino-terminal collagen-like domain and a carboxyl-terminal C-type lectin domain (see Section 2-4). Proteins of this type are called **collectins**. MBL monomers assemble into trimers through the formation of a triple helix by their collagen-like domains. Trimers then assemble into oligomers by disulfide bonding between the cysteine-rich collagen domains. The MBL present in the blood is composed of two to six trimers, with the major forms of human MBL being trimers and tetramers. A single carbohydrate-recognition domain of MBL has a low affinity for mannose, fucose, and *N*-acetylglucosamine (GlcNAc) residues, which are common on microbial glycans, but does not bind sialic acid residues, which terminate vertebrate glycans. Thus, multimeric MBL has high total binding strength, or **avidity**, for repetitive carbohydrate structures on a wide variety of microbial surfaces, including Gram-positive and Gram-negative bacteria, mycobacteria, yeasts, and some viruses and parasites, while not interacting with host cells. MBL is present at low concentrations in the plasma of most individuals, but in the presence of infection, its production is increased during the **acute-phase**

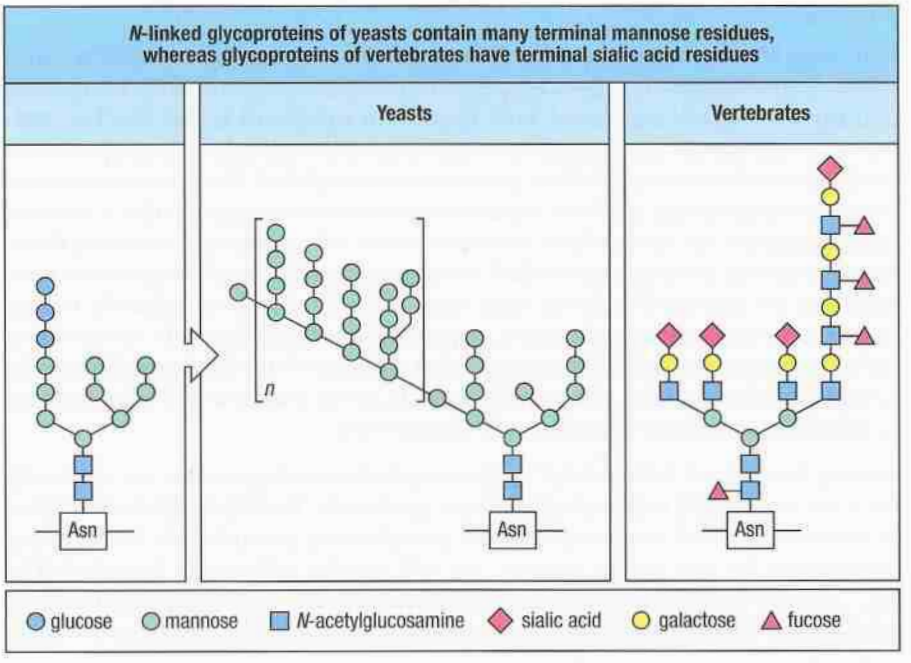

Fig. 2.18 The carbohydrate side chains on yeast and vertebrate glycoproteins are terminated with different patterns of sugars. *N*-linked glycosylation in fungi and animals is initiated by the addition of the same precursor oligosaccharide, Glc_3-Man_9-$GlcNAc_2$ (left panel), to an asparagine residue. In many yeasts this is processed to high-mannose glycans (middle panel). In contrast, in vertebrates, the initial glycan is trimmed and processed, and the *N*-linked glycoproteins have terminal sialic acid residues (right panel).

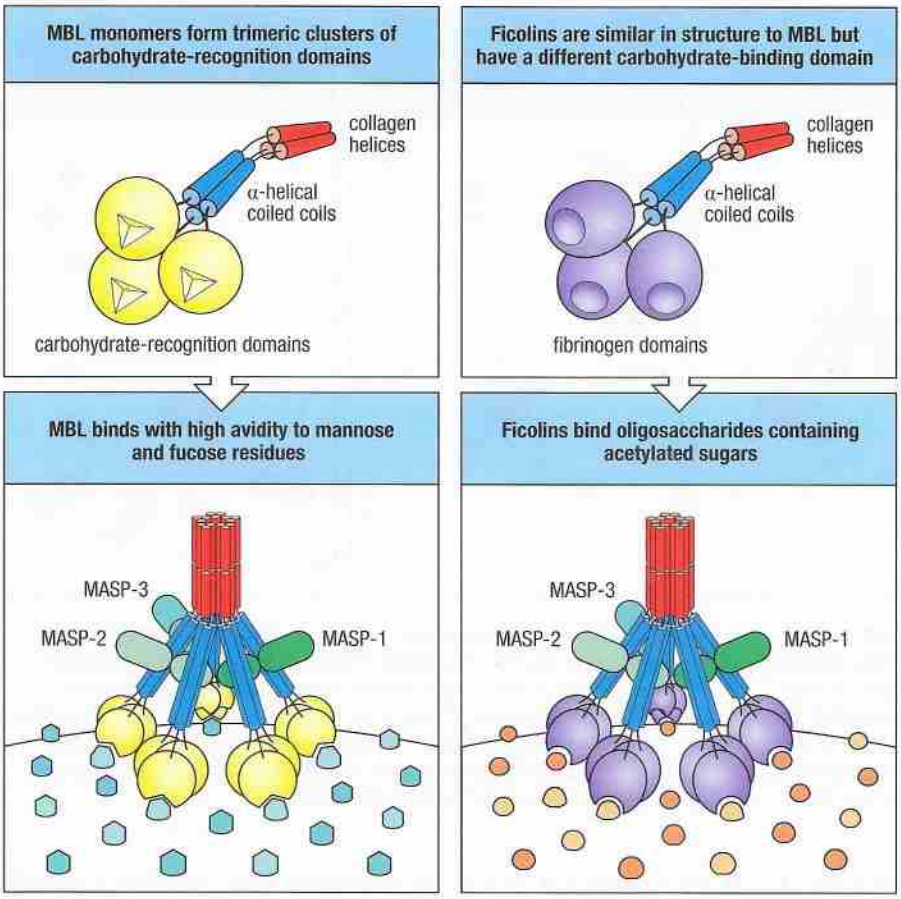

Fig. 2.19 Mannose-binding lectin and ficolins form complexes with serine proteases and recognize particular carbohydrates on microbial surfaces. Mannose-binding lectin (MBL; left panels) is an oligomeric protein in which two to six clusters of carbohydrate-binding heads arise from a central stalk that is formed from the collagen-like tails of the MBL monomers. An MBL monomer is composed of a collagen region (red), an α-helical neck region (blue), and a carbohydrate-recognition domain (yellow). Three MBL monomers associate to form a trimer (top left panel), and between two and six trimers assemble to form a mature MBL molecule (bottom left panel). MBL binds to bacterial surfaces that display a particular spatial arrangement of mannose or fucose residues. An MBL molecule associates with the serine proteases MASP-1, MASP-2, and MASP-3, and with the nonenzymatic proteins MAp19 and MAp44 (not shown), and can activate C4 and C2 after binding to carbohydrate molecules present on microbial surfaces. The ficolins (right panels) resemble MBL in their overall structure and activation mechanism. The carbohydrate-binding domain of ficolins is a fibrinogen-like domain, rather than the lectin domain present in MBL.

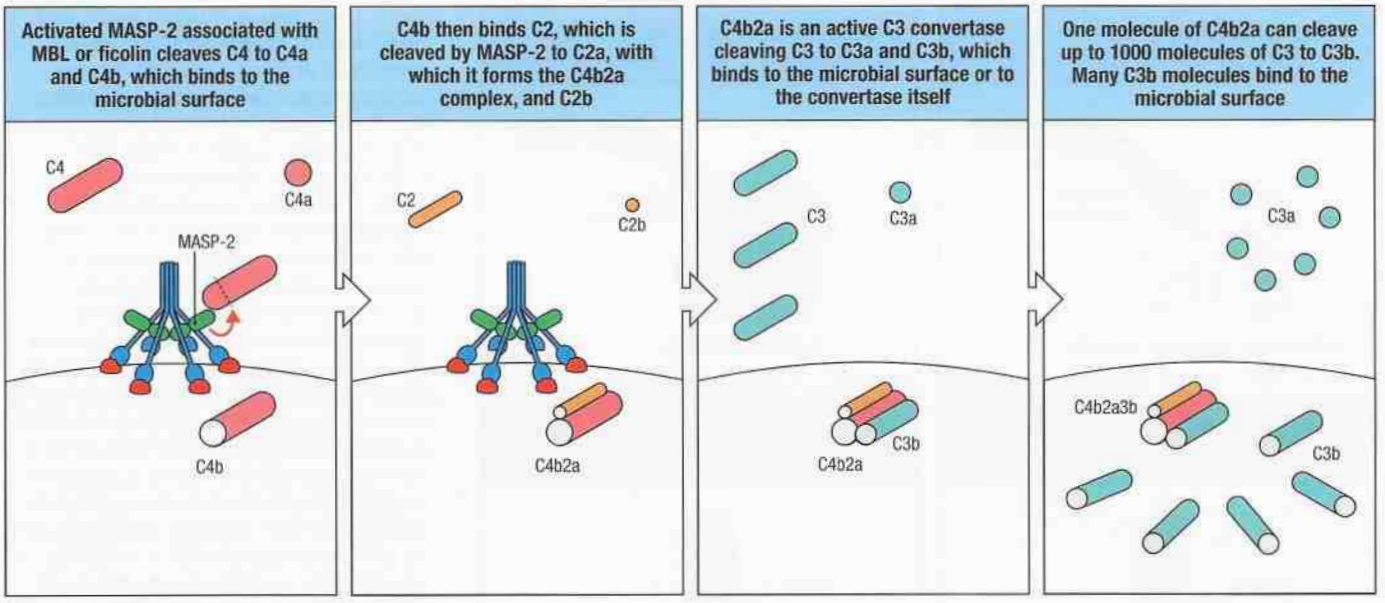
response. This is part of the induced phase of the innate immune response and is discussed in Chapter 3.

The other pathogen-recognition molecules used by the lectin pathway are known as **ficolins**. Although related in overall shape and function to MBL, they have a fibrinogen-like domain, rather than a lectin domain, attached to the collagen-like stalk (see Fig. 2.19). The fibrinogen-like domain gives ficolins a general specificity for oligosaccharides containing acetylated sugars, but it does not bind mannose-containing carbohydrates. Humans have three ficolins: ficolin-1 (M-ficolin), ficolin-2 (L-ficolin), and ficolin-3 (H-ficolin). Each binds to a spectrum of bacteria. Ficolins are secreted into the blood and tissues by various cells, including cells of the liver and lung, and by neutrophils.

MBL in plasma can bind to five proteins: three **MBL-associated serine proteases**, **MASP-1, MASP-2,** and **MASP-3**, and two nonenzymatic proteins, **MAp19** and **MAp44**. These five proteins are encoded by alternative splice variants of two genes: *MASP1*, which encodes MASP-1, MASP-3, and MAp44, and *MASP2*, which encodes MASP-2 and MAp19. MASP-1 and MASP-3 use different serine protease domains and have different substrate specificity. When MBL bound to MASP-1 and MASP-2 interacts with a pathogen surface, a conformational change occurs in MASP-1 that enables it to cleave and activate a MASP-2 molecule in the same MBL complex. Activated MASP-2 can then cleave complement components 4 and 2 (C4 and C2) to initiate the lectin and classical complement pathways (Fig. 2.20). When MBL bound to MASP-3 and MAp44 binds a pathogen surface, MASP-3 cleaves a pro-form of factor D, producing active factor D, which is a key event in the initiation of the alternative complement pathway. Like MBL, ficolins form oligomers that make a complex with MASP-1 and MASP-2, which similarly activate complement upon recognition of a microbial surface by the ficolin. **C4**, like C3, contains a buried



Activated MASP-2 associated with MBL or ficolin cleaves C4 to C4a and C4b, which binds to the microbial surface
C4b then binds C2, which is cleaved by MASP-2 to C2a, with which it forms the C4b2a complex, and C2b
C4b2a is an active C3 convertase cleaving C3 to C3a and C3b, which binds to the microbial surface or to the convertase itself
One molecule of C4b2a can cleave up to 1000 molecules of C3 to C3b. Many C3b molecules bind to the microbial surface

Fig. 2.20 The actions of the C3 convertase result in the binding of large numbers of C3b molecules to the pathogen surface. Binding of mannose-binding lectin or ficolins to their carbohydrate ligands on microbial surfaces induces MASP-1 to cleave and activate the serine protease MASP-2. MASP-2 then cleaves C4, exposing the thioester bond in C4b that allows it to react covalently with the pathogen surface. C4b then binds C2, making C2 susceptible to cleavage by MASP-2 and thus generating the C3 convertase C4b2a. C2a is the active protease component of the C3 convertase and cleaves many molecules of C3 to produce C3b, which binds to the pathogen surface, and C3a, an inflammatory mediator. The covalent attachment of C3b and C4b to the pathogen surface is important in confining subsequent complement activity to pathogen surfaces.

thioester bond. When MASP-2 cleaves C4, it releases C4a, allowing a conformational change in C4b that exposes the reactive thioester as described for C3b (see Fig. 2.16). C4b bonds covalently via this thioester to the microbial surface nearby, where it then binds one molecule of C2 (see Fig. 2.20). C2 is cleaved by MASP-2, producing C2a, an active serine protease that remains bound to C4b to form **C4b2a**, which is the C3 convertase of the lectin and classical pathways. (Remember, we use the original convention by which C2a is the active large C2 fragment.) C4b2a now cleaves many molecules of C3 into C3a and C3b. The C3b fragments bond covalently to the nearby pathogen surface, and the released C3a initiates a local inflammatory response. The complement-activation pathway initiated by ficolins proceeds like the MBL lectin pathway (see Fig. 2.20).

Individuals deficient in MBL or MASP-2 experience substantially more respiratory infections by common extracellular bacteria during early childhood, indicating the importance of the lectin pathway for host defense. This susceptibility illustrates the particular importance of innate defense mechanisms in early childhood, when adaptive immune responses are not yet fully developed but the maternal antibodies transferred across the placenta and present in the mother's milk are gone. Other members of the collectin family are the **surfactant proteins A and D (SP-A and SP-D)**, which are present in the fluid that bathes the epithelial surfaces of the lung. There they coat the surfaces of pathogens, making them more susceptible to phagocytosis by macrophages that have left the subepithelial tissues to enter the alveoli. Because SP-A and SP-D do not associate with MASPs, they do not activate complement.

We have used MBL here as our prototype activator of the lectin pathway, but the ficolins are more abundant than MBL in plasma and so may actually be more important. Ficolin-2 recognizes acetylated sugars, such as GlcNAc and *N*-acetylgalactosamine (GalNAc), and particularly recognizes lipoteichoic acid, a component of the cell walls of Gram-positive bacteria that contains

GalNAc. It can also activate complement after binding to a variety of capsulated bacteria. Ficolin-1 also recognizes acetylated sugar residues; ficolin-3 shows a more restricted binding specificity, for D-fucose and D-galactose, and has been linked to activity against the Gram-positive bacterium *Aerococcus viridans*, a cause of bacterial endocarditis.

2-7 The classical pathway is initiated by activation of the C1 complex and is homologous to the lectin pathway.

In its overall scheme, the classical pathway is similar to the lectin pathway, except that it uses a pathogen sensor known as the **C1 complex,** or **C1**. Because C1 interacts directly with some pathogens but can also interact with antibodies, C1 allows the classical pathway to function both in innate immunity, which we describe now, and in adaptive immunity, which we examine in more detail in Chapter 10.

Like the MBL:MASP complex, the C1 complex is composed of a large subunit (**C1q**), which acts as the pathogen sensor, and two serine proteases (**C1r** and **C1s**), which are initially in their inactive form (Fig. 2.21). C1q is a hexamer of trimers, composed of monomers that contain an amino-terminal globular domain and a carboxyl-terminal collagen-like domain. The trimers assemble through interactions of the collagen-like domains, bringing the globular domains together to form a globular head. Six of these trimers assemble to form a complete C1q molecule, which has six globular heads held together by their collagen-like tails. C1r and C1s are closely related to MASP-2 and somewhat more distantly related to MASP-1 and MASP-3; all five enzymes are likely to have evolved from the duplication of a gene for a common precursor. C1r and C1s interact noncovalently and form tetramers that fold into the arms of C1q, with at least part of the C1r:C1s complex being external to C1q, as illustrated in Fig. 2.21.

The recognition function of C1 resides in the six globular heads of C1q. When two or more of these heads interact with a ligand, this causes a conformational change in the C1r:C1s complex, which leads to the activation of an autocatalytic enzymatic activity in C1r; the active form of C1r then cleaves its associated C1s to generate an active serine protease. The activated C1s acts on the next two components of the classical pathway, C4 and C2. C1s cleaves C4 to produce C4b, which binds covalently to the pathogen surface as described earlier for the lectin pathway (see Fig. 2.20). C4b then also binds one molecule of C2, which is cleaved by C1s to produce the serine protease C2a. This produces the active C3 convertase C4b2a, which is the C3 convertase of both the lectin and the classical pathways. However, because it was first discovered as part of the classical pathway, C4b2a is often known as the **classical C3 convertase** (see Fig. 2.17). The proteins involved in the classical pathway, along with their active forms, are listed in Fig. 2.22.

C1q can attach itself to the surface of pathogens in several different ways. One is by binding directly to surface components on some bacteria, including certain proteins of bacterial cell walls and polyanionic structures, such as the lipoteichoic acid on Gram-positive bacteria. A second is through binding to C-reactive protein, an acute-phase protein in human plasma that binds to phosphocholine residues in bacterial surface molecules such as pneumococcal C polysaccharide—hence the name C-reactive protein. We discuss the acute-phase proteins in detail in Chapter 3. However, a main function of C1q in an immune response is to bind to the constant, or Fc, regions of antibodies (see Section 1-9) that have bound pathogens via their antigen-binding sites. C1q thus links the effector functions of complement to recognition provided by adaptive immunity. This might seem to limit the usefulness of C1q in fighting the first stages of an infection, before the adaptive immune response has

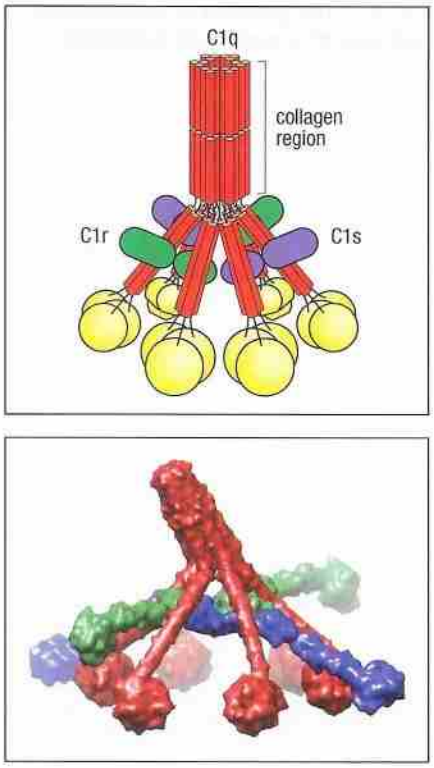

Fig. 2.21 The first protein in the classical pathway of complement activation is C1, which is a complex of C1q, C1r, and C1s. Upper panel: C1q is composed of six identical subunits with globular heads (yellow) and long collagen-like tails (red); it has been described as looking like "a bunch of tulips." The tails combine to bind to two molecules each of C1r and C1s, forming the C1 complex C1q:$C1r_2$:$C1s_2$. The heads can bind to the constant regions of immunoglobulin molecules or directly to the pathogen surface, causing a conformational change in C1r, which then cleaves and activates the C1s zymogen (proenzyme). The C1 complex is similar in overall structure to the MBL:MASP complex, and it has an identical function, cleaving C4 and C2 to form the C3 convertase C4b2a (see Fig. 2.20). Lower panel: Structure of the C1 complex solved by cryo-electron microscopy (cryo-EM): C1q (red), C1r (green), C1s (blue). Modified from Sharp, T.H., et al.: *Proc. Natl. Acad. Sci. USA* 2019, 116:11900–11905.

Fig. 2.22 The proteins of the classical pathway of complement activation.

Proteins of the classical pathway of complement activation		
Native component	**Active form**	**Function of the active form**
C1 (C1q: $C1r_2$:$C1s_2$)	C1q	Binds directly to pathogen surfaces or indirectly to antibody bound to pathogens, thus allowing autoactivation of C1r
	C1r	Cleaves C1s to active protease
	C1s	Cleaves C4 and C2
C4	C4b	Covalently binds to pathogen and opsonizes it. Binds C2 for cleavage by C1s
	C4a	Peptide mediator of inflammation (weak activity)
C2	C2a	Active enzyme of classical pathway C3/C5 convertase: cleaves C3 and C5
	C2b	Inactive small fragment
C3	C3b	Binds to pathogen surface and acts as opsonin. Initiates amplification via the alternative pathway. Binds C5 for cleavage by C2a
	C3a	Peptide mediator of inflammation (intermediate activity)

generated pathogen-specific antibodies. However, some antibodies, called **natural antibodies**, are produced by the immune system in the apparent absence of infection. These antibodies have a low affinity for many microbial pathogens and are highly cross-reactive, recognizing common membrane constituents such as phosphocholine and even recognizing some antigens of the body's own cells (that is, self antigens). Natural antibodies may be produced in response to commensal microbiota or to self antigens, but do not seem to be the consequence of an adaptive immune response to infection by pathogens. Most natural antibody is of the isotype, or class, known as IgM (see Chapter 5) and represents a considerable amount of the total IgM circulating in humans. IgM is the class of antibody most efficient at binding C1q, making natural antibodies an effective means of activating complement on microbial surfaces immediately after infection and leading to the clearance of bacteria such as *Streptococcus pneumoniae* (the pneumococcus) before they become dangerous.

2-8 Complement activation is largely confined to the surface on which it is initiated.

We have seen that both the lectin and the classical pathways of complement activation are initiated by proteins that bind to pathogen surfaces. During the triggered enzyme cascade that follows, it is important that activating events are confined to this same site, so that C3 activation also occurs on the surface of the pathogen and not in the plasma or on host-cell surfaces. This is achieved principally by the covalent binding of C4b to the pathogen surface. In innate immunity, C4 cleavage is catalyzed by a ficolin or MBL complex that is bound to the pathogen surface, and so the C4b cleavage product can bind adjacent proteins or carbohydrates on the pathogen surface. If C4b does not rapidly form this bond, the thioester bond is cleaved by reaction with water, and C4b is irreversibly inactivated. This helps to prevent C4b from diffusing from its site of activation on the microbial surface and becoming attached to healthy host cells.

C2 becomes susceptible to cleavage by C1s only when it is bound by C4b, and the active C2a serine protease is thereby also confined to the pathogen surface, where it remains associated with C4b, forming the C3 convertase C4b2a. Cleavage of C3 to C3a and C3b is thus also confined to the surface of the pathogen. Like C4b, C3b is inactivated by hydrolysis unless its exposed thioester rapidly makes a covalent bond (see Fig. 2.16), and it therefore opsonizes only the surface on which complement activation has taken place. Opsonization by C3b is more effective when antibodies are also bound to the pathogen surface, as phagocytes have receptors for both complement and Fc receptors that bind the Fc region of antibody (see Sections 1-20 and 10-20). Because the reactive forms of C3b and C4b are able to form a covalent bond with any adjacent protein or carbohydrate, when complement is activated by bound antibody a proportion of the reactive C3b or C4b will become linked to the antibody molecules themselves. Antibody that is chemically cross-linked to complement is likely the most efficient trigger for phagocytosis.

2-9 The alternative pathway is an amplification loop for C3b formation that is accelerated by properdin in the presence of pathogens.

Although probably the most ancient of the complement pathways, the alternative pathway is so named because it was discovered as a second, or 'alternative,' pathway for complement activation after the classical pathway had been defined. Its key feature is its ability to be spontaneously activated. It has a unique C3 convertase, the **alternative pathway C3 convertase**, which differs from the C4b2a convertase of the lectin or classical pathways (see Fig. 2.17). The alternative pathway C3 convertase is composed of C3b itself bound to Bb, which is a cleavage fragment of the plasma protein **factor B**. This C3 convertase, designated **C3bBb**, has a special place in complement activation because, by producing C3b, it can generate more of itself. This means that once some C3b has been formed, by whichever pathway, the alternative pathway can act as an amplification loop to increase C3b production rapidly.

The alternative pathway can be activated in two different ways. The first is by the action of the lectin or classical pathway. C3b generated by either of these pathways and covalently linked to a microbial surface can bind factor B (Fig. 2.23). This alters the conformation of factor B, enabling a plasma protease

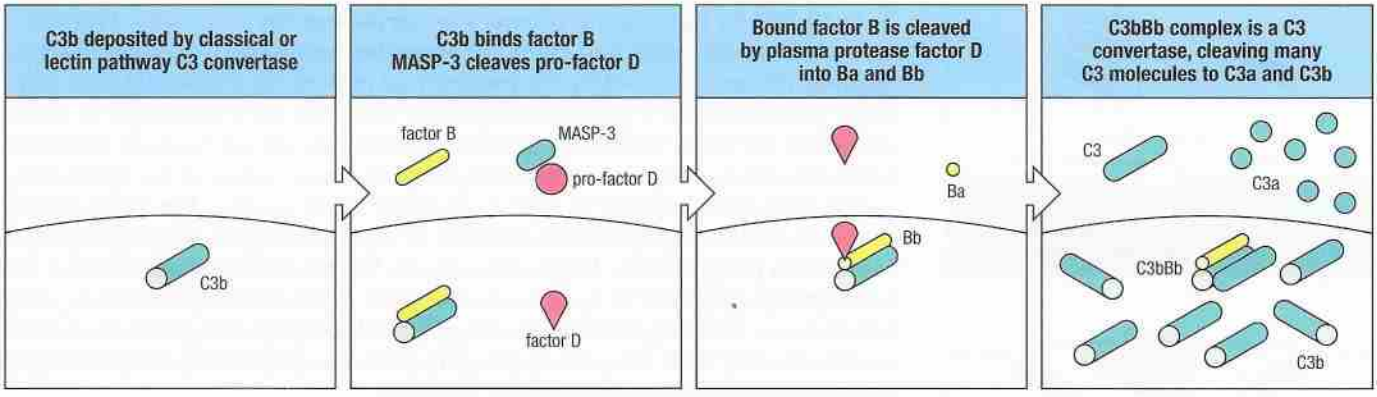

Fig. 2.23 The alternative pathway of complement activation can amplify the classical or the lectin pathway by forming an alternative C3 convertase and depositing more C3b molecules on the pathogen. C3b deposited by the classical or lectin pathway can bind factor B, making it susceptible to cleavage by factor D. MASP-3 cleaves pro-factor D (red circle) to form the active form of factor D (red fan). Cleavage of factor B produces the C3bBb complex, which is the C3 convertase of the alternative pathway of complement activation. This action of this C3 convertase, like that of C4b2a, results in the deposition of many molecules of C3b on the pathogen surface.

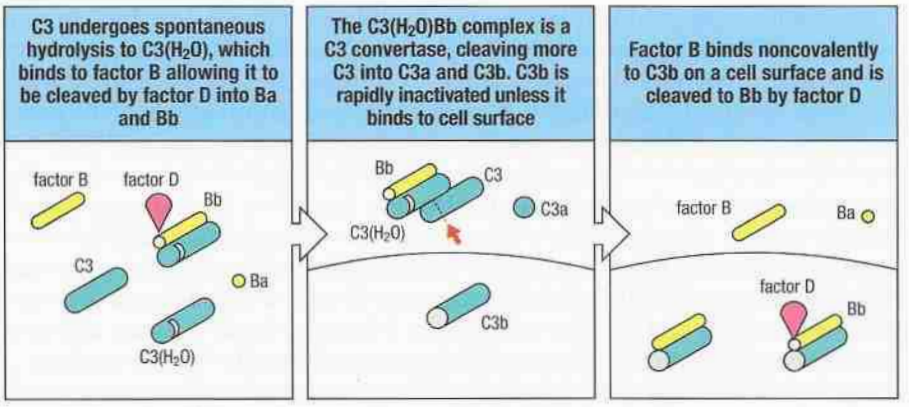

C3 undergoes spontaneous hydrolysis to C3(H2O), which binds to factor B allowing it to be cleaved by factor D into Ba and Bb
The C3(H2O)Bb complex is a C3 convertase, cleaving more C3 into C3a and C3b. C3b is rapidly inactivated unless it binds to cell surface
Factor B binds noncovalently to C3b on a cell surface and is cleaved to Bb by factor D

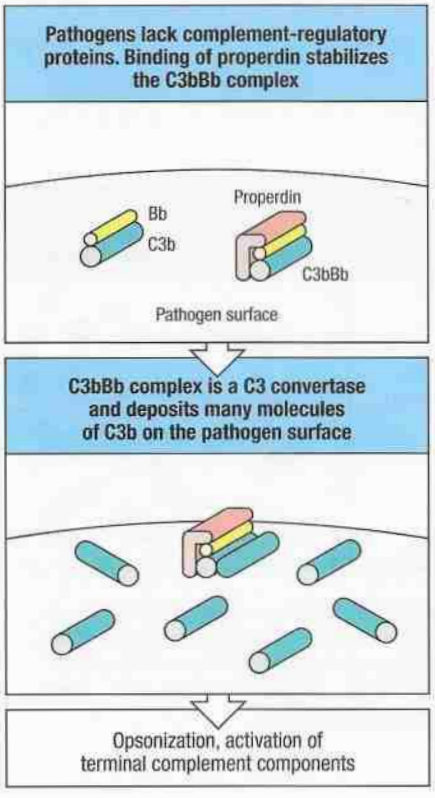
Fig. 2.24 The alternative pathway can be activated by spontaneous activation of C3. Complement component C3 hydrolyzes spontaneously in plasma to give C3(H_2O), which binds factor B and enables the bound factor B to be cleaved by factor D (first panel). The resulting 'soluble C3 convertase' cleaves C3 to give C3a and C3b, which can attach to host cells or pathogen surfaces (second panel). Covalently bound to the cell surface, C3b binds factor B; in turn, factor B is rapidly cleaved by factor D to Bb, which remains bound to C3b to form a C3 convertase (C3bBb), and Ba, which is released (third panel). This convertase functions in the alternative pathway as the C3 convertase C4b2a does in the lectin and classical pathways (see Fig. 2.17).

called **factor D** to cleave it into Ba and Bb. Bb remains stably associated with C3b, forming the C3bBb C3 convertase. The second way of activating the alternative pathway involves the spontaneous hydrolysis (known as '**tickover**') of the thioester bond in C3 to form C3(H_2O), as shown in Fig. 2.24. C3 is abundant in plasma, and tickover causes a steady, low-level production of C3(H_2O). This C3(H_2O) can bind factor B, which is then cleaved by factor D, producing a short-lived **fluid-phase C3 convertase, C3(H_2O)Bb**. Although formed in only small amounts by C3 tickover, fluid-phase C3(H_2O)Bb can cleave many molecules of C3 to C3a and C3b. Much of this C3b is inactivated by hydrolysis, but some attaches covalently via its thioester bond to the surfaces of any microbes present. C3b formed in this way is no different from C3b produced by the lectin or classical pathways and binds factor B, leading to the formation of C3 convertase and a stepping up of C3b production (see Fig. 2.23).

On their own, the alternative pathway C3 convertases C3bBb and C3(H_2O)Bb are very short-lived (~90 seconds). They are stabilized, however, by around 5- to 10-fold by binding the plasma protein **properdin** (Fig. 2.25). Properdin is made by neutrophils and stored in secondary granules. It is released when neutrophils are activated by the presence of pathogens. Properdin may have some properties of a pattern-recognition receptor, as it can bind to some microbial surfaces. Properdin-deficient individuals are particularly susceptible to infections with *Neisseria meningitidis*, the main agent of bacterial meningitis. Properdin's ability to bind to bacterial surfaces may direct the activity of the alternative complement pathway to these pathogens, thus aiding their removal by phagocytosis. Properdin can also bind to mammalian cells that are undergoing apoptosis or have been damaged or modified by ischemia, viral infection, or antibody binding, leading to the deposition of C3b on these cells and facilitating their removal by phagocytosis. The distinctive components of the alternative pathway are listed in Fig. 2.26.



Pathogens lack complement-regulatory proteins. Binding of properdin stabilizes the C3bBb complex

C3bBb complex is a C3 convertase and deposits many molecules of C3b on the pathogen surface
Opsonization, activation of terminal complement components

Fig. 2.25 Properdin stabilizes the alternative pathway C3 convertase on pathogen surfaces. Bacterial surfaces do not express complement-regulatory proteins and favor the binding of properdin, which stabilizes the C3bBb convertase. This convertase activity is the equivalent of C4b2a of the lectin and classical pathways. C3bBb then cleaves many more molecules of C3, coating the pathogen surface with bound C3b.

Proteins of the alternative pathway of complement activation		
Native component	**Active fragments**	**Function**
C3	C3b	Binds to pathogen surface; binds B for cleavage by D; C3bBb is a C3 convertase and $C3b_2Bb$ is a C5 convertase
Factor B (B)	Ba	Small fragment of B, unknown function
	Bb	Bb is the active enzyme of the C3 convertase C3bBb and the C5 convertase $C3b_2Bb$
Factor D (D)	D	Plasma serine protease, cleaves B when it is bound to C3b to Ba and Bb
Properdin (P)	P	Plasma protein that binds to bacterial surfaces and stabilizes the C3bBb convertase

2-10 Membrane and plasma proteins that regulate the formation and stability of C3 convertases determine the extent of complement activation.

Several mechanisms ensure that complement activation will proceed only on the surface of a pathogen or on damaged host cells, and not on normal host cells and tissues. After initial complement activation by any pathway, the extent of amplification via the alternative pathway is critically dependent on the stability of the C3 convertase C3bBb. This stability is controlled by both positive and negative regulatory proteins. We have already described how properdin acts as a positive regulatory protein on foreign surfaces, such as those of bacteria or damaged host cells, by stabilizing C3bBb.

Several negative regulatory proteins, present in plasma and in host-cell membranes, protect healthy host cells from the injurious effects of inappropriate complement activation on their surfaces. These **complement-regulatory proteins** interact with C3b and either prevent the convertase from forming or promote its rapid dissociation (Fig. 2.27). For example, a membrane-attached protein known as **decay-accelerating factor (DAF** or **CD55)** competes with factor B for binding to C3b on the cell surface and can displace Bb from a convertase that has already formed. Convertase formation can also be prevented by cleaving C3b to an inactive derivative, **iC3b**. This is achieved by a plasma protease, **factor I**, in conjunction with C3b-binding proteins that act as cofactors, such as **membrane cofactor of proteolysis (MCP** or **CD46)**, another host-cell membrane protein (see Fig. 2.27). Cell-surface complement receptor type 1 (**CR1**, also known as **CD35**) behaves similarly to DAF and MCP in that it inhibits C3 convertase formation and promotes the catabolism of C3b to inactive products, respectively, but it has a more limited tissue distribution. **Factor H** is another complement-regulatory protein in plasma that binds C3b, and like CR1, it is able to compete with factor B to displace Bb from the convertase; in addition, it acts as a cofactor for factor I. Factor H binds preferentially to C3b bound to vertebrate cells because it has an affinity for the sialic acid residues present on their cell surfaces (see Fig. 2.18). Thus, the amplification loop of the alternative pathway is allowed to proceed on the surface of a pathogen or on damaged host cells, but not on normal host cells or on tissues that express these negative regulatory proteins.

The C3 convertase of the classical and lectin pathways (C4b2a) is molecularly distinct from that of the alternative pathway (C3bBb). However, understanding of the complement system is simplified somewhat by recognition of the close evolutionary relationships between the different complement proteins (Fig. 2.28). Thus the complement zymogens factor B and C2 are closely related proteins encoded by homologous genes located in tandem within the major

Fig. 2.26 The proteins of the alternative pathway of complement activation.

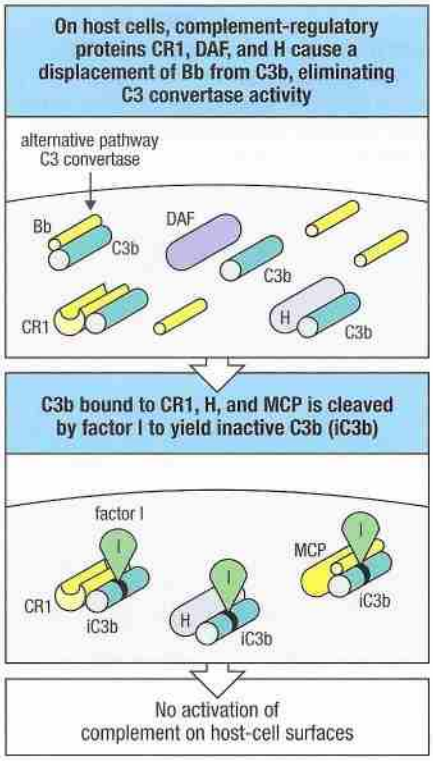

Fig. 2.27 Complement activation spares host cells, which are protected by complement-regulatory proteins. If C3bBb forms on the surface of host cells, it is rapidly inactivated by complement-regulatory proteins expressed by the host cell: complement receptor 1 (CR1), decay-accelerating factor (DAF), and membrane cofactor of proteolysis (MCP). Host-cell surfaces also favor the binding of factor H from plasma. CR1, DAF, and factor H displace Bb from C3b, and CR1, MCP, and factor H catalyze the cleavage of bound C3b by the plasma protease factor I to produce inactive C3b (known as iC3b).

Step in pathway	Protein serving function in pathway			Relationship
	Alternative	Lectin	Classical	
Initiating serine protease	D	MASP	C1s	Homologous (C1s and MASP)
Covalent binding to cell surface	C3b	C4b		Homologous
C3/C5 convertase	Bb	C2a		Homologous
Control of activation	CR1 H	CR1 C4BP		Identical Homologous
Opsonization	C3b			Identical
Initiation of effector pathway	C5b			Identical
Local inflammation	C5a, C3a			Identical
Stabilization	P	None		Unique

Fig. 2.28 There is a close evolutionary relationship among the factors of the alternative, lectin, and classical pathways of complement activation. Most of the factors are either identical or the homologous products of genes that have duplicated and then diverged in sequence. The proteins C4 and C3 are homologous and contain the unstable thioester bond by which their large fragments, C4b and C3b, bind covalently to membranes. The genes encoding proteins C2 and factor B are adjacent in the MHC region of the genome and arose by gene duplication. The regulatory proteins factor H, CR1, and C4BP share a repeat sequence common to many complement-regulatory proteins. The greatest divergence between the pathways is in their initiation: in the classical pathway the C1 complex binds either to certain pathogens or to bound antibody, and in the latter circumstance it serves to convert antibody binding into enzyme activity on a specific surface; in the lectin pathway, mannose-binding lectin (MBL) associates with a serine protease, activating MBL-associated serine protease (MASP), to serve the same function as C1r:C1s; in the alternative pathway this enzyme activity is provided by factor D.

histocompatibility complex (MHC) on human chromosome 6. Furthermore, their respective binding partners, C3 and C4, both contain thioester bonds that provide the means of covalently attaching the C3 convertases to a pathogen surface.

Only one component of the alternative pathway seems entirely unrelated to its functional equivalents in the classical and lectin pathways: the initiating serine protease, factor D. Factor D can also be singled out as the only activating protease of the complement system to circulate as an active enzyme rather than a zymogen. This is both necessary for the initiation of the alternative pathway (through the cleavage of factor B bound to spontaneously activated C3) and safe for the host, because factor D has no other substrate than factor B bound to C3b. This means factor D finds its substrate only at pathogen surfaces and at a very low level in plasma, where the alternative pathway of complement activation can be allowed to proceed.

2-11 Complement developed early in the evolution of multicellular organisms.

The complement system was originally known only from vertebrates, but homologs of C3 and factor B and a prototypical 'alternative pathway' have been discovered in nonchordate invertebrates. This is not altogether surprising as C3, which is cleaved and activated by serine proteases, is evolutionarily related to the serine protease inhibitor α_2-macroglobulin, whose first appearance likely was in an ancestor to all modern vertebrates. The amplification loop of the alternative pathway also has an ancestral origin, as it is present in echinoderms (which include sea urchins and sea stars) and is based on a C3 convertase formed by the echinoderm homologs of C3 and factor B. These factors are expressed by phagocytic cells called **amoeboid coelomocytes** present in the coelomic fluid. Expression of C3 by these cells increases when bacteria are present. This simple system seems to function to opsonize bacterial cells and other foreign particles and facilitate their uptake by coelomocytes. C3 homologs in invertebrates are clearly related to each other. They all contain the distinctive thioester linkage and form a family of proteins, the **thioester-containing proteins**, or **TEPs**. In the mosquito *Anopheles*, the production of protein TEP1 is induced in response to infection, and the protein may directly bind to bacterial surfaces to mediate phagocytosis of Gram-negative bacteria. Some form of C3 activity may even predate the evolution of the Bilateria—animals with bilateral symmetry, flatworms being the most primitive modern

representatives—because genomic evidence of C3, factor B, and some later-acting complement components has been found in the Anthozoa (corals and sea anemones).

After its initial appearance, the complement system seems to have evolved by the acquisition of new activation pathways that allow specific targeting of microbial surfaces. The first to evolve was likely the ficolin pathway, which is present both in vertebrates and in some closely related invertebrates, such as the urochordates. Evolutionarily, the ficolins may predate the collectins, which are also first seen in the urochordates. Homologs of MBL and of the classical pathway complement component 1q (C1q), both collectins, have been identified in the genome of the ascidian urochordate *Ciona* (sea squirt). Two invertebrate homologs of mammalian MASPs also have been identified in *Ciona*, and it seems likely that they may be able to cleave and activate C3. Thus, the minimal complement system of the echinoderms appears to have been expanded in the urochordates by the recruitment of a specific activation system that may target C3 deposition onto microbial surfaces. This also suggests that when adaptive immunity evolved, much later, the ancestral antibody molecule used an already diversified C1q-like collectin member to activate the complement pathway, and that the complement activation system evolved further by use of this collectin and its associated MASPs to become the initiating components of the classical complement pathway; namely, C1q, C1r, and C1s.

2-12 Surface-bound C3 convertase deposits large numbers of C3b fragments on pathogen surfaces and generates C5 convertase activity.

We now return to the present-day complement system. The formation of C3 convertases is the point at which the three pathways of complement activation converge. The convertase of the lectin and classical pathways, C4b2a, and the convertase of the alternative pathway, C3bBb, initiate the same subsequent events—they cleave C3 to C3b and C3a. C3b binds covalently through its thioester bond to adjacent molecules on the pathogen surface; otherwise it is inactivated by hydrolysis. C3 is the most abundant complement protein in plasma, occurring at a concentration of 1.2 mg/ml, and up to 1000 molecules of C3b can bind in the vicinity of a single active C3 convertase (see Fig. 2.23). Thus the main effect of complement activation is to deposit large quantities of C3b on the surface of the infecting pathogen, where the C3b forms a covalently bonded coat that can signal the ultimate destruction of the pathogen by phagocytes.

The next step in the complement cascade is the generation of the C5 convertases. C5 is a member of the same family of proteins as C3, C4, α_2-macroglobulin, and the thioester-containing proteins of invertebrates. C5 does not form an active thioester bond during its synthesis, but, like C3 and C4, it is cleaved by a specific protease into C5a and C5b fragments, each of which exerts specific downstream actions that are important in propagating the complement cascade. In the classical and the lectin pathways, a C5 convertase is formed by the binding of C3b to C4b2a to yield **C4b2a3b**. The C5 convertase of the alternative pathway is formed by the binding of C3b to the C3bBb convertase to form **C3b$_2$Bb**. A C5 is captured by these C5 convertase complexes through binding to an acceptor site on C3b and is thus rendered susceptible to cleavage by the serine protease activity of C2a or Bb. This reaction, which generates C5b and C5a, is much more limited than cleavage of C3, because C5 can be cleaved only when it binds to C3b that is in turn bound to C4b2a or C3bBb to form the active C5 convertase complex. Thus, complement activated by all three pathways leads to the binding of large numbers of C3b molecules on the surface of the pathogen, the generation of a more limited number of C5b molecules, and the release of C3a and a smaller amount of C5a (Fig. 2.29).

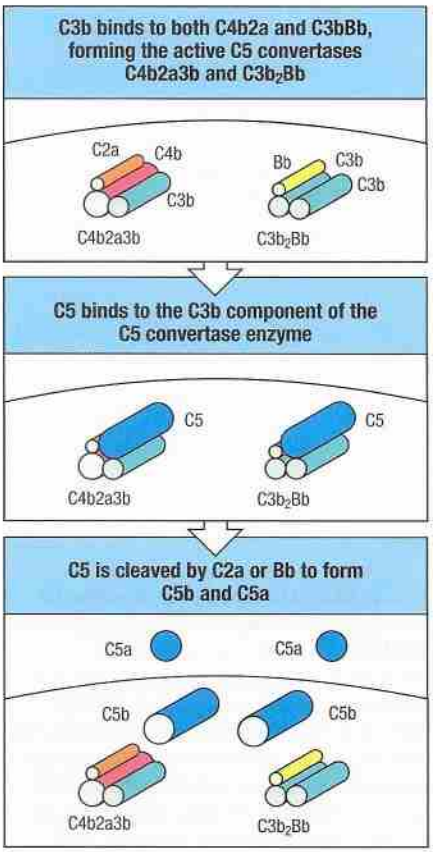

Fig. 2.29 Complement component 5 (C5) is cleaved when captured by a C3b molecule that is part of a C5 convertase complex. As shown in the top panel, C5 convertases are formed when C3b binds either the classical or lectin pathway C3 convertase C4b2a to form C4b2a3b or the alternative pathway C3 convertase C3bBb to form C3b$_2$Bb. C5 binds to C3b in these complexes (center panel). The bottom panel shows that C5 is cleaved by the active enzyme C2a or Bb to form C5b and the inflammatory mediator C5a. Unlike C3b and C4b, C5b is not covalently bound to the cell surface. The production of C5b initiates the assembly of the terminal complement components.

2-13 Ingestion of complement-tagged pathogens by phagocytes is mediated by receptors for the bound complement proteins.

The most important action of complement is to facilitate the uptake and destruction of pathogens by phagocytic cells. This occurs by the specific recognition of bound complement components by **complement receptors (CRs)** on phagocytes. These complement receptors bind pathogens opsonized with complement components: opsonization of pathogens is a major function of C3b and its proteolytic derivatives. C4b also acts as an opsonin but has a relatively minor role, largely because so much more C3b than C4b is generated.

The known receptors for bound complement components and for C5a and C3a are listed, with their functions and distributions, in Fig. 2.30. The C3b receptor CR1, described in Section 2-10, is a negative regulator of complement activation (see Fig. 2.27). CR1 is expressed on many types of immune cells, including macrophages and neutrophils. Binding of C3b to CR1 cannot by itself stimulate phagocytosis, but it can lead to phagocytosis in the presence of other immune mediators that activate macrophages. For example, the small complement fragment C5a can activate macrophages to ingest bacteria that are bound to their CR1 receptors (Fig. 2.31). C5a accomplishes this by binding to another receptor expressed by macrophages, the **C5a receptor 1** (C5aR1, CD88), which has seven membrane-spanning domains. Receptors of this type transduce their signals via intracellular guanine nucleotide–binding proteins

Receptor	Specificity	Functions	Cell types
CR1 (CD35)	C3b, C4b	Promotes C3b and C4b decay Stimulates phagocytosis (requires C5a) Erythrocyte transport of immune complexes	Erythrocytes, macrophages, monocytes, neutrophils, B cells, FDCs
CR2 (CD21)	C3d, iC3b, C3dg	Enhances B-cell response to antigens bearing C3d, iC3b, or C3dg, part of B-cell co-receptor Epstein–Barr virus receptor	B cells, FDCs
CR3 (Mac-1) (CD11b: CD18)	iC3b	Stimulates phagocytosis	Macrophages, monocytes, polymorphonuclear leukocytes, FDCs
CR4 (gp150, 95) (CD11c: CD18)	iC3b	Stimulates phagocytosis	Macrophages, monocytes, polymorphonuclear leukocytes, dendritic cells
CRIg	C3b, iC3b	Phagocytosis of circulating pathogens	Tissue-resident macrophages Hepatic sinusoid macrophages
C5aR1 (CD88)	C5a	Binding of C5a, activates G protein	Neutrophils, macrophages, endothelial cells, mast cells
C5aR2 (C5L2, GPR77)	C5a	Decoy receptor, regulates C5a receptor	Neutrophils, macrophages
C3a receptor	C3a	Binding of C3a, activates G protein	Macrophages, endothelial cells, mast cells
PAR1 PAR4	C4a	Increases vascular permeability Coagulation	Epithelium, platelets

Fig. 2.30 Distribution and function of cell-surface receptors for complement proteins. A variety of complement receptors are specific for bound C3b and its cleavage products (iC3b and C3dg). CR1 and CR3 are important in inducing the phagocytosis of bacteria with complement components bound to their surface. CR2 is found mainly on B cells, where it is part of the B-cell co-receptor complex. CR1 and CR2 share structural features with the complement-regulatory proteins that bind C3b and C4b. CR3 and CR4 are integrins composed of integrin β2 (also known as CD18, and sometimes gp95) paired with either integrin αM (CD11b) or integrin αX (CD11c), respectively (see eAppendix II, found in the ebook and on the Digital Landing Page for this book); CR3, also called Mac-1, is also important for leukocyte adhesion and migration, as we shall see in Chapter 3, whereas CR4 is only known to function in phagocytosis. The receptors for C5a and C3a are seven-span G protein–coupled receptors. FDCs (follicular dendritic cells) are not involved in innate immunity and are discussed in later chapters.

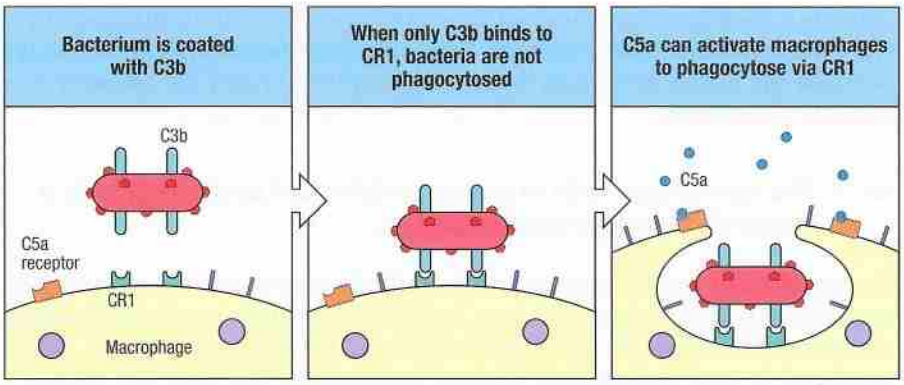

Fig. 2.31 The anaphylatoxin C5a can enhance the phagocytosis of microorganisms opsonized in an innate immune response. Activation of complement leads to the deposition of C3b on the surface of microorganisms (left panel). C3b can be bound by complement receptor 1 (CR1) on the surface of phagocytes, but this on its own is insufficient to induce phagocytosis (center panel). Phagocytes also express receptors for the anaphylatoxin C5a, and binding of C5a will activate the cell to phagocytose microorganisms bound through CR1 (right panel).

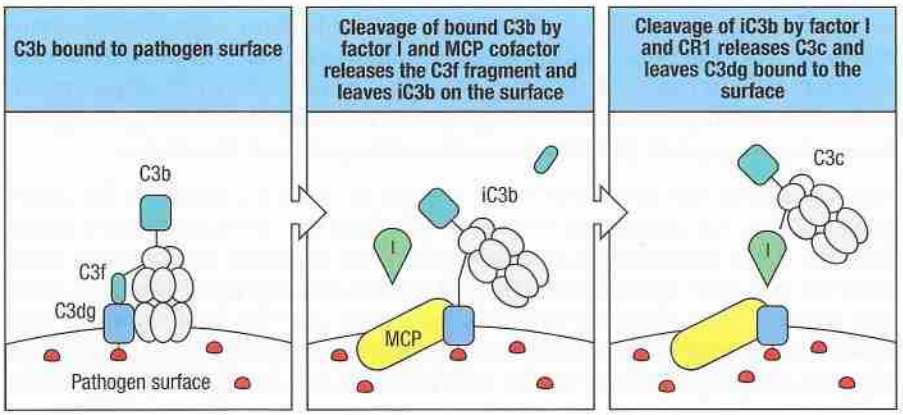
called G proteins and are known generally as **G protein–coupled receptors (GPCRs)**; they are discussed in Section 3-2. **C5a receptor 2** (C5L2, GPR77) is expressed by neutrophils and macrophages, but its function is not firmly established. It is a nonsignaling receptor that may act as a decoy receptor for C5a and regulate activity of the C5a receptor. Proteins associated with the extracellular matrix, such as fibronectin, can also contribute to phagocyte activation; these are encountered when phagocytes are recruited to connective tissue and activated there.

Four other complement receptors—**CR2** (also known as **CD21**), **CR3 (CD11b:CD18)**, **CR4 (CD11c:CD18)**, and **CRIg** (complement receptor of the immunoglobulin superfamily)—bind to forms of C3b that have been cleaved by factor I but that remain attached to the pathogen surface. Like several other key components of complement, C3b is subject to regulatory mechanisms that cleave it into derivatives, such as iC3b, that cannot form an active convertase. C3b bound to the microbial surface can be cleaved by factor I and MCP to remove the small fragment C3f, leaving the inactive iC3b form bound to the surface (Fig. 2.32). iC3b is recognized by several complement receptors—CR2, CR3, CR4, and CRIg. Unlike the binding of C3b to CR1, the binding of iC3b to the receptor CR3 is sufficient on its own to stimulate phagocytosis. Factor I and CR1 cleave iC3b to release C3c, leaving C3dg bound to the pathogen. C3dg is recognized only by CR2. CR2 is found on B cells as part of a co-receptor complex that can augment the signal received through the antigen-specific immunoglobulin receptor. Thus, a B cell whose antigen receptor is specific for an antigen of a pathogen will receive a strong signal on binding this antigen if it or the pathogen is also coated with C3dg. The activation of complement can therefore contribute to producing a strong antibody response.

The importance of opsonization by C3b and its inactive fragments in destroying extracellular pathogens can be seen in the effects of various complement deficiencies. For example, individuals deficient in C3 or in molecules that



C3b bound to pathogen surface

Fig. 2.32 The cleavage products of C3b are recognized by different complement receptors. After C3b is deposited on the surface of pathogens, it can undergo several conformational changes that alter its interaction with complement receptors. Factor I and MCP can cleave the C3f fragment from C3b, producing iC3b, which is a ligand for the complement receptors CR3, CR4, CRIg, and weakly for CR2, but not CR1. Factor I and CR1 cleave iC3b to release C3c, leaving C3dg bound. C3dg is then recognized by CR2.

catalyze C3b deposition show an increased susceptibility to infection by a wide range of extracellular bacteria, including *Streptococcus pneumoniae*. We describe the effects of various defects in complement and the diseases they cause in Chapter 13.

2-14 The small fragments of some complement proteins initiate a local inflammatory response.

The small complement fragments C3a and C5a act on specific receptors on endothelial cells and mast cells (see Fig. 2.30) to produce local inflammatory responses. Like C5a, C3a also signals through a GPCR family member. When produced in large amounts or injected systemically, C3a and C5a induce a generalized circulatory collapse, producing a shocklike syndrome similar to that seen in a systemic allergic reaction involving antibodies of the IgE class, discussed in Chapter 14. Such a reaction is termed **anaphylactic shock**, and these small fragments of complement are therefore often referred to as **anaphylatoxins**. C5a has the highest specific biological activity, but both C3a and C5a induce the contraction of smooth muscle, increase vascular permeability, and act on the endothelial cells lining blood vessels to induce the synthesis of adhesion molecules. In addition, C3a and C5a can activate the mast cells that populate submucosal tissues to release inflammatory molecules such as histamine and the cytokine tumor necrosis factor-α (TNF-α), which cause similar effects. C4a is also generated during C4 cleavage and is inactive at C3a and C5a receptors. Instead, C4a acts at two other GPCRs, protease-activated receptor 1 (PAR1) and protease-activated receptor 4 (PAR4), which are expressed on endothelial cells and platelets and are also activated by thrombin, a protease activated in the clotting cascade. C4a activates signaling in these cells to increase endothelial-cell permeability and by actions on platelets may link complement activation with the clotting cascade.

The changes induced by C5a, C3a, and C4a combine to recruit antibody, complement, and phagocytic cells to the site of an infection (Fig. 2.33). The increased fluid in the tissues hastens the movement of pathogen-bearing antigen-presenting cells to the local lymph nodes, contributing to the prompt initiation of the adaptive immune response. C5a also acts directly on neutrophils and monocytes to increase their adherence to vessel walls, their migration toward sites of antigen deposition, and their ability to ingest particles; it also increases the expression of CR1 and CR3 on the surfaces of these cells. In this way, C5a, and to a lesser extent C3a and C4a, act in concert with other complement components to hasten the destruction of pathogens by phagocytes.

2-15 The terminal complement proteins polymerize to form pores in membranes that can kill certain pathogens.

Deficiency of the C8 Complement Component

One of the important effects of complement activation is the assembly of the terminal components of complement (Fig. 2.34) to form a membrane-attack complex. The reactions leading to the formation of this complex are shown schematically in Fig. 2.35. The end result is a pore in the lipid bilayer membrane that destroys membrane integrity. This is thought to kill the pathogen by destroying the proton gradient across the pathogen's cell membrane.

The first step in the formation of the membrane-attack complex is the cleavage of C5 by a C5 convertase to release C5b (see Fig. 2.29). In the next stages (see Fig. 2.35), C5b initiates the assembly of the terminal complement components and their insertion into the cell membrane. The process begins when one molecule of C5b binds one molecule of **C6**, and the C5b6 complex then binds one molecule of **C7**. This reaction leads to a conformational change that exposes a hydrophobic site on C7, which inserts into the lipid bilayer. Similar

Fig. 2.33 Local inflammatory responses can be induced by small complement fragments, especially C5a. The small complement fragments are differentially active: C5a is more active than C3a. C5a and C3a cause local inflammatory responses by acting directly on local blood vessels, stimulating an increase in blood flow, increased vascular permeability, and increased binding of phagocytes to endothelial cells. C3a and C5a also activate mast cells (not shown) to release mediators, such as histamine and TNF-α, which contribute to the inflammatory response. C4a binds to receptors expressed on endothelium and platelets that are normally activated by thrombin, PAR1, and PAR4, and so also promotes vascular permeability and local coagulation. In response to all these signals, an increase in vessel diameter and permeability leads to the accumulation of fluid and protein in the surrounding tissue. Fluid accumulation increases lymphatic drainage, bringing pathogens and their antigenic components to nearby lymph nodes. The antibodies, complement, and cells thus recruited participate in pathogen clearance by enhancing phagocytosis. The small complement fragments can also directly increase the activity of the phagocytes.

hydrophobic sites are exposed on the later components **C8** and **C9** when they are bound to the complex, allowing these proteins also to insert into the lipid bilayer. C8 is a complex of two proteins, C8β and C8α-γ. The C8β protein binds to C5b, and this binding of C8β to the membrane-associated C5b67 complex allows the hydrophobic domain of C8α-γ to insert into the lipid bilayer. Finally, C8α-γ induces the polymerization of 10–16 molecules of C9 into a pore-forming structure called the membrane-attack complex. The membrane-attack complex has a hydrophobic external face, allowing it to associate with the lipid bilayer, but a hydrophilic internal channel. The diameter of this channel

The terminal complement components that form the membrane-attack complex

Native protein	Active component	Function
C5	C5a	Small peptide mediator of inflammation (high activity)
	C5b	Initiates assembly of the membrane-attack system
C6	C6	Binds C5b; forms acceptor for C7
C7	C7	Binds C5b6; amphiphilic complex inserts into lipid bilayer
C8	C8	Binds C5b67; initiates C9 polymerization
C9	$C9_n$	Polymerizes to C5b678 to form a membrane-spanning channel, lysing the cell

Fig. 2.34 The terminal complement components.

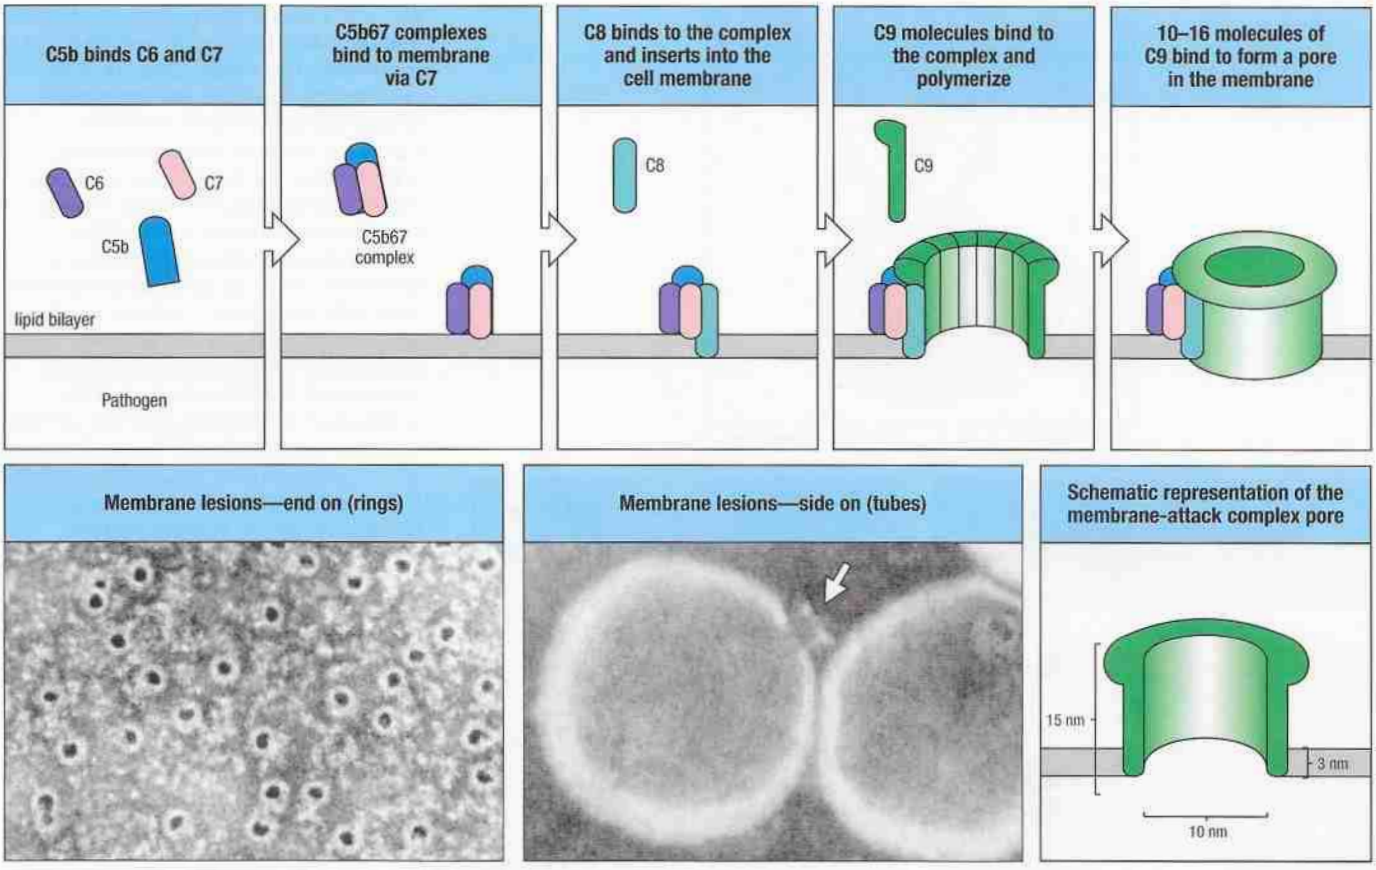

Fig. 2.35 Assembly of the membrane-attack complex generates a pore in the lipid bilayer membrane. The sequence of steps and their approximate appearance are shown here in schematic form. C5b triggers the assembly of a complex of one molecule each of C6, C7, and C8, in that order. C7 and C8 undergo conformational changes, exposing hydrophobic domains that insert into the membrane. This complex causes moderate membrane damage in its own right, and also serves to induce the polymerization of C9, again with the exposure of a hydrophobic site. Up to 16 molecules of C9 are then added to the assembly to generate a channel 10 nm in diameter in the membrane. This channel disrupts the bacterial cell membrane, killing the bacterium. The electron micrographs show erythrocyte membranes with membrane-attack complexes in two orientations, end on and side on.

is about 10 nm, allowing the free passage of solutes and water across the lipid bilayer. The pore damage to the lipid bilayer leads to the loss of cellular homeostasis, the disruption of the proton gradient across the membrane, the penetration of enzymes such as lysozyme into the cell, and the eventual destruction of the pathogen.

Although the effect of the membrane-attack complex is very dramatic, particularly in experimental demonstrations in which antibodies against red blood cell membranes are used to trigger the complement cascade, the significance of these components in host defense seems to be quite limited. So far, deficiencies in C5–C9 have been associated with susceptibility only to *Neisseria* species, the bacteria that cause the sexually transmitted disease gonorrhea and a common form of bacterial meningitis. Thus, the opsonizing and inflammatory actions of the earlier components of the complement cascade are clearly more important for host defense against infection. Formation of the membrane-attack complex seems to be important only for the killing of a few pathogens, although, as we will see in Chapter 15, this complex might well have a major role in immunopathology.

2-16 Complement-control proteins regulate all three pathways of complement activation and protect the host from their destructive effects.

Complement activation usually is initiated on a pathogen surface, and the activated complement fragments that are produced usually bind nearby on the pathogen surface or are rapidly inactivated by hydrolysis. Even so, all complement components are activated spontaneously at a low rate in plasma, and these activated complement components will sometimes bind proteins on host cells. Section 2-10 introduced the soluble host proteins factor I and factor H

Regulatory proteins of the classical and alternative pathways			
Soluble factors regulating complement			
Name	**Ligand/ Binding factor**	**Action**	**Pathology if defective**
C1 inhibitor (C1INH)	C1r, C1s (C1); MASP-2 (MBL)	Binds and deactivates C1r, C1s, and MASP-2	Hereditary angiodema
C4-binding protein (C4BP)	C4b	Displaces C2a from C4b cofactor for C4b cleavage by factor I	
CPN1 (Carboxypeptidase N)	C3a, C5a	Inactivates C3a and C5a	Recurrent angioedema
Factor H	C3b	Displaces Bb from C3b, cofactor for C3b cleavage by factor I	Age-related macular degeneration, atypical hemolytic uremic syndrome
Factor I	C3b, C4b	Serine protease, cleaves C3b and C4b	Low C3 levels, atypical hemolytic uremic syndrome
Membrane-bound factors regulating complement			
Name	**Ligand/ Binding factor**	**Action**	**Pathology if defective**
CRIg	C3b, iC3b	Inhibits activation of alternative pathway	Increased susceptibility to blood-borne infections
Complement receptor 1 (CR1, CD35)	C3b, C4b	Cofactor for factor I; displaces Bb from C3b, and C2a from C4b	
Decay-accelerating factor (DAF, CD55)	C3 convertase	Displaces Bb and C2a from C3b and C4b respectively	Paroxysmal nocturnal hemoglobinuria
Membrane cofactor of proteolysis (MCP, CD46)	C3b, C4b	Cofactor for factor I	Atypical hemolytic uremic syndrome
Protectin (CD59)	C8	Inhibits MAC formation	Paroxysmal nocturnal hemoglobinuria

Fig. 2.36 The soluble and membrane-bound proteins that regulate the activity of complement.

and the membrane-bound proteins MCP and DAF that regulate the alternative pathway of complement activation. In addition, several other soluble and membrane-bound complement-control proteins can regulate the complement cascade at various steps to protect normal host cells while allowing complement activation to proceed on pathogen surfaces (Fig. 2.36).

The activation of C1 is controlled by the **C1 inhibitor (C1INH)**, which is a plasma **serine protease inhibitor**, or **serpin**. C1INH binds to the catalytic sites of C1r and C1s and irreversibly inactivates them (Fig. 2.37). In this way, C1INH limits cleavage and activation of C4 and C2 by C1. By the same means, C1INH limits the spontaneous activation of C1 in plasma. Its importance can be seen in the C1INH deficiency disease **hereditary angioedema (HAE)**, in which chronic spontaneous complement activation leads to the production of excess cleaved fragments of C4 and C2. The large activated fragments from this cleavage (C2a and C4b), which normally combine to form the C3 convertase, do not damage host cells in such individuals because C4b is rapidly inactivated by hydrolysis in plasma, and the convertase does not form. C1INH also regulates the plasma protease kallikrein, a component of the kinin system (discussed in Section 3-3). Kallikrein is normally activated by tissue damage,

Hereditary Angioedema

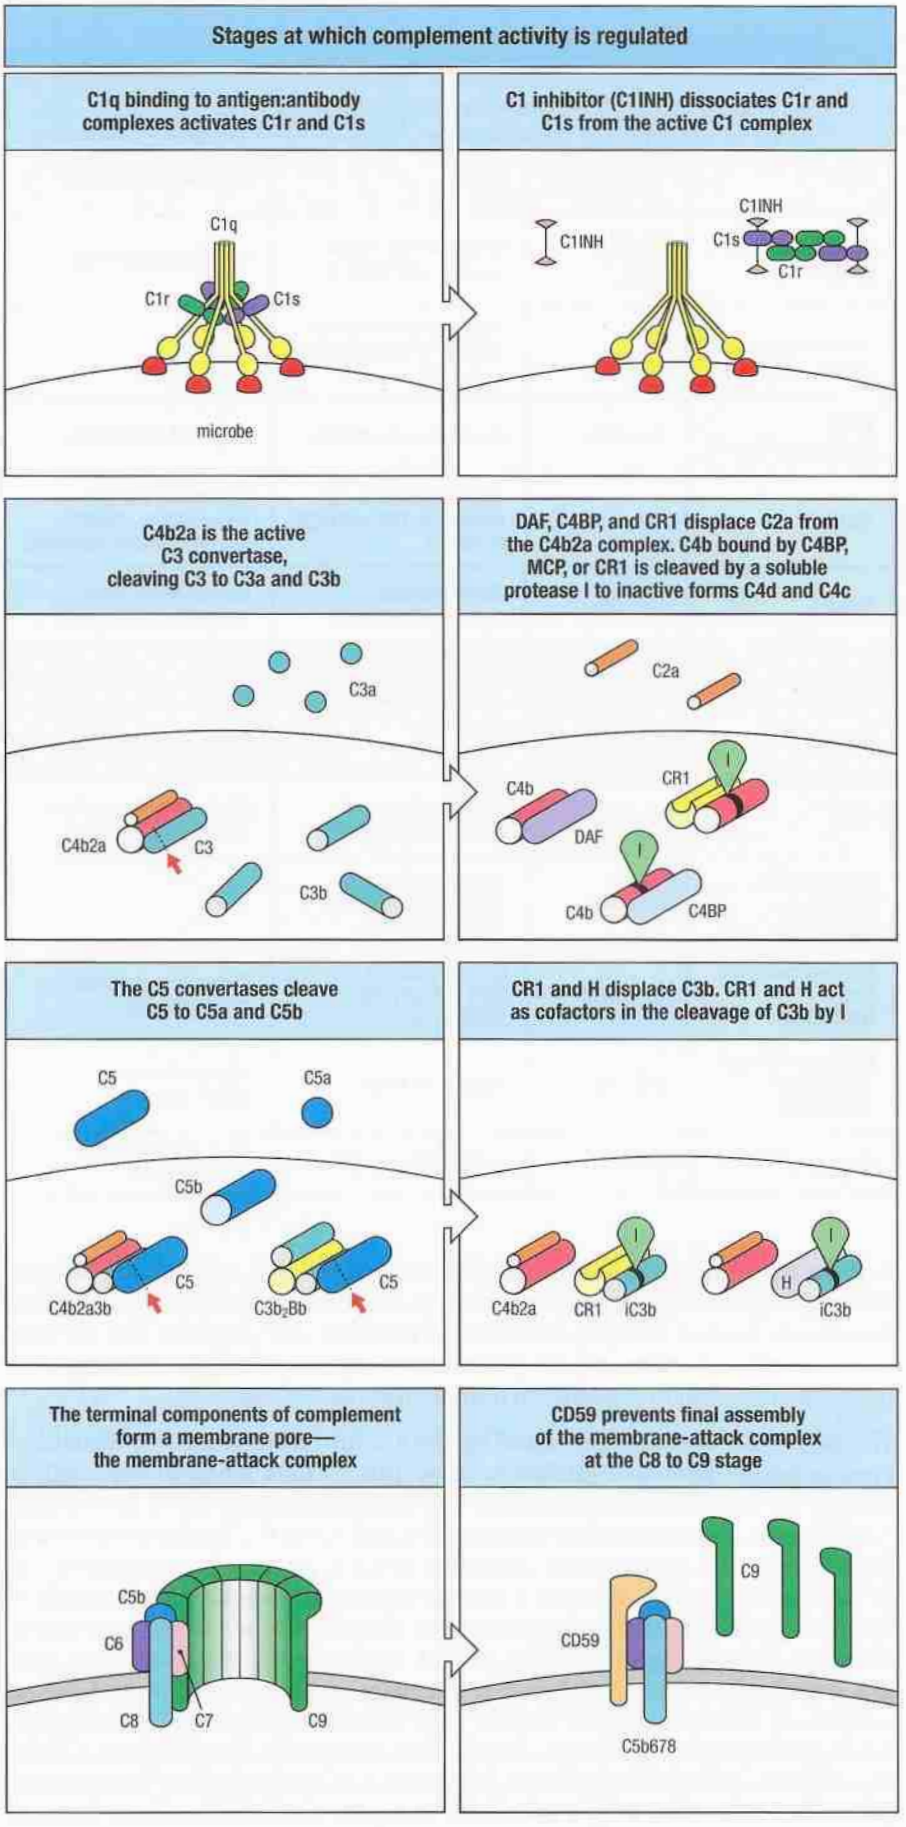

Fig. 2.37 Complement activation is regulated by a series of proteins that serve to protect host cells from accidental damage. These act on different stages of the complement cascade, dissociating complexes or catalyzing the enzymatic degradation of covalently bound complement proteins. Stages in the complement cascade are shown schematically down the left side of the figure, with the regulatory reactions on the right. The alternative pathway C3 convertase is similarly regulated by DAF, CR1, MCP, and factor H.

but in HAE the lack of C1INH leads to increased kallikrein activity and thus to the uncontrolled production of bradykinin. Hereditary angioedema is fully corrected by replacing C1INH. A similar, extremely rare human disease stems from a partial deficiency of **carboxypeptidase N (CPN)**, a metalloproteinase that inactivates the anaphylatoxins C3a and C5a as well as bradykinin and kallikrein. Humans with partial CPN deficiency exhibit recurrent angioedema due to delayed inactivation of serum C3a and bradykinin.

Because the highly reactive thioester bond of activated C3 and C4 cannot distinguish acceptor groups on a host cell from those on the surface of a pathogen, mechanisms have evolved to prevent the small amounts of C3 or C4 molecules deposited on host cells from fully triggering complement activation. We introduced these mechanisms in the context of control of the alternative pathway (see Fig. 2.27), but they are also important regulators of the classical pathway convertase (see Fig. 2.37, second and third rows). Section 2-10 described the proteins that inactivate any C3b or C4b that has bound to host cells. These are the plasma factor I and its cofactors MCP and CR1, which are membrane proteins. Circulating factor I is an active serine protease, but it can cleave C3b and C4b only when they are bound to MCP, factor H, or CR1 (see Fig. 2.27). In these circumstances, factor I cleaves C3b, first into iC3b and then further to C3dg, thus permanently inactivating it. C4b is similarly inactivated by cleavage into C4c and C4d. Microbial cell walls lack MCP and CR1 and thus cannot promote the breakdown of C3b and C4b, which instead act as binding sites for factor B and C2, promoting complement activation. The importance of factor I can be seen in people with genetically determined **factor I deficiency**. Because of uncontrolled complement activation, complement proteins rapidly become depleted, and such people suffer repeated bacterial infections, especially with ubiquitous pyogenic bacteria.

There are also plasma proteins with cofactor activity for factor I, most notably **C4b-binding protein (C4BP)** (see Fig. 2.36). It binds C4b and acts mainly as a regulator of the classical pathway in the fluid phase. Factor H binds C3b in the fluid phase, as well as at cell membranes, and helps to distinguish the C3b that is bound to host cells from that bound to microbial surfaces. The higher affinity of factor H for sialic acid residues on host-membrane glycoproteins allows it to displace factor B in binding to C3b on host cells. Also, C3b at host-cell membranes is bound by cofactor protein MCP. Factor H competes with factor B for binding to C3b bound to host cells, so that the bound C3b is catabolized by factor I into iC3b and C3dg, and complement activation is inhibited. In contrast, microbial membranes do not express MCP and lack the sialic acid modifications that attract factor H, and so factor B is favored for binding C3b on these surfaces. The greater amount of factor B on a microbial surface stimulates formation of more C3bBb, the alternative pathway C3 convertase, and thus amplifies complement activation.

2-17 Genetic and acquired disorders in complement regulation can produce various inflammatory conditions.

The critical balance between the inhibition and the activation of complement on cell surfaces is illustrated in individuals heterozygous for mutations in various complement-regulatory proteins. Several renal diseases are caused by complement dysregulation. A condition known as **atypical hemolytic uremic syndrome (aHUS)** can be caused by relatively rare mutations in factor H, factor I, and MCP. The reduced action of these regulatory factors can increase the alternative pathway activation on the surface of platelets and red blood cells. The damage that this produces can lead to low levels of platelets (thrombocytopenia) and red blood cells (anemia) and can damage the kidneys. aHUS can also be caused by an acquired autoantibody that binds to factor H and reduces its activity, again leading to increased alternative pathway activity. A

related condition, called **C3 glomerulopathy**, can be caused by similar mutations in these factors. It is characterized by deposition of C3b in the renal glomerulus but is not associated with thrombocytopenia or anemia. Like aHUS, C3 glomerulopathy is more commonly caused by autoantibodies that inhibit factor H. Such autoantibodies are called **nephritic factors**, as they lead to inflammation in the kidney, and they can be directed at other components of complement. One type of nephritic factor is targeted to C3, and stabilizes the alternative pathway C3 convertase C3bBb, rather than inhibiting a complement regulatory protein.

Another serious health problem related to complement malfunction is a significantly increased risk of **age-related macular degeneration (AMD)**. AMD is the leading cause of blindness in the elderly in developed countries. It has been linked to single-nucleotide polymorphisms in the factor H gene, where tyrosine 402 is changed to histidine (Y402H). This polymorphism in factor H is not the primary cause of AMD, but it influences the response to retinal injury. Cellular debris produced during injury or renewal of photoreceptors, such as oxidized lipids, can activate complement and induce local inflammation. Normal factor H can bind these oxidized lipids and inactivate C3b that would otherwise trigger further complement activation. The Y402H variant of factor H interacts more weakly with oxidized lipids than does normal factor H, and consequently allows a chronic background of complement activation and inflammation to take place, which damages retinal epithelial cells and activates macrophages. Polymorphisms in other complement genes have also been found to be either detrimental or protective for this disease. Thus, even small alterations in the efficiency of either the activation or the regulation of this powerful effector system can contribute to the progression of degenerative or inflammatory disorders.

DAF and MCP also mediate protection against complement through a third mechanism, which augments the dissociation of C4b2a and C3bBb convertases that have already formed. CR1 is among the host-cell membrane molecules that regulate complement through both these mechanisms; that is, by promoting the dissociation of convertase and exhibiting cofactor activity. All the proteins that bind the homologous C4b and C3b molecules contain three or more tandem copies of a structural element called the short consensus repeat (SCR), the complement-control protein (CCP) repeat, or (especially in Japan) the sushi domain.

In addition to the mechanisms for preventing C3 convertase formation and C4 and C3 deposition on cell membranes, there are also inhibitory mechanisms that prevent the inappropriate insertion of the membrane-attack complex (MAC) into membranes. We saw in Section 2-15 that the membrane-attack complex polymerizes onto C5b molecules created by the action of C5 convertase. The membrane-attack complex mainly inserts into cell membranes adjacent to the site of the C5 convertase; that is, close to the site of complement activation on a pathogen. However, some newly formed membrane-attack complexes may diffuse from the site of complement activation and insert into adjacent host-cell membranes. Several plasma proteins, including, notably, **vitronectin** (also known as **S-protein**), bind to the C5b67, C5b678, and C5b6789 complexes and thereby inhibit their random insertion into cell membranes. Host-cell membranes also contain the intrinsic protein **CD59**, or **protectin**, which inhibits the binding of C9 to the C5b678 complex (see Fig. 2.37, bottom row). CD59 and DAF are both linked to the cell surface by a **glycosylphosphatidylinositol (GPI) tail**, like many other peripheral membrane proteins. One of the enzymes involved in the synthesis of GPI tails is encoded by a gene, *PIGA*, on the X chromosome. In people with a somatic mutation in this gene in a clone of hematopoietic cells, both CD59 and DAF fail to function. This causes the disease **paroxysmal nocturnal hemoglobinuria**, which is characterized by episodes of intravascular red blood cell lysis by complement. Red blood cells that lack only CD59 are also susceptible to destruction as a result of spontaneous activation of the complement cascade.

2-18 Pathogens produce several types of proteins that can inhibit complement activation.

Bacterial pathogens have evolved various strategies to avoid activation of complement, and thereby to avoid elimination by this first line of innate defense (Fig. 2.38). One strategy that many pathogens employ is to mimic host surfaces by attracting host complement regulators to their own surfaces. A mechanism to achieve this is for the pathogen to express surface proteins that bind to soluble complement-regulatory proteins such as C4BP and factor H; for example, the Gram-negative pathogen *Neisseria meningitidis* produces **factor H binding protein (fHbp)**, which recruits factor H (see Section 2-10), and the outer membrane protein **PorA**, which binds to C4BP. By recruiting factor H and C4BP to the pathogen membrane, the pathogen is able to inactivate C3b that is deposited on its surface and thereby avoid the consequences of complement activation. Complement is important in defense against *Neisseria* species, and several complement deficiencies are associated with increased susceptibility to this pathogen.

Another strategy employed by pathogens is to secrete proteins that directly inhibit components of complement. The Gram-positive pathogen *Staphylococcus aureus* provides several examples of this type of strategy. **Staphylococcal protein A (Spa)** binds to the Fc regions of immunoglobulins and interferes with the recruitment and activation of C1. This binding specificity was used as an early biochemical technique in the purification of antibodies. The staphylococcal protein **staphylokinase (SAK)** acts by cleaving immunoglobulins bound to the pathogen membrane, preventing complement activation and avoiding phagocytosis. The **staphylococcal complement inhibitor (SCIN)** protein binds to the classical C3 convertase, C4b2a, and the alternative pathway C3 convertase, C3bBb, and inhibits their activity. Other stages of complement activation, including formation of the C5 convertase, are targets of inhibition by proteins produced by these and other pathogens.

Pathogen	Evasion molecule	Host target	Mechanism of action
Membrane proteins			
Neisseria meningitidis	Factor H binding protein (fHbp)	Factor H	Inactivates bound C3b
Borrelia burgdorferi	Outer surface protein E (OspE)	Factor H	Inactivates bound C3b
Streptococcus pneumoniae	Pneumococcal surface protein C (PspC)	Factor H	Inactivates bound C3b
Secreted proteins			
Neisseria meningitidis	PorA	C4BP	Inactivates bound C3b
Staphylococcus aureus	Clumping factor A (ClfA)	Factor I	Inactivates bound C3b
Staphylococcus aureus	Staphylococcal protein A (Spa)	Immunoglobulin	Binds to Fc regions and interferes with C1 activation
Staphylococcus aureus	Staphylokinase (SAK)	Immunoglobulin	Cleaves immunoglobulins
Staphylococcus aureus	Complement inhibitor (SCIN, CINB, SCINC)	C3 convertase (C4b2a, C3bBb)	Inhibition of convertase activity

Fig. 2.38 Complement evasion proteins produced by various pathogens.

We will return to this topic of complement regulation in Chapter 13 when we discuss how the immune system sometimes fails or is evaded by pathogens.

Summary.

The complement system is one of the major mechanisms by which pathogen recognition is converted into an effective host defense against initial infection. Complement is a system of plasma proteins that can be activated directly by pathogens or indirectly by pathogen-bound antibody, leading to a cascade of reactions that occurs on the surface of pathogens and generates active components with various effector functions. There are three pathways of complement activation: the lectin pathway, triggered by the pattern-recognition receptors MBL and the ficolins; the classical pathway, triggered directly by antibody binding to the pathogen surface; and the alternative pathway, which utilizes spontaneous C3 deposition onto microbial surfaces, is augmented by properdin, and provides an amplification loop for the other two pathways. The early events in all pathways consist of a sequence of cleavage reactions in which the larger cleavage product binds covalently to the pathogen surface and contributes to the activation of the next component. The pathways converge with the formation of a C3 convertase enzyme, which cleaves C3 to produce the active cleavage product C3b. The binding of large numbers of C3b molecules to the pathogen is the central event in complement activation. Bound complement components, especially bound C3b and its inactive fragments, are recognized by specific complement receptors on phagocytic cells, which engulf pathogens opsonized by C3b and its inactive fragments. The small cleavage fragments of C3, C4, and C5 act on specific trimeric G protein–coupled receptors to recruit phagocytes, such as neutrophils, to sites of infection or to alter local vascular permeability and coagulation. Together, these activities promote the uptake and destruction of pathogens by phagocytes. The molecules of C3b that bind the C3 convertase itself initiate the late events of complement, binding C5 to make it susceptible to cleavage by C2a or Bb. The larger C5b fragment triggers the assembly of a membrane-attack complex, which can result in the lysis of certain pathogens. A system of soluble and membrane-bound complement-regulatory proteins acts to limit complement activation on host tissues, in order to prevent tissue damage from the inadvertent binding of activated complement components to host cells or from the spontaneous activation of complement components in plasma. Many pathogens produce a variety of soluble and membrane-associated proteins that can counteract complement activation and contribute to infection of the host by the microbe.

Summary to Chapter 2.

This chapter has described the preexisting, constitutive components of innate immunity. The body's epithelial surfaces are a constant but imperfect barrier to pathogen entry. In addition to their other specialized functions, epithelia have specialized adaptations, such as cilia, various antimicrobial molecules, and mucus that provide the simplest form of innate immunity. The complement system is a more specialized system that combines direct recognition of microbes with a complex effector system. The lectin pathway relies on pattern-recognition receptors that detect microbial membranes, while the alternative pathway relies on spontaneous complement activation that is down-regulated by host molecules expressed on self membranes. The main event in complement activation is accumulation of C3b on microbial membranes, which is recognized by complement receptors on phagocytic cells to promote microbial clearance by cells recruited to sites of infection by C3a and C5a. In addition, C5b initiates the membrane-attack complex that is able to lyse some microbes directly. The complement cascade is under regulation to prevent attack on host tissues, and genetic variation in regulatory pathways can result in autoimmune syndromes and age-related tissue damage.

Discussion Questions

2.1 What activities and structural features of the skin, lungs, and intestine are used to keep microbes from penetrating beyond the epithelial boundary?

2.2 Most antimicrobial peptides do not exert their actions within the host cells that produce them. What structural features of such peptides prevent their activation within neutrophils and Paneth cells?

2.3 The proteins of the complement cascade all circulate freely within the blood plasma. How is it that complement is normally activated only during an infection?

2.4 Recognition of bacteria by mannose-binding lectin and ficolins leads to their destruction by the same mechanisms as those of recognition of bacteria by antibodies. Explain how this is so. What evolutionary adaptation was necessary to allow for this?

2.5 Spontaneous hydrolysis of the thioester bond in C3 occurs continually at a low rate even in the absence of infection. Contrast the reactions that occur as a consequence of this C3 'tickover' in a healthy person with those that occur in a person infected with bacteria.

2.6 What is the central feature of the amplification loop in the alternative pathway? As this pathway is initiated spontaneously, how are host tissues protected from nonspecific damage by this pathway?

2.7 How do acquired antibodies directed against factor H lead to atypical hemolytic uremic syndrome? What are such antibodies called?

2.8 Age-related macular degeneration is associated with inherited variants of factor H. If this disease is not caused by these polymorphisms, how does this variant contribute to this disease?

Cellular Mechanisms of Innate Immunity

3

IN THIS CHAPTER

Pathogen recognition by cells of the innate immune system.

Consequences of innate immune activation.

In Chapter 2 we introduced the innate defenses—such as epithelial barriers, secreted antimicrobial proteins, and the complement system—that act immediately upon encounter with microbes to protect the body from infection. We also introduced the phagocytic cells that lie beneath the epithelial barriers and stand ready to engulf and digest invading microorganisms that have been flagged for destruction by complement. These phagocytes also initiate the next phase, the induced innate immune response, leading to an inflammatory reaction that recruits new phagocytic cells and circulating effector molecules to the site of infection.

In this chapter we describe how phagocytic cells of the innate immune system detect microbes or the cellular damage they cause, how they destroy these pathogens, and how they orchestrate downstream inflammatory responses through production of cytokines and chemokines (chemoattractant cytokines). We also introduce other cells of the innate immune system—a diverse array of specialized innate lymphoid cells (ILCs) including the natural killer cells (NK cells)—that contribute to innate host defenses against viruses and other intracellular pathogens. Also in this stage of infection, dendritic cells initiate adaptive immune responses.

Pathogen recognition by cells of the innate immune system.

The basis of the adaptive immune system's enormous capacity for antigen recognition has long been appreciated. In contrast, the basis of recognition of microorganisms by innate immune receptors was discovered only in the late 1990s. Overall, the diversity of features recognized by innate immune receptors is quite limited compared with the diversity of features recognized by antigen receptors of the adaptive immune system. Nevertheless, the innate immune system has the capacity to recognize essentially any microorganism because innate immune receptors recognize conserved molecular features shared by related groups of microbes. These features are often referred to as **pathogen-associated molecular patterns (PAMPs)**, and the receptors that recognize them are called **pattern-recognition receptors (PRRs)**.

We will discuss specific examples of PAMPs and PRRs later in this chapter, but before doing so it is useful to establish some key principles that shape our understanding of innate immunity and distinguish it from adaptive immunity. The general characteristics of PRRs are contrasted with those of the antigen-specific receptors of adaptive immunity in Fig. 3.1. One key feature of PRRs is that their specificities are genetically encoded and inherited through the germline, in contrast to the random generation of antigen receptors of the adaptive immune system. Therefore, the specificities of PRRs have been shaped through evolution to recognize PAMPs, which are typically molecules that cannot be mutated without a significant fitness cost to the microbe. This selection of receptors that recognize conserved, largely invariant microbial features is how the innate immune system can recognize the broad diversity of potential pathogens with a limited number of receptors. In general, ligands for PRRs do not occur in healthy host cells, which ensures that immune responses

and are considered to be part of innate immunity; they are discussed in detail later in the chapter.

Because most microorganisms enter the body through the mucosa of the gut and respiratory system, the skin, or the urogenital tract, macrophages in the submucosal tissues are the first cells to encounter most pathogens, but they are soon reinforced by the recruitment of large numbers of neutrophils to sites of infection. Macrophages and neutrophils recognize pathogens by means of cell-surface PRRs that bind PAMPs on the surface of pathogens, as discussed at the beginning of this chapter. Although they are both phagocytic, macrophages and neutrophils have distinct properties and functions in innate immunity.

The process of **phagocytosis** is initiated when certain receptors on the surface of the cell—typically a macrophage, neutrophil, or dendritic cell—interact with the microbial surface. The bound pathogen is first surrounded by the phagocyte plasma membrane and then internalized in a large membrane-enclosed endocytic vesicle known as a **phagosome**. The phagosome fuses with one or more lysosomes to generate a **phagolysosome**, in which the lysosomal contents are released. The phagolysosome also becomes acidified, acquires antimicrobial peptides and enzymes, and undergoes enzymatic processes that produce highly reactive **superoxide radicals** and **nitric oxide radicals**, which together kill the microbe (Fig. 3.2). Neutrophils are highly specialized for the intracellular killing of microbes and contain different types of cytoplasmic granules—the **primary granules** and **secondary granules** described in Section 2-4. These granules fuse with phagosomes, releasing additional enzymes and antimicrobial peptides that attack the microbe. Another pathway by which extracellular material, including microbial material, can be taken up into the endosomal compartment of cells and degraded is **receptor-mediated endocytosis**, which is not restricted to phagocytes. Dendritic cells and other phagocytes can also take up pathogens by a nonspecific process called **macropinocytosis**, in which large amounts of extracellular fluid and its contents are ingested.

Macrophages and neutrophils constitutively express a number of cell-surface PRRs that stimulate the phagocytosis and intracellular killing of microbes bound to them, although some also signal through other pathways to trigger responses such as cytokine production. This set of phagocytic PRRs includes several members of the C-type lectin–like family (see Fig. 3.2). For example, **Dectin-1** is strongly expressed by macrophages and neutrophils and recognizes β-(1,3)–linked glucans (polymers of glucose), which are common components of fungal cell walls in particular. Dendritic cells also express Dectin-1, as well as several other C-type lectin–like phagocytic receptors. Another C-type lectin, the **mannose receptor** expressed by macrophages and dendritic cells, recognizes various mannosylated ligands, including some present on fungi, bacteria, and viruses; it was once suspected of having an important role in resistance to microbes. However, experiments with mice that lack this

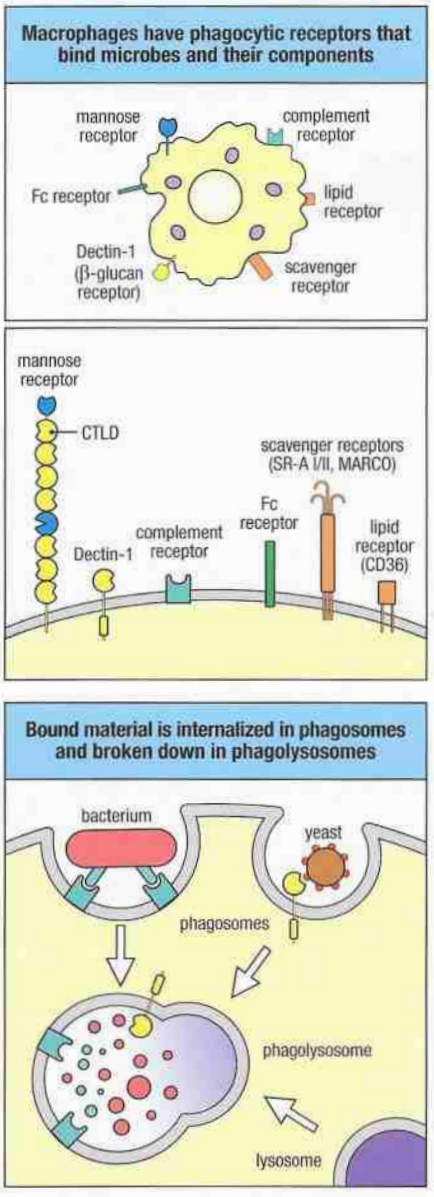

Fig. 3.2 Macrophages express receptors that enable them to take up microbes by phagocytosis. First panel: Macrophages residing in tissues throughout the body are among the first cells to encounter and respond to pathogens. They carry cell-surface receptors that bind to various molecules on microbes, in particular carbohydrates and lipids, and induce phagocytosis of the bound material. Second panel: Dectin-1 is a member of the C-type lectin–like family built around a single C-type lectin–like domain (CTLD). Lectins in general are based on a carbohydrate-recognition domain (CRD). The macrophage mannose receptor contains many CTLDs and has a fibronectin-like domain and a cysteine-rich region at its amino terminus. Class A scavenger receptors, such as MARCO, are built from collagen-like domains and form trimers. The receptor protein CD36 is a class B scavenger receptor that recognizes and internalizes lipids. Various complement receptors bind and internalize complement-coated bacteria. Third panel: In phagocytosis, receptor-bound material is taken into intracellular phagosomes, which fuse with lysosomes to form an acidified phagolysosome in which the ingested material is broken down by lysosomal hydrolases.

receptor do not support this idea. The macrophage mannose receptor is now thought to function mainly as a clearance receptor for host glycoproteins such as β-glucuronidase and lysosomal hydrolases, which have mannose-containing carbohydrate side chains and whose extracellular concentrations are raised during inflammation.

Another set of phagocytic PRRs on macrophages, called **scavenger receptors**, recognize various anionic polymers and acetylated low-density lipoproteins. These receptors are structurally heterogeneous, consisting of at least six different molecular families. Class A scavenger receptors are membrane proteins composed of trimers of collagen domains (see Fig. 3.2). They include **SR-A I**, **SR-A II**, and **MARCO** (macrophage receptor with a collagenous structure), all of which bind various bacterial cell-wall components and help to internalize bacteria, although the basis of their specificity is poorly understood. Class B scavenger receptors bind high-density lipoproteins, and they internalize lipids. One of these receptors is CD36, which binds many ligands, including long-chain fatty acids.

A third set of receptors of crucial importance in macrophage and neutrophil phagocytosis is the complement receptors and Fc receptors introduced in Chapters 1 and 2. These receptors bind to complement-coated microbes or to antibodies that have bound to the surface of microbes and facilitate the phagocytosis of a wide range of microorganisms.

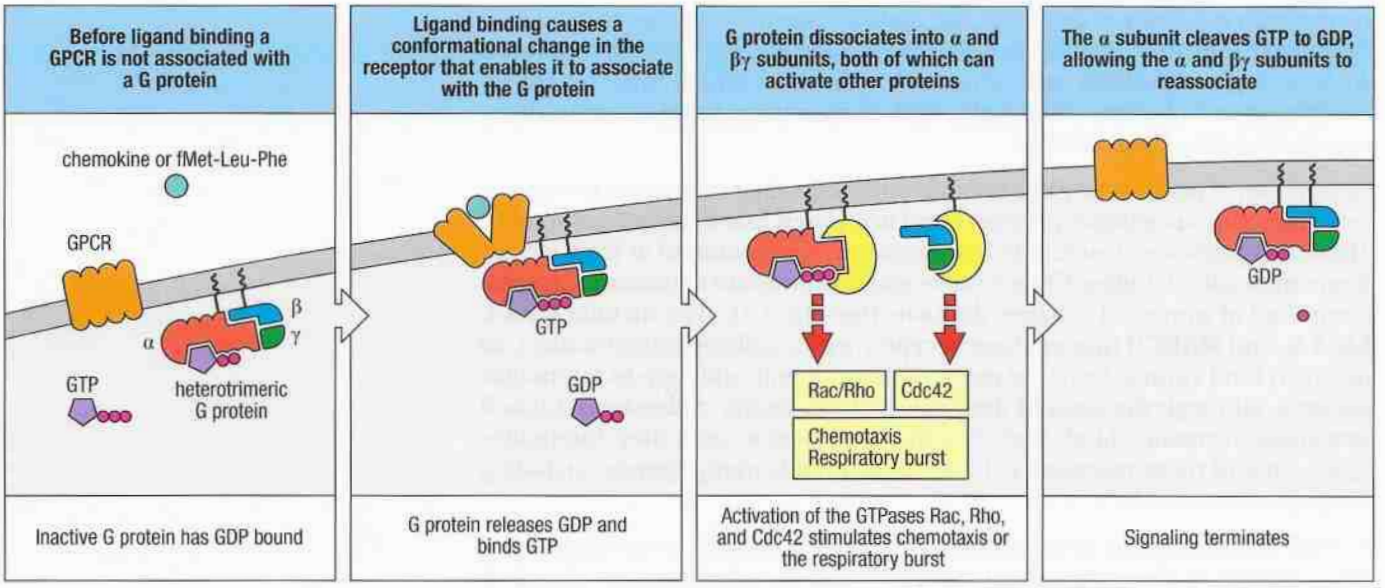
3-2 G protein–coupled receptors on phagocytes link microbe recognition with increased efficiency of intracellular killing.

Phagocytosis of microbes by macrophages and neutrophils is generally followed by the death of the microbe inside the phagocyte. In addition to the phagocytic receptors described above, macrophages and neutrophils have other receptors that signal to stimulate antimicrobial killing. These receptors belong to the evolutionarily ancient family of **G protein–coupled receptors (GPCRs)**, which are characterized by seven membrane-spanning segments. Members of this family are crucial to immune-system function because they also direct responses to anaphylatoxins such as the complement fragment C5a (see Section 2-14), leukotrienes, and to many chemokines, recruiting phagocytes to sites of infection and promoting inflammation.

The **fMet-Leu-Phe (fMLF) receptor** is a G protein–coupled receptor that senses the presence of bacteria by recognizing a unique feature of bacterial polypeptides. Protein synthesis in bacteria is typically initiated with an *N*-formylmethionine (fMet) residue, an amino acid present in prokaryotes but not in eukaryotes. The fMLF receptor is named after a tripeptide, formylmethionyl-leucyl phenylalanine, for which it has a high affinity, although it also binds other peptide motifs. Bacterial polypeptides binding to this receptor activate intracellular signaling pathways that direct the cell to move toward the most concentrated source of the ligand. Signaling through the fMLF receptor also induces the production of microbicidal **reactive oxygen species (ROS)** in the phagolysosome. The C5a receptor 1 recognizes the small fragment of C5 generated when complement is activated, usually by the presence of microbes (see Section 2-13), and signals by a similar pathway as the fMLF receptor. Thus, stimulation of these receptors both guides monocytes and neutrophils toward a site of infection and leads to increased antimicrobial activity; these cell responses can be activated by directly sensing unique bacterial products or by messengers such as C5a that indicate previous recognition of a microbe.

ANIMATION 3.3

The G protein–coupled receptors are so named because ligand binding activates a member of a class of intracellular GTP-binding proteins called



Before ligand binding a GPCR is not associated with a G protein
Ligand binding causes a conformational change in the receptor that enables it to associate with the G protein
G protein dissociates into α and βγ subunits, both of which can activate other proteins
The α subunit cleaves GTP to GDP, allowing the α and βγ subunits to reassociate
chemokine or fMet-Leu-Phe
GPCR
β
γ
α
GTP
heterotrimeric G protein
GTP
GDP
Rac/Rho
Cdc42
Chemotaxis
Respiratory burst
GDP
Inactive G protein has GDP bound
G protein releases GDP and binds GTP
Activation of the GTPases Rac, Rho, and Cdc42 stimulates chemotaxis or the respiratory burst
Signaling terminates

Fig. 3.3 G protein–coupled receptors signal by coupling with intracellular heterotrimeric G proteins. First panel: G protein–coupled receptors (GPCRs) such as the fMet-Leu-Phe (fMLF) and chemokine receptors signal through GTP-binding proteins known as heterotrimeric G proteins. In the inactive state, the α subunit of the G protein binds GDP and is associated with the β and γ subunits. Second panel: The binding of a ligand to the receptor induces a conformational change that allows the receptor to interact with the G protein, which results in the displacement of GDP and binding of GTP by the α subunit. Third panel: GTP binding triggers the dissociation of the G protein into the α subunit and the βγ subunit, each of which can activate other proteins at the inner face of the cell membrane. In the case of fMLF signaling in macrophages and neutrophils, the α subunit of the activated G protein indirectly activates the GTPases Rac and Rho, whereas the βγ subunit indirectly activates the GTPase Cdc42. The actions of these proteins result in the assembly of NADPH oxidase, resulting in a respiratory burst, a brief spurt in oxygen consumption leading to the production of reactive oxygen species. Chemokine signaling acts by a similar pathway and activates chemotaxis, which is the process whereby a cell migrates toward the source of chemokine. Fourth panel: The activated response ceases when the intrinsic GTPase activity of the α subunit hydrolyzes GTP to GDP, and the α and βγ subunits reassociate. The intrinsic rate of GTP hydrolysis by α subunits is relatively slow, and signaling is regulated by additional GTPase-activating proteins (not shown), which accelerate the rate of GTP hydrolysis.

G proteins, sometimes referred to as **heterotrimeric G proteins** to distinguish them from the family of 'small' GTPases typified by Ras. Heterotrimeric G proteins are composed of three subunits: Gα, Gβ, and Gγ, of which the α subunit is similar to the small GTPases (Fig. 3.3). In the resting state, the G protein is inactive, not associated with the receptor, and a molecule of GDP is bound to the α subunit. Ligand binding induces conformational changes in the receptor that allow it to bind the G protein, which results in the displacement of the GDP from the G protein and its replacement with GTP. The active G protein dissociates into two components, the Gα subunit and a complex consisting of a Gβ and a Gγ subunit. Each of these components can interact with other intracellular signaling molecules to transmit and amplify the signal. G proteins can activate a wide variety of downstream enzymatic targets, such as adenylate cyclase, which produces the second messenger cyclic AMP, and phospholipase C, whose activation gives rise to the second messenger inositol 1,4,5-trisphosphate (IP_3) and the release of Ca^{2+} from stores in the endoplasmic reticulum. The subsequent increase in cytosolic Ca^{2+} can induce several signaling pathways, including the activation of protein kinase C (PKC) (see Chapter 7 for a more detailed discussion of these and other signaling pathways).

Signaling by fMLF and C5a receptors influences cell motility, metabolism, gene expression, and cell division through activation of several **Rho family small GTPase proteins**. The α subunit of the activated G protein indirectly activates **Rac** and **Rho**, while the βγ subunit indirectly activates the small GTPase Cdc42 (see Fig. 3.3). Activation of these GTPases is controlled by **guanine nucleotide exchange factors (GEFs)** (see Fig. 7.5), which exchange GTP for GDP bound to the GTPase. The G proteins activated by fMLF activate the GEF protein **PREX1** (phosphatidylinositol 3,4,5-trisphosphate–dependent

Antimicrobial mechanisms of phagocytes		
Class of mechanism	**Macrophage products**	**Neutrophil products**
Acidification	pH ≈ 3.5–4.0, bacteriostatic or bactericidal	
Toxic oxygen–derived products	Superoxide O_2^-, hydrogen peroxide H_2O_2, singlet oxygen $^1O_2^*$, hydroxyl radical $^*OH$, hypochlorite OCl^-	
Toxic nitrogen oxides	Nitric oxide NO	
Antimicrobial peptides	Cathelicidin, macrophage elastase–derived peptide	α-Defensins (HNP1–4), β-defensin HBD4, cathelicidin, azurocidin, bacterial permeability inducing protein (BPI), lactoferricin
Enzymes	Lysozyme: digests cell walls of some Gram-positive bacteria Acid hydrolases (e.g., elastase and other proteases): break down ingested microbes	
Competitors		Lactoferrin (sequesters Fe^{2+}), vitamin B_{12}–binding protein

Fig. 3.4 Bactericidal agents produced or released by phagocytes after uptake of microorganisms. Most of the agents listed are directly toxic to microbes and can act directly in the phagolysosome. They can also be secreted into the extracellular environment, and many of these substances are toxic to host cells. Other phagocyte products sequester essential nutrients in the extracellular environment, rendering them inaccessible to microbes and hindering microbial growth. Besides being directly bacteriostatic or bactericidal, acidification of lysosomes also activates the many acid hydrolases that degrade the contents of the vacuole.

Rac exchanger 1 protein), which can directly activate Rac. Other GEFs, including members of the Vav family that are controlled by other types of receptors (see Section 7-19), can also activate Rac activity, and their activity synergizes with the actions of fMLF and C5a.

The activation of Rac and Rho helps to increase the microbicidal capacity of macrophages and neutrophils that have ingested pathogens. Upon phagocytosing microbes, macrophages and neutrophils produce a variety of toxic products that help to kill the engulfed microorganism (Fig. 3.4). The most important of these are the antimicrobial peptides described in Section 2-4, reactive nitrogen species such as nitric oxide (NO), and ROS such as the superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2). Nitric oxide is produced by a high-output form of nitric oxide synthase, inducible NOS2 (iNOS2), whose expression is induced by a variety of stimuli, including fMLF.

Activation of phagocytic receptors, including the fMLF and C5a receptors, can promote ROS generation by inducing assembly of a multicomponent, membrane-associated **NADPH oxidase**, also called **phagocyte oxidase**. In unstimulated phagocytes, this enzyme is inactive because it is not fully assembled. One set of subunits, the cytochrome b_{558} complex (composed of p22 and gp91), is localized in the plasma membranes of resting macrophages and neutrophils, and it appears in lysosomes after the maturation of phagolysosomes. The other components, p40, p47, and p67, are in the cytosol. Activation of phagocytes induces the cytosolic subunits to join with the membrane-associated cytochrome b_{558} to form a complete, functional NADPH oxidase in the phagolysosome membrane (Fig. 3.5). Activation of Rac promotes the movement of the cytosolic components to the membrane to assemble the active NADPH oxidase. Phosphorylation of certain residues of the NADPH oxidase complex also plays a critical role in activation and is mediated by PKC activation downstream of GPCRs. PKC activation can also occur downstream of phagocytic receptors, such as Dectin-1 and Fc receptors, which contain **immunoreceptor tyrosine-based activation motifs (ITAMs)** in their cytosolic tails. The signaling mediated by ITAMs is discussed in greater detail later in this chapter (Section 3-26) as well as in later chapters.

The NADPH oxidase reaction results in a transient increase in oxygen consumption by the cell, which is known as the **respiratory burst**. It generates superoxide anion within the lumen of the phagolysosome, and this is converted

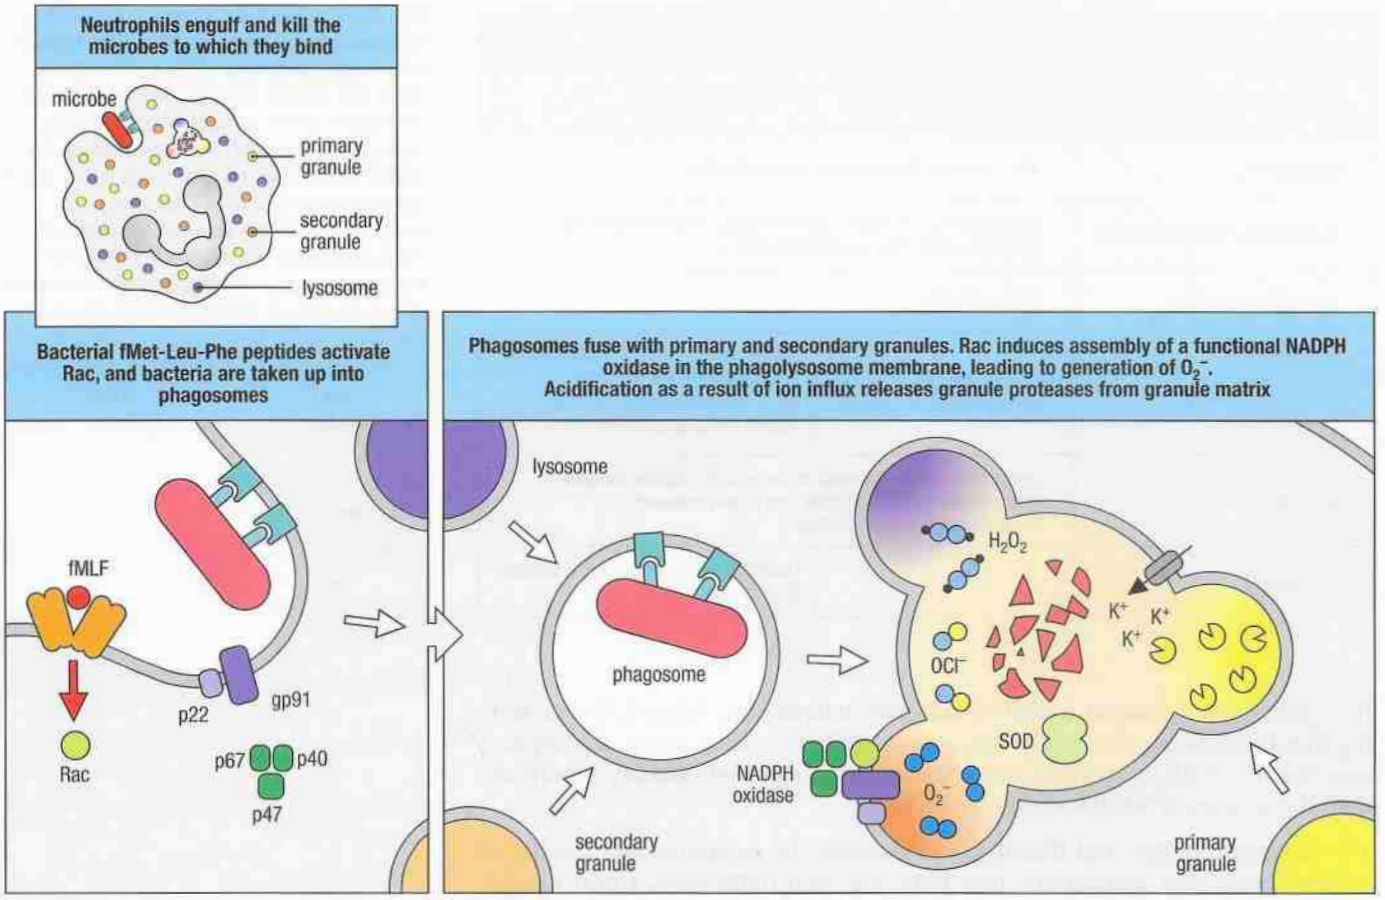


Fig. 3.5 The microbicidal respiratory burst in phagocytes is initiated by activation-induced assembly of the phagocyte NADPH oxidase. First panel: Neutrophils are highly specialized for the uptake and killing of pathogens and contain several different kinds of cytoplasmic granules, such as the primary and secondary granules shown in the first panel. These granules contain antimicrobial peptides and enzymes. Second panel: In resting neutrophils, the cytochrome b_{558} subunits (gp91 and p22) of NADPH oxidase are localized in the plasma membrane; the other oxidase components (p40, p47, and p67) are located in the cytosol. Signaling by phagocytic receptors and by fMLF or C5a receptors synergizes to activate Rac and induce the assembly of the complete, active NADPH oxidase in the membrane of the phagolysosome, which has formed by the fusion of the phagosome with lysosomes and primary and secondary granules. Third panel: Active NADPH oxidase transfers electrons from NADPH to molecular oxygen, forming the superoxide ion O_2^- (blue) and other free oxygen radicals in the lumen of the phagolysosome. Potassium and hydrogen ions are then drawn into the phagolysosome to neutralize the charged superoxide ion, increasing acidification of the vesicle. Acidification dissociates granule enzymes such as cathepsin G and elastase (yellow) from their proteoglycan matrix, leading to their cleavage and activation by lysosomal proteases. O_2^- is converted by superoxide dismutase (SOD) to hydrogen peroxide (H_2O_2), which can kill microorganisms and can be converted by myeloperoxidase, a heme-containing enzyme, to microbicidal hypochlorite (OCl^-) and by chemical reaction with ferrous (Fe^{2+}) ions to the hydroxyl radical (•OH).

by the enzyme **superoxide dismutase (SOD)** into H_2O_2. Further chemical and enzymatic reactions produce a range of toxic ROS from H_2O_2, including the hydroxyl radical (•OH), hypochlorite (OCl^-), and hypobromite (OBr^-). In this way, the direct recognition of bacterially derived polypeptides or previous pathogen recognition by the complement system activates a potent killing mechanism within macrophages and neutrophils that have ingested microbes via their phagocytic receptors. However, phagocyte activation can also cause extensive tissue damage because hydrolytic enzymes, membrane-disrupting peptides, and reactive oxygen species can be released into the extracellular environment and are toxic to host cells.

Neutrophils use the respiratory burst described above in their role as an early responder to infection. Neutrophils are not tissue-resident cells, and they need to be recruited to a site of infection from the bloodstream. Their main function is to ingest and kill microorganisms, but they also produce cytokines and lipid mediators that promote and orchestrate the inflammatory response. Although

neutrophils are eventually present in much larger numbers than macrophages in some types of acute infection, they are short-lived, dying soon after they have accomplished a round of phagocytosis and used up their primary and secondary granules. Dead and dying neutrophils are a major component of the **pus** that forms in abscesses and in wounds infected by certain extracellular capsulated bacteria such as streptococci and staphylococci, which are thus known as **pus-forming, or pyogenic, bacteria**. Macrophages, in contrast, are long-lived cells and continue to generate new lysosomes.

Individuals with a disease called **chronic granulomatous disease (CGD)** have a genetic deficiency of NADPH oxidase, which means their phagocytes do not produce the toxic oxygen derivatives characteristic of the respiratory burst and so are less able to kill ingested microorganisms and clear an infection. The most common form of CGD is an X-linked heritable disease that arises from inactivating mutations in the gene encoding the gp91 subunit of cytochrome b_{558}. People with this defect are unusually susceptible to bacterial and fungal infections, especially in infancy, though they remain susceptible for life. One autosomal recessive form of NADPH oxidase deficiency, p47phox deficiency, has very low but detectable activity and causes a milder form of CGD.

Chronic Granulomatous Disease

In addition to killing microbes engulfed by phagocytosis, neutrophils use another rather novel mechanism of destruction that is directed at extracellular pathogens. During infection, some activated neutrophils undergo a unique form of cell death in which the nuclear chromatin, rather than being degraded as occurs during apoptosis, is released into the extracellular space and forms a fibril matrix known as **neutrophil extracellular traps, or NETs** (Fig. 3.6). It has been proposed that NETs act to capture microorganisms, which may then be more efficiently phagocytosed by other neutrophils or macrophages, but the importance of this mechanism during infection remains rather unclear.

ANIMATION 3.4

Macrophages can phagocytose pathogens and produce the respiratory burst immediately upon encountering an infecting microorganism, and this can be sufficient to prevent an infection from becoming established. In the 19th century, the immunologist Élie Metchnikoff believed that the innate response of macrophages encompassed all host defenses; indeed, invertebrates such as the sea star that he was studying rely entirely on innate immunity to overcome infection. Although this is not the case in humans and other vertebrates, the innate response of macrophages still provides an important front line of defense that must be overcome if a microorganism is to establish an infection that can be passed on to a new host.

Pathogens have, however, developed a variety of strategies to avoid immediate destruction by macrophages and neutrophils. Many extracellular pathogenic bacteria coat themselves with a thick polysaccharide capsule that is not recognized by any phagocytic receptor. In such cases, however, the complement system can recognize microbial surfaces and coat them with C3b, thereby flagging them for phagocytosis via complement receptors, as described in Chapter 2. Other pathogens, for example, mycobacteria, have evolved ways to grow inside macrophage phagosomes by inhibiting their acidification and fusion with lysosomes. Without such strategies, a microorganism must enter the body in sufficient numbers to overwhelm the immediate innate host defenses and to establish a focus of infection.

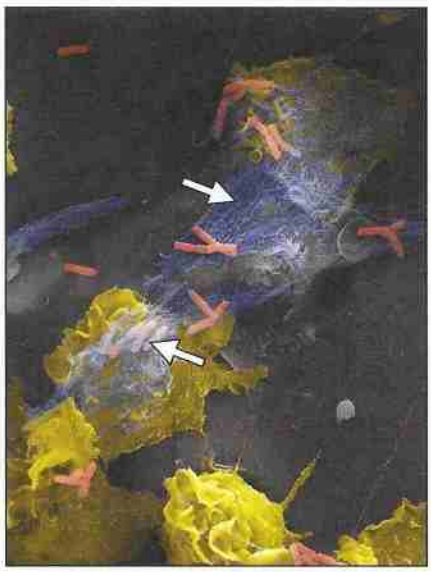

Fig. 3.6 Neutrophil extracellular traps (NETs) can trap bacteria and fungi. This scanning electron micrograph of activated human neutrophils infected with a virulent strain of *Shigella flexneri* (pink rods) shows the stimulated neutrophils forming NETs (blue, indicated by arrows). Bacteria trapped within NETs are visible (lower arrow).

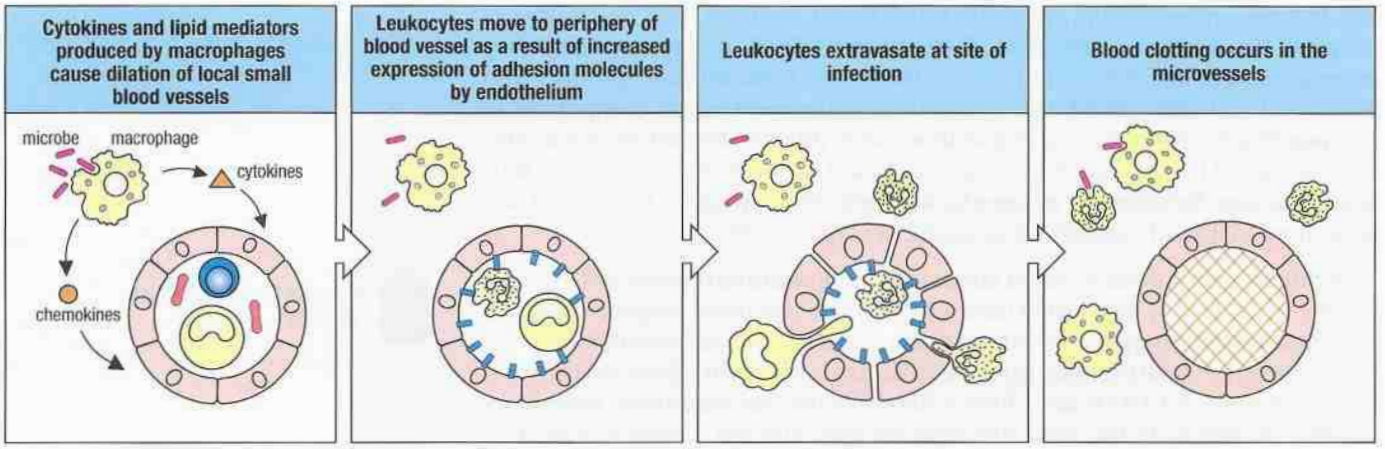
3-3 Microbial recognition and tissue damage initiate an inflammatory response.

An important effect of the interaction between microbes and tissue macrophages is the activation of macrophages and other immune cells to release small proteins called **cytokines** and **chemokines**, and other chemical mediators, such as lipid mediators. Collectively, these signals induce a state of



Cytokines and lipid mediators produced by macrophages cause dilation of local small blood vessels

Blood clotting occurs in the microvessels
microbe
macrophage
cytokines
chemokines

Fig. 3.7 Infection stimulates macrophages to release cytokines and chemokines that initiate an inflammatory response. Cytokines and lipid mediators produced by tissue macrophages at the site of infection cause the dilation of local small blood vessels and changes in the endothelial cells of their walls. These changes lead to the movement of leukocytes, such as neutrophils and monocytes, out of the blood vessel (extravasation) and into the infected tissue; this movement is guided by chemokines produced by the activated macrophages. The blood vessels also become more permeable, allowing plasma proteins and fluid to leak into the tissues. Together, these changes cause the characteristic inflammatory signs of heat, pain, redness, and swelling at the site of infection.

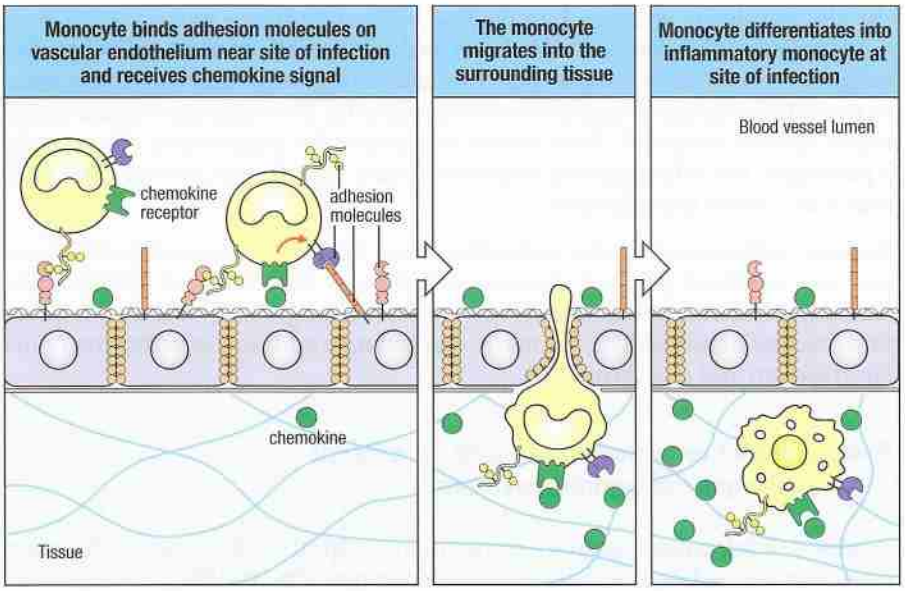
inflammation in the tissue, attract monocytes and neutrophils to the infection, and allow plasma proteins to enter the tissue from the blood. An inflammatory response is usually initiated within minutes to hours of infection or wounding. Macrophages are stimulated to secrete **pro-inflammatory** cytokines, such as TNF-α, and chemokines by interactions between microbes or microbial products and specific receptors expressed by macrophages. We will examine how the cytokines interact with pathogens later in the chapter, but first we describe some general aspects of inflammation and how it contributes to host defense.

Inflammation has three essential roles in combating infection. The first is to deliver additional effector molecules and cells from the blood into sites of infection, and so increase the destruction of invading microorganisms. The second is to induce local blood clotting, which provides a physical barrier to the spread of the infection in the bloodstream. The third is to promote the repair of injured tissue, which occurs during the resolution phase, after the infection has been cleared.

Inflammatory responses are characterized by heat, pain, redness, and swelling at the site of an infection, reflecting four types of change in the local blood vessels, as shown in Fig. 3.7. The first is an increase in vascular diameter, leading to increased local blood flow—hence the heat and redness—and a reduction in the velocity of blood flow, especially along the inner walls of small blood vessels. The second change is the activation of endothelial cells lining the blood vessel to express **cell-adhesion molecules** that promote the binding of circulating leukocytes. The combination of slowed blood flow and adhesion molecules allows leukocytes to attach to the endothelium and migrate into the tissues, a process known as **extravasation**. All these changes are initiated by the pro-inflammatory cytokines and chemokines produced by activated macrophages and other cells in the tissue.

Once inflammation has begun, the first white blood cells attracted to the site are neutrophils. These are followed by monocytes (Fig. 3.8), which upon activation are called **inflammatory monocytes**. Monocytes can produce various pro-inflammatory cytokines but are distinguishable from macrophages by their lack of expression of the adhesion G protein–coupled receptor E1, commonly called F4/80. Monocytes are also able to give rise to dendritic cells in the tissues, depending on signals that they receive from their environment. In the later stages of inflammation, other leukocytes such as eosinophils and lymphocytes also enter the infected site.

The third major change in local blood vessels is an increase in vascular permeability. Thus, instead of being tightly joined together, the endothelial cells lining the blood vessel walls become separated, leading to an exit of fluid and proteins from the blood and their local accumulation in the tissue. This accounts for the swelling, or **edema**, and pain—as well as the accumulation



Monocyte binds adhesion molecules on vascular endothelium near site of infection and receives chemokine signal

Tissue

Fig. 3.8 Monocytes circulating in the blood migrate into infected and inflamed tissues. Adhesion molecules on the endothelial cells of the blood vessel wall capture the monocyte and cause it to adhere to the vascular endothelium. Chemokines bound to the vascular endothelium then signal the monocyte to migrate across the endothelium into the underlying tissue. The monocyte, now differentiating into an inflammatory monocyte, continues to migrate, under the influence of chemokines released during inflammatory responses, toward the site of infection. Monocytes leaving the blood are also able to differentiate into dendritic cells (not shown), depending on the signals that they receive from their environment.

in tissues of plasma proteins such as complement and mannose-binding lectin (MBL) that aid in host defense. The changes that occur in endothelium as a result of inflammation are known generally as **endothelial activation**. The fourth change, clotting in microvessels in the site of infection, prevents the spread of the pathogen via the blood.

These changes are induced by a variety of inflammatory mediators released as a consequence of the recognition of pathogens by macrophages, and later by neutrophils and other white blood cells. Macrophages and neutrophils secrete lipid mediators of inflammation—**prostaglandins**, **leukotrienes**, and **platelet-activating factor (PAF)**—which are rapidly produced by enzymatic pathways that degrade membrane phospholipids. Their actions are followed by those of the chemokines and cytokines that are synthesized and secreted by macrophages and inflammatory monocytes in response to pathogens. The cytokine **tumor necrosis factor-α (TNF-α, also known simply as TNF)**, for example, is a potent activator of endothelial cells. We describe TNF-α and related cytokines in more detail in Section 3-15.

Besides stimulating the respiratory burst in phagocytes and acting as a chemoattractant for neutrophils and monocytes, C5a also promotes inflammation by increasing vascular permeability and inducing the expression of certain adhesion molecules on endothelium. C5a also activates local **mast cells** (see Section 1-4), which are stimulated to release their granules containing the small inflammatory molecule histamine as well as TNF-α and cathelicidins.

If wounding has occurred, the injury to blood vessels immediately triggers two protective enzyme cascades. One is the **kinin system** of plasma proteases that is triggered by tissue damage to generate several polypeptides that regulate blood pressure, coagulation, and pain. Although we will not fully describe its components here, one inflammatory mediator produced is the vasoactive peptide **bradykinin**, which increases vascular permeability to promote the influx of plasma proteins to the site of tissue injury. It also causes pain. Although unpleasant to the victim, pain draws attention to the problem and leads to immobilization of the affected part of the body, which helps to limit the spread of the infection.

The **coagulation system** is another protease cascade that is triggered in the blood after damage to blood vessels, although its full description is also outside our present scope. Its activation leads to the formation of a fibrin clot, whose normal role is to prevent blood loss. With regard to innate immunity, however,

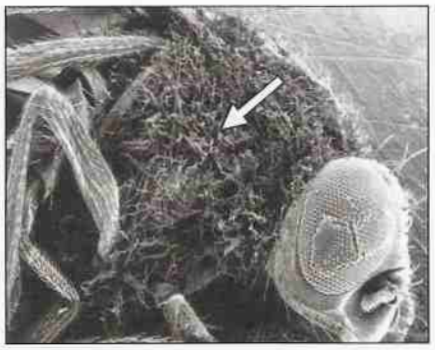

Fig. 3.9 Toll is required for antifungal responses in Drosophila *melanogaster*. Flies that are deficient in the Toll receptor are dramatically more susceptible than wild-type flies to fungal infection. This is illustrated here by the uncontrolled hyphal growth (arrow) of the normally weak pathogen *Aspergillus fumigatus* in a Toll-deficient fly.

the clot physically encases the infectious microorganisms and prevents their entry into the bloodstream. The kinin and the coagulation cascades are also triggered by activated endothelial cells, and so they can have important roles in the inflammatory response to pathogens even if wounding or gross tissue injury has not occurred. Thus, within minutes of the penetration of tissues by a pathogen, the inflammatory response causes an influx of proteins and cells that may control the infection.

Damage to tissues can occur in the absence of infection by microbes; for example, as a result of physical trauma, ischemia, or metabolic or autoimmune disorders. In such **sterile injury**, many of the changes associated with infection, such as neutrophil recruitment, can occur, in addition to activation of the kinin system and clot formation.

3-4 Toll-like receptors represent an ancient pathogen-recognition system.

Section 1-5 introduced pattern-recognition receptors (PRRs), which function as sensors for pathogen-associated molecular patterns (PAMPs). The existence of these receptors was predicted by Charles Janeway, Jr., before mechanisms of innate recognition of PAMPs were known, to explain how complex mixtures of microbial molecules, called adjuvants, were able to stimulate adaptive immune responses to purified antigens. The first example of such a receptor was the **Toll** protein, discovered in the fruit fly *Drosophila melanogaster*. Although Toll was identified earlier as a gene controlling the dorso-ventral patterning during development of *Drosophila*, in 1996 Jules Hoffmann discovered that Toll signaling induces the expression of several host-defense mechanisms. The importance of this mechanism was illustrated by the decreased production of antimicrobial peptides and the enhanced susceptibility to infection of adult flies with mutations in the Toll pathway (Fig 3.9). For this work, Hoffmann was awarded part of the 2011 Nobel Prize in Physiology or Medicine.

In 1997, Janeway and Ruslan Medzhitov discovered a human homolog of Toll, subsequently termed **Toll-like receptor (TLR)**, and showed that signaling by this receptor activates innate and adaptive immune responses. Subsequently, numerous TLRs associated with resistance to infection by pathogens have been found in humans and other animals. In plants, proteins with domains resembling the ligand-binding regions of TLR proteins are involved in the production of antimicrobial peptides, indicating the ancient association of these domains with host defense.

ANIMATION 3.5

3-5 Mammalian Toll-like receptors are activated by many different pathogen-associated molecular patterns.

There are 10 expressed TLR genes in humans and 12 in mice. Each TLR recognizes one or more distinct molecular 'patterns' present on microbes, which are referred to as pathogen-associated molecular patterns (PAMPs), as discussed at the beginning of this chapter. These molecules are general components of both pathogenic and nonpathogenic microorganisms and are sometimes called microbial-associated molecular patterns, or MAMPs, to reflect this fact. Collectively, the mammalian TLRs recognize molecules from bacteria, fungi, viruses, and protozoa. The mammalian TLRs and their known microbial ligands are listed in Fig. 3.10. Note that in almost all cases the ligands represent highly conserved features that are characteristic of these microbial groups. For example, **lipoteichoic acids** of Gram-positive bacterial cell walls and **lipopolysaccharide (LPS)** of the outer membrane of Gram-negative bacteria (see Fig. 2.9) are recognized by TLRs. In general, these microbial molecules are not found in vertebrate cells, which prevents inappropriate immune recognition of host cells. The major exceptions to this

Innate immune recognition by mammalian Toll-like receptors	
Toll-like receptor	**Ligand**
TLR-1:TLR-2 heterodimer	Lipomannans (mycobacteria) Diacyl and triacyl lipopeptides (bacteria) Lipoteichoic acids (Gram-positive bacteria) Cell-wall β-glucans (fungi)
TLR-2:TLR-6 heterodimer	
TLR-3	Double-stranded RNA (viruses), poly I:C
TLR-4	LPS (Gram-negative bacteria)
TLR-5	Flagellin (bacteria)
TLR-7	Single-stranded RNA (viruses)
TLR-8	Single-stranded RNA (viruses)
TLR-9	DNA with unmethylated CpG (bacteria and DNA viruses)
TLR-10 (human only)	Unknown
TLR-11 (mouse only)	Profilin and profilin-like proteins (*Toxoplasma gondii*, uropathogenic bacteria)
TLR-12 (mouse only)	Profilin (*Toxoplasma gondii*)
TLR-13 (mouse only)	Single-stranded RNA (bacterial ribosomal RNA)

Fig. 3.10 Innate immune recognition by Toll-like receptors. Each of the human or mouse TLRs recognizes one or more microbial molecular patterns, generally by direct interaction with molecules on the pathogen surface. Some Toll-like receptor proteins form heterodimers (for example, TLR-1:TLR-2 and TLR-2:TLR-6). LPS, lipopolysaccharide.

rule, however, are the DNA and RNA ligands for certain TLRs. As discussed later in this section, additional mechanisms are used to distinguish between microbial and host DNA and RNA.

TLRs are sensors for microbes present in extracellular spaces. Some mammalian TLRs are cell-surface receptors, but others are located intracellularly in the membranes of endosomes, where they detect pathogens or their components that have been taken into cells by phagocytosis, receptor-mediated endocytosis, or macropinocytosis (Fig. 3.11). TLRs localized to the plasma membrane

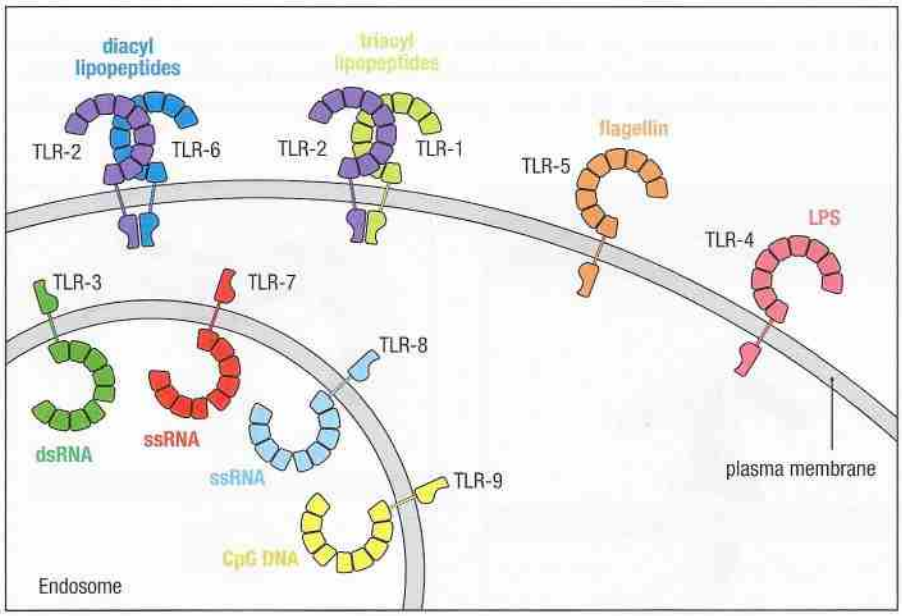

Fig. 3.11 The cellular locations of the mammalian Toll-like receptors. TLRs are transmembrane proteins where the extracellular region of the monomer contains 18–25 copies of the leucine-rich repeat (LRR), but these diagrams depict only 9 LRRs in each monomer for simplicity. Some TLRs are located on the cell surface of dendritic cells, macrophages, and other cells, where they are able to detect extracellular pathogen molecules. TLRs are thought to act as dimers. Only those that form heterodimers are shown in dimeric form here; the rest act as homodimers but are shown as monomers for simplicity. TLRs located intracellularly, in the membranes of endosomes, can recognize microbial components, such as DNA or RNA, that are accessible only after the microbe has been broken down. The ectodomains of TLR-3, TLR-7, TLR-8, and TLR-9 undergo proteolytic cleavage once they reach the endosome. This cleavage is required for their function and is thought to prevent responses to self nucleic acids in the extracellular space (see text for further discussion). TLR-11, TLR-12, and TLR-13 (also localized to endosomes) are not shown.

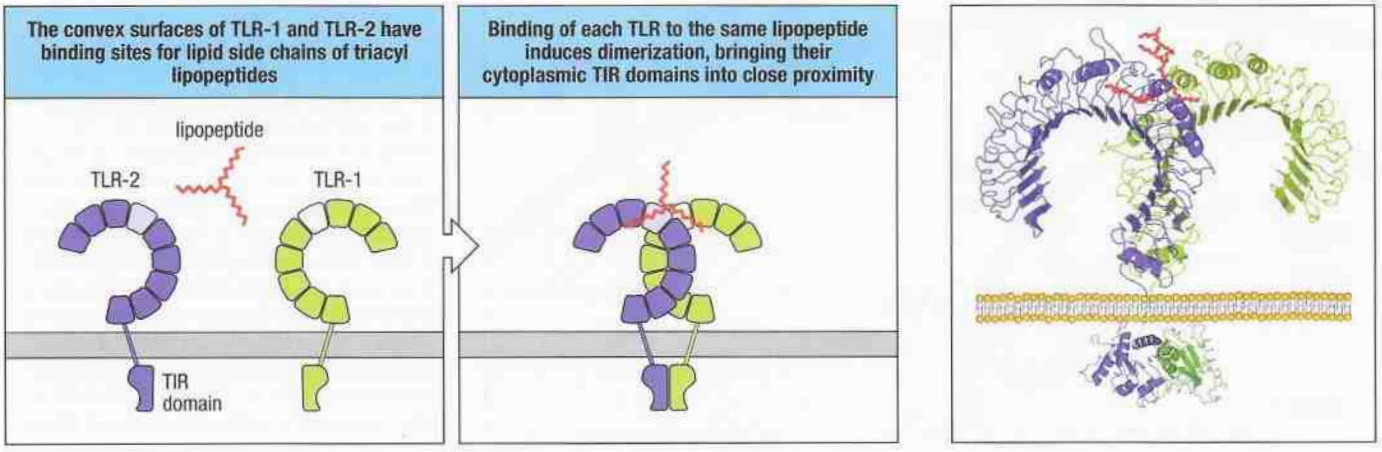
can also be incorporated into phagosomes, which further enables detection of phagocytosed microbes. TLRs are transmembrane proteins in which the extracellular region of the monomer is composed of 18–25 copies of a **leucine-rich repeat (LRR)**. Each LRR of a TLR protein is composed of approximately 20–25 amino acids, and multiple LRRs create a horseshoe-shaped protein scaffold that is adaptable for ligand binding and recognition on both the outer (convex) and inner (concave) surfaces. Signaling by mammalian TLRs is activated when binding of a ligand induces formation of a dimer or induces conformational changes in a preformed TLR dimer. All mammalian TLR proteins have in their cytoplasmic tails a **TIR (for Toll–IL-1 receptor) domain**, which is also found in the cytoplasmic tail of the receptor for the cytokines interleukin-1α (**IL-1α**) and interleukin-1β (**IL-1β**). The TLR TIR domains mediate interaction with other TIR domain–containing signaling molecules, discussed in greater detail in Section 3-7. For years after the discovery of the mammalian TLRs it was not known whether they made direct contact with microbial products or whether they sensed the presence of microbes by some indirect means. *Drosophila* Toll, for example, does not recognize pathogen products directly, but instead is activated when it binds a cleaved version of a self protein, Spätzle. *Drosophila* has other direct pathogen-recognition molecules, and these trigger the proteolytic cascade that ends in the cleavage of Spätzle. In this sense, Toll is not a classical pattern-recognition receptor. However, X-ray crystal structures of several mammalian dimeric TLRs bound to their ligands show that mammalian TLRs make direct contact with microbial ligands.

TLRs are expressed on many cell types, including macrophages, dendritic cells, B cells, stromal cells, and certain epithelial cells, enabling the initiation of antimicrobial responses in many tissues. Mammalian **TLR-1**, **TLR-2**, and **TLR-6** are cell-surface receptors that are activated by various ligands, including lipoteichoic acid from Gram-positive bacteria and **diacyl** and **triacyl lipoproteins** present in both Gram-positive and Gram-negative bacteria. Ligand binding induces the formation of heterodimers of TLR-2 and TLR-1 or of TLR-2 and TLR-6. The X-ray crystal structure of a synthetic triacyl lipopeptide ligand bound to TLR-1 and TLR-2 shows exactly how ligand binding induces dimerization (Fig. 3.12). Two of the three lipid chains bind to the convex surface of TLR-2, while the third binds to the convex surface of TLR-1. Dimerization brings the cytoplasmic TIR domains of the TLR chains into close proximity with each other to initiate signaling. Similar interactions are presumed to occur with the diacyl lipopeptide ligands that induce the dimerization of TLR-2 and TLR-6.

TLR-5 is expressed on the cell surface of certain macrophages and dendritic cells and also in intestinal epithelial cells; it recognizes flagellin, a protein subunit of bacterial flagella. TLR-5 recognizes a highly conserved site on flagellin



The convex surfaces of TLR-1 and TLR-2 have binding sites for lipid side chains of triacyl lipopeptides
Binding of each TLR to the same lipopeptide induces dimerization, bringing their cytoplasmic TIR domains into close proximity

TLR-1
TIR domain

Fig. 3.12 Direct recognition of pathogen-associated molecular patterns by TLR-1 and TLR-2 induces dimerization of the TLRs and signaling. TLR-1 and TLR-2 are located on cell surfaces (left panel), where they can directly recognize bacterial triacyl lipoproteins (middle panel). The convex surfaces of their extracellular domains have binding sites for the lipid side chains of triacyl lipopeptides. In the crystal structure (right panel), the ligand is a synthetic lipid that can activate TLR-1:TLR-2 dimers; it has three fatty-acid chains bound to a polypeptide backbone. Two fatty-acid chains bind to a pocket on the convex surface of the TLR-2 ectodomain, and the third chain associates with a hydrophobic channel in the convex binding surface of TLR-1, inducing dimerization of the two TLR subunits and bringing their cytoplasmic Toll–IL-1 receptor (TIR) domains together to initiate signaling.

that is buried and inaccessible in the assembled flagellar filament. This means the receptor is activated only by monomeric flagellin, which can be shed during flagellar assembly or when flagella are degraded.

Mice, but not humans, express **TLR-11** and **TLR-12**. TLR-11–deficient mice develop urinary infections caused by uropathogenic strains of *Escherichia coli*, although the bacterial ligand for TLR-11 has not yet been identified. TLR-11 and TLR-12 also both recognize protozoan parasites such as *Toxoplasma gondii* and *Plasmodium falciparum*. They bind to motifs that are present in the protozoan actin-binding protein **profilin** but absent in mammalian profilins. TLR-11 and TLR-12 are both required in macrophages and conventional dendritic cells for activation by *T. gondii* profilin, but TLR-12 plays a more dominant role. Mice lacking TLR-11 develop more severe tissue injury than normal mice on infection with *Toxoplasma*, whereas mice lacking TLR-12 die rapidly after infection.

Five of the mammalian TLRs (TLR3, TLR7, TLR8, TLR9, and TLR13) recognize nucleic acids. These receptors are all localized to endosomes. The endosome lumen is acidic and contains many proteases, which degrade internalized microbes and release their nucleic acids for recognition by TLRs. All microbes possess some form of nucleic acid and so can be recognized by one or more of the nucleic acid–sensing TLRs; however, analysis of mice and humans with defects in one or more of these TLRs indicates that these receptors are most important for detection of viruses. In general, viruses lack other conserved features that could serve as PAMPs.

TLR-7 and **TLR-8** share very similar amino acid sequences, and both receptors are activated by degradation products of **single-stranded RNA (ssRNA)**. Many viruses (for example, orthomyxoviruses such as influenza; flaviviruses such as West Nile virus; and coronaviruses such as SARS-CoV-2) utilize ssRNA genomes, and TLR-7 and TLR-8 bind to small RNA fragments released when viruses are degraded in endosomes. Recent X-ray crystal structures of TLR-7 and TLR-8 have revealed two pairs of binding sites for distinct RNA fragments: guanosine and a short RNA fragment bind TLR-7, while uridine and a short RNA fragment bind TLR-8. Whether differences in the RNA sequences that activate TLR-7 and TLR-8 have consequences for antiviral immunity remains unclear. In mice, TLR-7 plays a dominant role over TLR-8 for detection of ssRNA viruses. For example, mice lacking TLR-7 have impaired immune responses to influenza. A viral detection function for TLR-8 in mice has not been established as clearly. The difference between mice and humans may be based, at least in part, on which cell types express the receptors in each species. In mice, TLR-7 is expressed broadly in many innate immune cell types, but in humans TLR-7 expression is limited to plasmacytoid dendritic cells and B cells, while TLR-8 is expressed more broadly. **TLR-13** also binds RNA but has specificity for certain bacterial ribosomal RNA sequences instead of viral RNA. TLR-13 is present in mice but not humans.

TLR-9 recognizes single-stranded DNA sequences that contain **unmethylated CpG dinucleotides**. In mammals, CpG dinucleotides in genomic DNA are often methylated on the cytosine by DNA methyltransferases. In the genomes of bacteria and many viruses, CpG dinucleotides remain unmethylated, so these sequences serve as ligands for TLR-9. The requirement for unmethylated CpG sequences is thought to limit the potential for recognition of self DNA by TLR-9. The structure of the TLR-9 dimer bound to DNA reveals a ligand-binding modality similar to what was previously described for TLR-7 and TLR-8: two pairs of binding sites within the dimer bind distinct DNA sequences. While the DNA genomes of viruses and bacteria are typically double-stranded, TLR-9 recognizes single-stranded DNA, so the DNA strands of pathogen genomes must be melted apart within endosomes prior to TLR-9 binding.

TLR-3 is expressed by macrophages, conventional dendritic cells, and intestinal epithelial cells; it recognizes **double-stranded RNA (dsRNA)**. Some

viruses have genomes composed of dsRNA, but dsRNA is also generated when ssRNA viruses replicate or express genes. dsRNA can be recognized by TLR-3 after direct endocytosis of viruses with double-stranded RNA genomes, such as rotavirus, or by the phagocytosis of dying cells in which viruses are replicating. Crystallographic analysis shows that TLR-3 binds directly to dsRNA. TLR-3 has two contact sites for dsRNA: one on the amino terminus and a second near the membrane-proximal carboxyl terminus. Mutations in the ectodomain of human TLR-3, which produce a dominantly acting loss-of-function mutant receptor, have been associated with encephalitis that is caused by a failure to control the herpes simplex virus. This increased susceptibility is somewhat surprising because herpes simplex virus is a DNA virus; the most likely explanation for sensing by TLR-3 is generation of dsRNA after transcription of overlapping viral genes encoded on opposing strands of DNA.

To reach endosomes, TLR-3, TLR-7, TLR-8, TLR-9, TLR-11, TLR-12, and TLR-13 must interact with a specific protein, **UNC93B1**. UNC93B1, which is composed of 12 transmembrane domains, binds TLRs in the endoplasmic reticulum and shuttles them to endosomes. Mice lacking this protein have defects in signaling by these endosomal TLRs because the receptors cannot exit the endoplasmic reticulum. Rare human mutations in UNC93B1 have been identified as causing susceptibility to herpes simplex encephalitis, similarly to TLR-3 deficiency, but they do not impair immunity to many other viral pathogens, presumably because of the existence of other viral sensors, which are discussed later in this chapter.

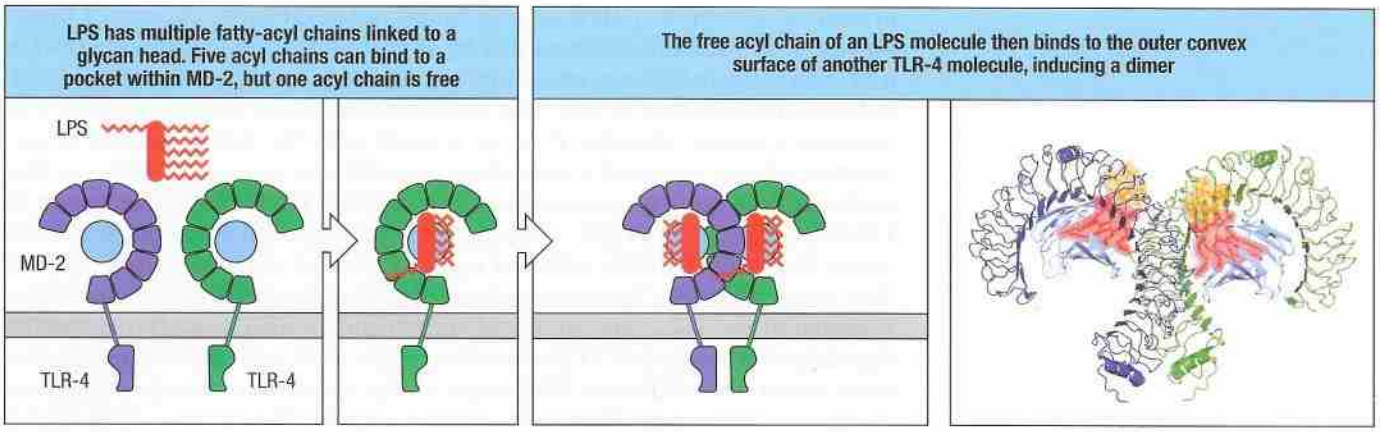
Recurrent Herpes Simplex Encephalitis

Sensing of nucleic acids enables broad recognition of diverse pathogens, but, in abnormal settings, TLRs may be activated by self-derived nucleic acids, leading to autoimmunity. In healthy cells, RNA and DNA are normally confined to the nucleus and cytoplasm and are not present in endosomes; however, nucleic acids can be released into the extracellular space during tissue damage or inflammation (for example, NETs). The localization of nucleic acid–sensing TLRs to endosomes reduces the likelihood that these receptors encounter such extracellular RNA and DNA. RNases and DNases in the extracellular space degrade RNA and DNA before they are taken up by endocytosis and delivered to TLRs. Another mechanism that limits TLR activation to endosomes is that the ectodomains of each of the nucleic acid–sensing TLRs must undergo proteolytic cleavage before the receptors can be activated; this cleavage occurs when TLRs arrive in endosomes, which prevents receptors from responding to ligands in other subcellular compartments, such as the cell surface (see Fig. 3.11). The two halves of the cleaved TLR remain associated and both contribute to ligand binding. Without this proteolytic event, the receptor cannot undergo the necessary conformational change required to initiate signaling.

In mouse models of systemic lupus erythematosus (SLE), an autoimmune disease associated with responses to self nucleic acids, TLR-7 and TLR-9 both contribute to disease. Several studies have identified polymorphisms in the human TLR-7 gene that are associated with increased risk of SLE, suggesting a potential role in this disease.

3-6 TLR-4 recognizes bacterial lipopolysaccharide in association with the host accessory proteins MD-2 and CD14.

Not all mammalian TLRs bind their ligands so directly. **TLR-4** is expressed by several types of immune-system cells, including dendritic cells and macrophages, and is important in sensing and responding to numerous bacterial infections. TLR-4 recognizes the LPS of Gram-negative bacteria by a mechanism that is partly direct and partly indirect. LPS varies in composition among different bacteria but essentially consists of a polysaccharide core attached to an amphipathic lipid, lipid A, with a variable number of fatty-acid chains per



LPS has multiple fatty-acyl chains linked to a glycan head. Five acyl chains can bind to a pocket within MD-2, but one acyl chain is free
The free acyl chain of an LPS molecule then binds to the outer convex surface of another TLR-4 molecule, inducing a dimer
LPS

TLR-4

Fig. 3.13 TLR-4 recognizes LPS in association with the accessory protein MD-2. A side view of the symmetrical complex of TLR-4, MD-2, and LPS. TLR-4 polypeptide backbones are shown in green and purple. The MD-2 protein is shown in light blue. Five of the LPS acyl chains (shown in red) are inserted into a hydrophobic pocket within MD-2. The remainder of the LPS glycan (orange in the crystal structure) and one lipid chain make contact with the convex surface of a second TLR-4 monomer. The crystal structure shows the entire extracellular region of TLR-4, composed of the LRR region (shown in green and purple), but lacks the intracellular signaling domains.

molecule. To recognize LPS, the ectodomain of TLR-4 uses an accessory protein, **MD-2**. MD-2 initially binds to TLR-4 within the cell and is necessary both for the correct trafficking of TLR-4 to the cell surface and for the recognition of LPS. MD-2 associates with the central section of the curved ectodomain of TLR-4, binding off to one side as shown in Fig. 3.13. When the TLR-4:MD-2 complex encounters LPS, five lipid chains of LPS bind to a deep hydrophobic pocket of MD-2, but not directly to TLR-4, while a sixth lipid chain remains exposed on the surface of MD-2. This last lipid chain and parts of the LPS polysaccharide backbone can then bind to the convex side of a second TLR-4 ectodomain, inducing TLR-4 dimerization, which activates intracellular signaling pathways.

TLR-4 activation by LPS involves two other accessory proteins besides MD-2. While LPS is normally an integral component of the outer membrane of Gram-negative bacteria, during infections it can become detached from the membrane and be picked up by the host **LPS-binding protein** present in the blood and in extracellular fluid in tissues. LPS is transferred from LPS-binding protein to a second protein, CD14, which is present on the surface of macrophages, neutrophils, and dendritic cells. On its own, CD14 can act as a phagocytic receptor, but on macrophages and dendritic cells it also acts as an accessory protein for TLR-4.

The systemic injection of LPS causes a collapse of the circulatory and respiratory systems, a condition known as **shock**. These dramatic effects of LPS are seen in humans as **septic shock**, which results from an uncontrolled systemic bacterial infection, or **sepsis**. In this case, LPS induces an overwhelming secretion of cytokines, including IL-1β and TNF-α, causing systemic vascular permeability, an undesirable effect of its normal role in containing local infections. Mutant mice lacking TLR-4 function are resistant to LPS-induced septic shock but are highly sensitive to LPS-bearing pathogens such as *Salmonella enterica* ssp. *typhimurium*. In fact, TLR-4 (the first human homolog of Toll discovered by Medzhitov and Janeway, as discussed earlier) was identified as a receptor for LPS by positional cloning of its gene from the LPS-resistant C3H/HeJ mouse strain, which harbors a naturally occurring mutation in the cytoplasmic tail of TLR-4 that interferes with the receptor's ability to signal. For this discovery, the 2011 Nobel Prize in Physiology or Medicine was partly awarded to Bruce Beutler.

3-7 TLRs activate NFκB, AP-1, and IRF transcription factors to induce the expression of inflammatory cytokines and type I interferons.

Signaling by mammalian TLRs in various cell types induces a diverse range of intracellular responses that together result in the production of inflammatory cytokines, chemotactic factors, antimicrobial peptides, and the antiviral

cytokines interferon-α (**IFN-α**) and interferon-β (**IFN-β**), the **type I interferons**. TLR signaling achieves this by activating several signaling pathways that each activate different transcription factors. As mentioned earlier, ligand-induced dimerization of two TLR ectodomains brings the cytoplasmic TIR domains together, allowing them to interact with the TIR domains of cytoplasmic adaptor molecules that initiate intracellular signaling. There are five such adaptors used by mammalian TLRs: **MyD88**, **TRIF**, **MAL** (also known as TIRAP), **TRAM**, and **BCAP**. It is significant that the TIR domains of the different TLRs interact with different combinations of these adaptors because the choice of adaptor influences which of several downstream signals will be activated by the TLR. Recruitment of MyD88 and/or TRIF controls most of the signaling downstream of TLR activation, while MAL and TRAM facilitate the recruitment of MyD88 and TRIF, respectively, but do not directly participate in signal transduction. Most TLRs interact with MyD88 and not TRIF. TLR-3 interacts only with TRIF, and TLR-4 interacts with both MyD88 and TRIF. BCAP links TLR activation to distinct signaling pathways, but the details of this signaling are less clear because BCAP was only recently discovered as a TLR adaptor.

Signaling by most TLRs activates the transcription factor **NFκB** (Fig. 3.14). Mammalian TLRs also activate several members of the **interferon regulatory factor (IRF)** transcription factor family through a second pathway, and they activate members of the **activator protein 1 (AP-1)** family, such as c-Jun, through yet another signaling pathway involving **mitogen-activated protein kinases (MAPKs)**. NFκB and AP-1 act primarily to induce the expression of pro-inflammatory cytokines and chemotactic factors. The IRF factors IRF3

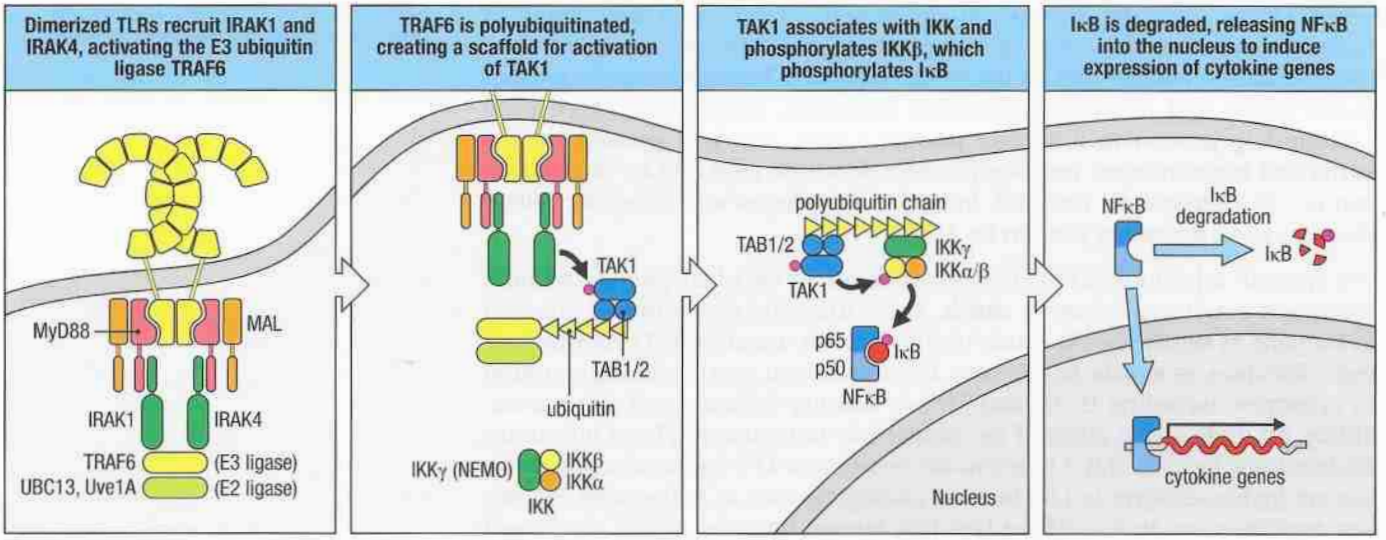

Fig. 3.14 TLR signaling can activate the transcription factor NFκB, which induces the expression of pro-inflammatory cytokines. First panel: TLRs signal via their cytoplasmic TIR domains, which are brought into proximity to each other by ligand-induced dimerization of their ectodomains. Some TLRs use the adaptor protein MyD88, and others use the MyD88/MAL pair to initiate signaling. The MyD88 death domain recruits the serine/threonine kinases IRAK1 and IRAK4, in association with the ubiquitin E3 ligase TRAF6. IRAK undergoes autoactivation and phosphorylates TRAF6, activating its E3 ligase activity. Second panel: TRAF6 cooperates with an E2 ligase (UBC13) and a cofactor (Uve1A) to generate polyubiquitin scaffolds (yellow triangles) by attachment of ubiquitin through its lysine 63 (K63) residue. This scaffold recruits a complex of proteins composed of the kinase TAK1 (transforming growth factor-β–activated kinase 1) and two adaptor proteins, TAB1 (TAK1-binding protein 1) and TAB2. TAB1 and TAB2 bind to polyubiquitin, bringing TAK1 into proximity with IRAK to become phosphorylated (red dot). Third panel: Activated TAK1 activates IKK, the IκB kinase complex. First, the IKKγ subunit (NEMO) binds to the polyubiquitin scaffold and brings the IKK complex into proximity to TAK1. TAK1 then phosphorylates and activates IKKβ. IKKβ then phosphorylates IκB, the cytoplasmic inhibitor of NFκB. Fourth panel: Phosphorylated IκB is targeted by a process of ubiquitination (not shown) that leads to its degradation. This releases NFκB, which is composed of two subunits, p50 and p65, into the nucleus, driving the transcription of many genes including those encoding inflammatory cytokines. TAK1 also stimulates activation of the mitogen-activated protein kinases (MAPKs) JNK and p38, which phosphorylate and activate AP-1 transcription factors (not shown).

and IRF7 are particularly important for inducing antiviral type I interferons, whereas a related factor, IRF5, is involved in the production of pro-inflammatory cytokines. Here we will describe how TLR signaling induces the transcription of various cytokine genes; later in the chapter, we will explain how those cytokines exert their various actions.

We consider first the signaling pathway triggered by TLRs that use MyD88. Two protein domains of MyD88 are responsible for its function as an adaptor. MyD88 has a TIR domain at its carboxyl terminus that associates with the TIR domains in the TLR cytoplasmic tails. At its amino terminus, MyD88 has a **death domain**, so named because it was first identified in signaling proteins involved in apoptosis, a type of programmed cell death. The MyD88 death domain associates with a similar death domain present in other intracellular signaling proteins. Both MyD88 domains are required for signaling, and rare mutations in either domain are associated with immunodeficiency characterized by recurrent bacterial infections in humans. The MyD88 death domain recruits and activates two serine/threonine protein kinases—**IRAK4** (IL-1 receptor-associated kinase 4) and **IRAK1**—via their death domains. This IRAK complex performs two functions: it recruits enzymes that produce a **signaling scaffold**, and it uses this scaffold to recruit other molecules that are then phosphorylated by the IRAKs.

Interleukin-1 Receptor–Associated Kinase 4 Deficiency

To form a signaling scaffold, the IRAK complex recruits the enzyme **TRAF6 (tumor necrosis factor receptor–associated factor 6)**, which is an E3 **ubiquitin ligase** that acts in cooperation with **UBC13**, an E2 ubiquitin ligase, and its cofactor **Uve1A** (together called **TRIKA1**) (see Fig. 3.14). The combined activity of TRAF6 and UBC13 is to ligate (unite with a chemical bond) one ubiquitin molecule to another protein, which can be another ubiquitin molecule, and thereby generate protein polymers. The polyubiquitin involved in signaling contains linkages between the lysine 63 residue on one ubiquitin and the carboxyl terminus of the next, forming **K63 linkages**. This polyubiquitin polymer can be initiated on other proteins, including TRAF6 itself, or produced as free linear ubiquitin polymers, and can be extended to produce **polyubiquitin chains** that act as a platform—or scaffold—to which other signaling molecules bind. Next, the scaffold recruits a signaling complex consisting of the polyubiquitin-binding adaptor proteins **TAB1**, **TAB2**, and the serine/threonine kinase **TAK1** (see Fig. 3.14). By being brought onto the scaffold, TAK1 is phosphorylated by the IRAK complex, and activated TAK1 propagates signaling by activating certain MAPKs, such as c-Jun terminal kinase (JNK) and MAPK14 (p38 MAPK). These then activate AP-1 family transcription factors that transcribe cytokine genes.

TAK1 also phosphorylates and activates the **IκB kinase (IKK)** complex, which is composed of three proteins: IKKα, IKKβ, and IKKγ (the latter also known as **NEMO**, for NFκB essential modifier). IKKγ functions by binding to polyubiquitin chains, which brings the IKK complex into proximity with TAK1. TAK1 phosphorylates and activates IKKβ. IKKβ then phosphorylates **IκB** (inhibitor of κB), which is a distinct molecule whose name should not be confused with IKKβ. IκB is a cytoplasmic protein that constitutively binds to the transcription factor NFκB, which is a family of transcription factors. One version of NFκB is composed of the subunits **p50** and **p65**, but other heterodimers and homodimers also exist. The binding of IκB traps the NFκB proteins in the cytoplasm. Phosphorylation by IKK induces the degradation of IκB, and this releases NFκB into the nucleus, where it can drive transcription of genes for pro-inflammatory cytokines such as TNF-α, IL-1β, and **IL-6**. The actions of these cytokines in the innate immune response are described in the second half of this chapter. The outcome of TLR activation can also vary depending on the cell type in which it occurs.

The ability of TLRs to activate NFκB is crucial to their role of alerting the immune system to the presence of bacterial pathogens. Rare instances of inactivating mutations in IRAK4 in humans cause an immunodeficiency, **IRAK4 deficiency**, which, like MyD88 deficiency, is characterized by recurrent

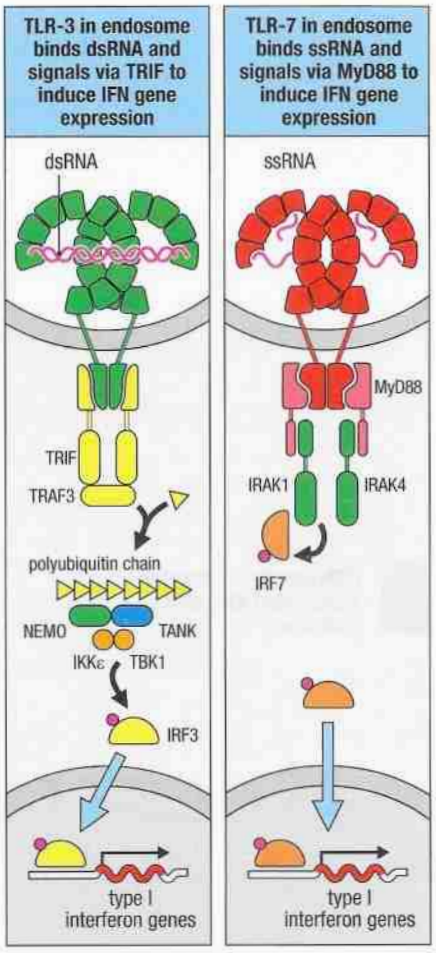

Fig. 3.15 Expression of antiviral interferons in response to viral nucleic acids can be stimulated by two different pathways from different TLRs. Left panel: TLR-3, expressed by dendritic cells and macrophages, senses double-stranded viral RNA (dsRNA). TLR-3 signaling uses the adaptor protein TRIF, which recruits the E3 ligase TRAF3 to generate K63-linked polyubiquitin chains. This scaffold recruits NEMO and TANK (TRAF family member–associated NFκB activator), which associate with the serine/threonine kinases IKKε (IκB kinase ε) and TBK1 (TANK-binding kinase 1). TBK1 phosphorylates (red dot) the transcription factor IRF3, and IRF3 then enters the nucleus and induces expression of type I interferon genes. Right panel: TLR-7, expressed by plasmacytoid dendritic cells, detects single-stranded RNA (ssRNA) and signals through MyD88. Here, IRAK1 directly recruits and phosphorylates IRF7, which is also highly expressed in plasmacytoid dendritic cells. IRF7 then enters the nucleus to induce expression of type I interferons.

bacterial infections. Mutations in human IKKγ(NEMO) produce a syndrome known as **X-linked hypohidrotic ectodermal dysplasia and immunodeficiency** or **NEMO deficiency**, which is characterized by both immunodeficiency and developmental defects.

TLR signaling also activates several members of the IRF family. IRF proteins reside in the cytoplasm and are inactive until they become phosphorylated on serine and threonine residues in their carboxyl termini. They then move to the nucleus as active transcription factors. Of the nine IRF family members, IRF3 and IRF7 are particularly important for TLR signaling and expression of antiviral type I interferons. For TLR-3, the cytoplasmic TIR domain interacts with the adaptor protein TRIF. TRIF interacts with the E3 ubiquitin ligase **TRAF3**, which, like TRAF6, generates a polyubiquitin scaffold. In TLR-3 signaling, this scaffold recruits a multiprotein complex containing the kinases **IKKε** and **TBK1**, which phosphorylate IRF3 (Fig. 3.15). TLR-4 also triggers this pathway by binding TRIF, but the IRF3 response induced by TLR-4 is relatively weak compared with that induced by TLR-3, and its functional role *in vivo* remains elusive. In contrast to TLR-3, the TLRs TLR-7, TLR-8, and TLR-9 use MyD88-dependent signaling to activate IRFs and induce expression of type I interferons. This signaling pathway is particularly relevant in plasmacytoid dendritic cells and represents a good example of how the outcome of TLR signaling can vary depending on the cell type in which it occurs. Upon TLR-7 and TLR-9 signaling in plasmacytoid dendritic cells, the MyD88 TIR domain recruits the IRAK1:IRAK4 complex as described earlier. However, the IRAK complex carries out a distinct function beyond recruiting TRAFs that generate a signaling scaffold. In these cells, IRAK1 can also physically associate with IRF7, which is highly expressed by plasmacytoid dendritic cells. This allows IRF7 to become phosphorylated by IRAK1, leading to induction of type I interferons (see Fig. 3.15). Not all IRF factors regulate type I interferon genes; IRF5, for example, plays a role in the induction of pro-inflammatory cytokines.

X-linked Hypohidrotic Ectodermal Dysplasia and Immunodeficiency

The collective ability of TLRs to activate both IRFs and NFκB means that they can stimulate either antiviral or antibacterial responses as needed. TLRs are expressed by different types of cells involved in innate immunity and by some stromal and epithelial cells, and the responses generated will differ in some respects depending on what type of cell is being activated.

3-8 The RIG-I–like receptors detect cytoplasmic viral RNAs and activate MAVS to induce type I interferon production and pro–inflammatory cytokines.

The TLRs, being expressed on the cell's plasma membrane or endocytic vesicles, are primarily sensors of extracellular microbial products. Since the discovery of the mammalian TLRs, additional families of innate sensors have been identified that detect microbial products in the cytosol (Fig. 3.16). Certain TLR family members detect extracellular viral RNAs and DNAs that enter the cell from the endocytic pathway. By contrast, viral RNAs produced within a

cell are sensed by a separate family of proteins called the **RIG-I–like receptors (RLRs)**. These proteins serve as viral sensors by binding to viral dsRNAs using an RNA helicase–like domain. The first of these sensors to be discovered was **RIG-I (retinoic acid–inducible gene I)**. RIG-I is widely expressed across tissues and cell types. Mice deficient in RIG-I are highly susceptible to infection by several kinds of single-stranded RNA viruses, including paramyxoviruses, rhabdoviruses, orthomyxoviruses, and flaviviruses, but not picornaviruses.

The RLR proteins also contain two amino-terminal **caspase recruitment domains (CARDs)**. CARD was initially recognized in a family of proteases called **caspases** (for cysteine–aspartic acid proteases), which are important in many intracellular pathways, including those leading to cell death by apoptosis. CARD is structurally related to the death domain in MyD88 and can dimerize with CARDs on other proteins to activate signaling to produce type I interferons when viral RNAs are bound (Fig. 3.17).

RIG-I discriminates between host and viral RNA by sensing differences at the 5′ end of RNA transcripts. Eukaryotic RNA is transcribed in the nucleus and contains a 5′-triphosphate group on its initial nucleotide that undergoes subsequent enzymatic modification called **capping** by the addition of a 7-methylguanosine to the 5′-triphosphate. Most RNA viruses do not replicate in the nucleus, where capping normally occurs, so their RNA genomes do not undergo this modification. Biochemical and structural studies have determined that RIG-I senses dsRNAs with the unmodified 5′-triphosphate. Many viruses produce dsRNAs with 5′-triphosphate that are detected by RIG-I, either during viral replication or due to hairpins that form when base pairing occurs within the viral RNA. In contrast, the picornaviruses, which include poliovirus and hepatitis A, replicate by a mechanism that involves the covalent attachment of a viral protein to the 5′ end of the viral RNA, so that the 5′-triphosphate is masked, which explains why RIG-I is not involved in sensing them.

MDA-5 (melanoma differentiation–associated 5) is similar in structure to RIG-I, but it senses longer dsRNAs and does not require the 5′-triphosphate for recognition. In contrast to RIG-I–deficient mice, mice deficient in MDA-5 are susceptible to picornaviruses, indicating that these two sensors of viral RNAs have crucial but distinct roles in host defense. The RLR family member **LGP2** (encoded by *DHX58*) contains a helicase domain but lacks CARDs. LGP2 appears to cooperate with RIG-I and MDA-5 in the recognition of viral RNA, as mice lacking LGP2 have impaired antiviral responses normally mediated by RIG-I or MDA-5. This cooperative viral recognition by LGP2 appears to depend on its helicase domain, because in mice, mutations that disrupt the helicase ATPase activity result in impaired IFN-β production in response to various RNA viruses.

Sensing of viral RNAs by RIG-I and MDA-5 activates signaling that leads to type I interferon production appropriate for defense against viral infection (see Fig. 3.17). Upon binding dsRNA, both RIG-I and MDA-5 assemble into filaments along the dsRNA, which promotes the aggregation of CARDs from multiple RIG-I or MDA-5 molecules. For RIG-I, aggregation of the CARDs is facilitated by recruitment of E3 ligases **Riplet** (encoded by *RNF153*) and **TRIM25**, which generate K63-linked polyubiquitin scaffolds (see Section 3-7) that stabilize interactions between the CARDs. The initiation of MDA-5 signaling does not require Riplet or TRIM25, most likely because MDA-5 more readily assembles into filaments along dsRNA, which enables aggregation of the CARDs. The aggregated CARDs interact with a downstream adaptor protein called **MAVS (mitochondrial antiviral signaling protein)**. MAVS is attached to the outer mitochondrial membrane and contains its own CARD that mediates interaction with RIG-I and MDA-5 assembled on dsRNAs. Activated MAVS also forms polymers. In this state, MAVS propagates signals by recruiting various TRAF family E3 ubiquitin ligases, including TRAF2, TRAF3, TRAF5, and TRAF6. The relative importance of each E3 ligase may differ between cell types, but their

Ligand	Recognition strategies
RIG-I	Triphosphate dsRNA
MDA-5	dsRNA
cGAS	DNA
NOD1	γ-Glutamyl diaminopimelic acid (iE-DAP)
NOD2	Muramyl dipeptide (MDP)
NLRP1	Pathogen protease activity
NLRP3	Reduced intracellular potassium, ROS, disruption of lysosomes
NAIP1 with NLRC4 (mouse)	Needle subunit of bacterial T3SS
NAIP2 with NLRC4 (mouse)	Rod subunit of bacterial T3SS
NAIP5 with NLRC4 (mouse)	Flagellin
NAIP with NLRC4 (human)	Flagellin
Pyrin	Inactivation of Rho GTPases
AIM2	DNA

Fig. 3.16 Ligands and recognition strategies for cytosolic innate immune receptors. Some cytosolic innate immune receptors detect pathogens directly, while others are activated by the activities of pathogens. This figure lists the major receptors for which the ligands or mechanisms of activation are known. ROS, reactive oxygen species; T3SS, type 3 secretion system.

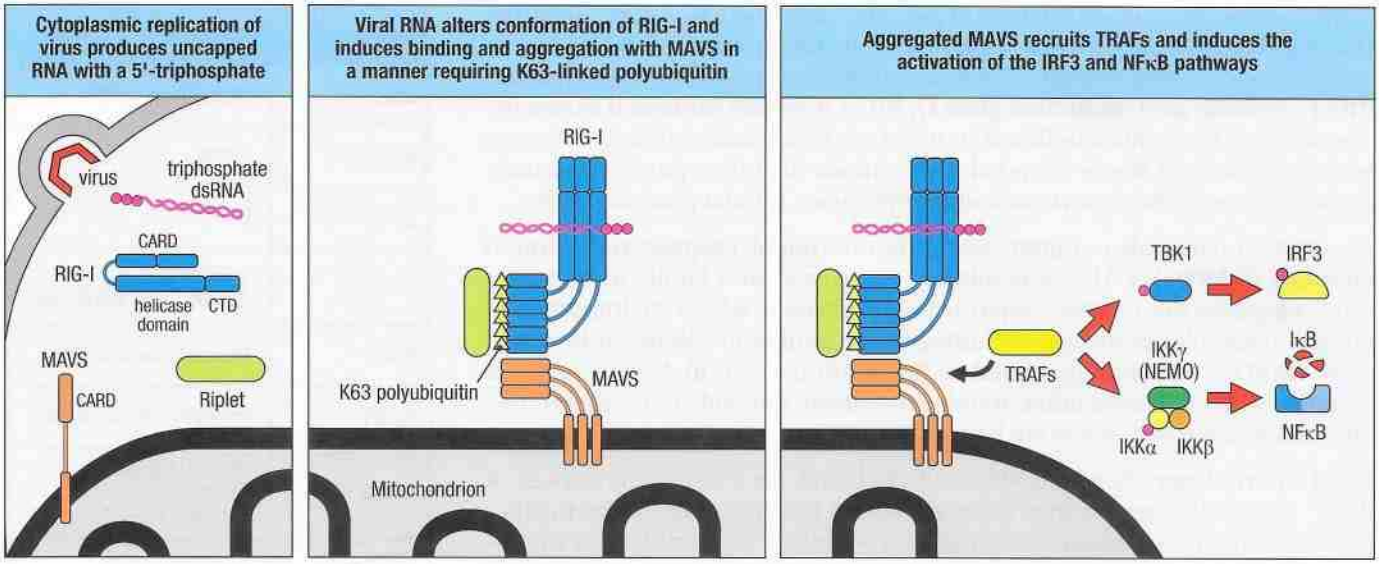

Fig. 3.17 RIG-I and other RLRs are cytoplasmic sensors of viral RNA. First panel: Before detecting viral RNA, RIG-I is cytoplasmic and in an inactive, autoinhibited conformation. The adaptor protein MAVS is attached to the mitochondrial outer membrane. Second panel: Detection of uncapped 5′-triphosphate dsRNA by RIG-I leads to assembly of RIG-I proteins along the dsRNA, enabling aggregation of the CARDs and interaction with the amino-terminal CARD of MAVS. This interaction involves the generation of K63-linked polyubiquitin from the E3 ligases Riplet and TRIM25 (the latter not shown). Third panel: The aggregation induces a proline rich region of MAVS to interact with TRAFs (see text) and leads to the generation of additional K63-linked polyubiquitin scaffold. As in TLR signaling, this scaffold recruits TBK1 and IKK complexes (see Figs. 3.14 and 3.15) to activate IRF3 and NFκB, producing type I interferons and pro-inflammatory cytokines, respectively. CTD, C-terminal domain.

further production of K63-linked polyubiquitin leads to activation of TBK1 and IRF3 and production of type I interferons, as described for TLR-3 signaling (see Fig. 3.15), and also to activation of NFκB.

The recognition of specific features of dsRNA (5′-triphosphate for RIG-I and longer dsRNAs for MDA-5) reduces the chance that cellular RNAs will trigger activation of RLRs. However, humans have been identified with mutations in RIG-I and MDA-5 that result in inappropriate activation of the receptors, which manifests as severe diseases such as SLE, Aicardi–Goutières syndrome, and Singleton–Merten syndrome. How these mutations facilitate RIG-I or MDA-5 activation is an area of active investigation, but in some cases they appear to enable the inappropriate activation of the receptors by endogenous RNAs.

3-9 Cytosolic DNA activates the cGAS–STING pathway to induce production of type I interferons.

Innate sensors that recognize cytosolic RNA use specific modifications, such as the 5′ cap, to discriminate between host and viral origin. Host DNA is generally restricted to the nucleus, but viral, microbial, or protozoan DNA may become located in the cytosol during various stages of infection. The fact that introduction of DNA into the cytosol induces the production of type I interferons was known for a number of years before the sensor or signaling proteins that mediate the response were identified. It is now known that the main sensor of cytosolic DNA is an enzyme called **cGAS, for cyclic GAMP synthase**. cGAS binds directly to cytosolic DNA, which stimulates its enzymatic activity to produce a second messenger molecule called **cyclic guanosine monophosphate–adenosine monophosphate (cyclic GMP–AMP), or cGAMP**. cGAMP binds to and activates **STING (stimulator of interferon genes)**, which is a protein encoded by *TMEM173* and localized within the endoplasmic reticulum membrane by an amino-terminal tetraspan transmembrane domain (Fig. 3.18). STING exists as an inactive homodimer until

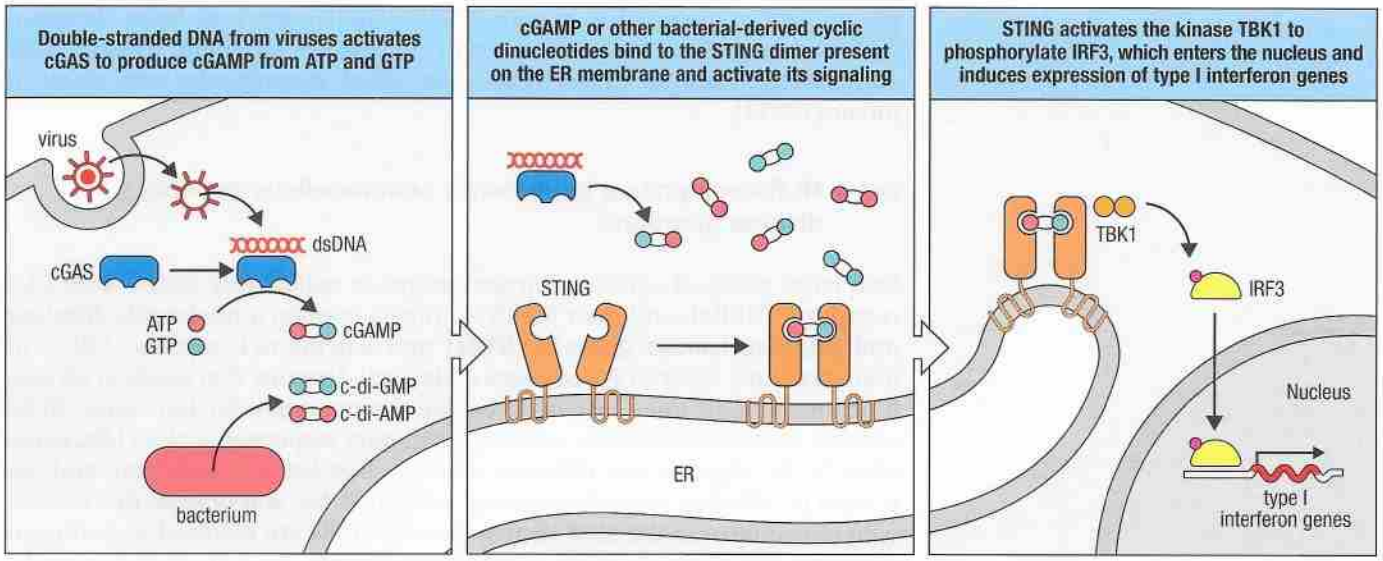

Fig. 3.18 cGAS is a cytosolic sensor of DNA that signals through STING to activate type I interferon production. First panel: cGAS resides in the cytoplasm and serves as a sensor of double-stranded DNA (dsDNA) from viruses. When cGAS binds dsDNA, its enzymatic activity is stimulated, leading to production of cyclic GMP–AMP (cGAMP). Bacteria that infect cells produce second messengers such as cyclic dinucleotides, including cyclic diguanylate monophosphate (c-di-GMP) and cyclic diadenylate monophosphate (c-di-AMP). Second panel: cGAMP and other bacterial dinucleotides can bind and activate the STING dimer present on the endoplasmic reticulum (ER) membrane. Third panel: In this state, STING activates TBK1. Active TBK1 activates IRF3, as described in Fig. 3.15.

cGAMP binding, which induces a conformation change, recruitment of TBK1, activation of IRF3, and production of type I interferons, similarly to signaling by TLR-3 and RLRs (see Figs. 3.15 and 3.17).

cGAMP is a member of a larger family of **cyclic dinucleotides (CDNs)** produced by diverse organisms. In fact, the importance of CDNs was first appreciated in bacteria, where CDNs such as cyclic diguanylate monophosphate (c-di-GMP) and cyclic diadenylate monophosphate (c-di-AMP) are synthesized by bacterial enzymes and function as signaling molecules. Before the discovery of mammalian cGAS and cGAMP, these bacterial CDNs were shown to bind and activate STING directly, suggesting that STING may itself serve as a direct sensor of intracellular bacterial infection.

cGAS and STING are expressed in most immune-cell types and many nonimmune cells, and there is good evidence that detection of DNA by the cGAS–STING pathway is important for the immune response to infection, especially viral infection. Mice harboring inactivated cGAS or STING genes show increased susceptibility to a number of DNA viruses. The cGAS–STING pathway can also be activated during infections with certain intracellular bacterial pathogens, either by bacterial DNA released during infection or by bacterial CDNs that bind STING directly, as discussed above. However, the relevance of cGAS–STING signaling for the host response to bacterial infections remains rather unclear, as the type I interferon response induced by cGAS–STING signaling is predominantly antiviral. In some contexts, the production of type I interferons can impair the response to bacteria, so it is possible that activation of cGAS–STING by some pathogens represents a pathogen-evolved mechanism of immune evasion. It is also possible that STING activation can induce other host-defense mechanisms besides production of type I interferons, such as autophagy, which may help to degrade intracellular bacteria.

As with many of the nucleic acid–sensing PRRs discussed earlier, inappropriate activation of the cGAS–STING pathway can lead to inflammatory diseases. An enzyme called **Trex1** limits activation of cGAS by degrading DNA present in the cytosol. Mice and humans with defective Trex1 develop autoimmune diseases similar to those described earlier for humans with gain-of-function mutations in MDA-5 and RIG-I (see Section 3-8). DNA accumulates in the cytosol of Trex1-deficient cells, where it activates cGAS. Accordingly, loss of cGAS reverses disease symptoms seen in Trex1-mutant mice. The origin of the cytosolic DNA in Trex1-mutant cells is an area of active investigation, but one source appears to be endogenous retroelements, mobile genetic elements

present within mammalian genomes. Other individuals have been identified with mutations in STING that result in constitutive signaling, leading to an autoimmune disorder called STING-associated vasculopathy with onset in infancy (SAVI).

3-10 NLRs comprise a large family of intracellular sensors with diverse functions.

One large group of cytosolic innate sensors is collectively called **NOD-like receptors (NLRs)**, and their family members contain a **nucleotide-binding and oligomerization domain (NOD)** and leucine-rich repeats (LRRs) in their structure. Each NLR possesses additional domains that result in diverse functions and, in some instances, enable detection of infection. Some NLRs activate NFκB to initiate the same inflammatory responses as the TLRs, while other NLRs trigger a very different response that leads to cell death and the release of different pro-inflammatory cytokines. We will discuss this second type of response in the next section. Not all NLRs are involved in pathogen detection. For example, NLRC5 and CIITA regulate the transcription of MHC class I and class II genes, respectively.

NOD1 and NOD2 are NLRs that recognize fragments of bacterial cell-wall peptidoglycans, although it is not known whether this occurs through direct binding or via accessory proteins. **NOD1** senses **γ-glutamyl diaminopimelic acid (iE-DAP)**, a breakdown product of peptidoglycans of Gram-negative bacteria such as *Salmonella* and some Gram-positive bacteria such as *Listeria*, whereas **NOD2** recognizes **muramyl dipeptide (MDP)**, which is present in the peptidoglycans of most bacteria. NOD ligands may enter the cytoplasm as a result of intracellular infection, but they may also be transported from materials captured by endocytosis, as mice lacking certain oligopeptide transporters have reduced responses to NOD ligands.

Both NOD1 and NOD2 contain CARDs. When NOD1 or NOD2 is activated, it recruits the CARD-containing serine/threonine kinase **RIP2** (also known as RICK and RIPK2) (Fig. 3.19). RIP2 associates with the E3 ligases cIAP1, cIAP2, and XIAP, whose activity generates a polyubiquitin scaffold similar to the scaffold already discussed in the context of TLR signaling. This scaffold recruits TAK1 and IKK and results in activation of NFκB as shown in Fig. 3.14. NFκB then induces the expression of genes for inflammatory cytokines and for enzymes involved in the production of **nitric oxide (NO)**, which is toxic to bacteria and intracellular parasites. In keeping with their role as sensors of bacterial components, NOD proteins are expressed in cells that are routinely exposed to bacteria. These include epithelial cells forming the barrier that bacteria must cross to establish an infection in the body and the macrophages and dendritic cells that ingest bacteria that have succeeded in entering the body. Macrophages and dendritic cells express TLRs as well as NOD1 and NOD2 and are activated by both pathways.

NOD2 seems to have a more specialized role, being strongly expressed in the Paneth cells of the gut, where it regulates the expression of potent antimicrobial peptides such as the α- and β-defensins (see Chapter 2). Loss-of-function mutations in NOD2 in humans are associated with the inflammatory bowel condition known as **Crohn's disease** (discussed in Chapter 15). Lack of NOD2 function is thought to diminish the production of defensins and other antimicrobial peptides, thereby weakening the natural barrier function of the intestinal epithelium and leading to the inflammation characteristic of this disease. Gain-of-function mutations in human NOD2 are associated with the inflammatory disorders **early-onset sarcoidosis** and **Blau syndrome**, which are characterized by spontaneous inflammation in tissues such as the liver or in the joints, eyes, and skin. Activating mutations in the NOD domain seem to promote the signaling cascade in the absence of ligand, leading to an inappropriate inflammatory response in the absence of pathogens.

Crohn's Disease

Hereditary Periodic Fever Syndromes

ANIMATION 3.6

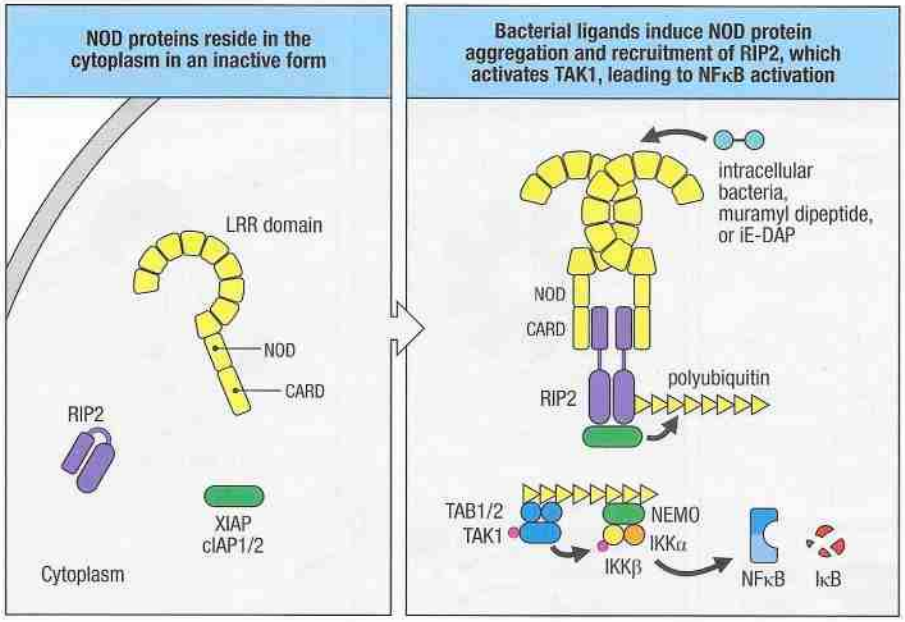

Fig. 3.19 Intracellular NOD proteins sense the presence of bacteria by recognizing bacterial peptidoglycans and activate NFκB to induce the expression of pro-inflammatory genes. First panel: NOD proteins reside in an inactive state in the cytoplasm, where they serve as sensors for various bacterial components. Second panel: Degradation of bacterial cell-wall peptidoglycans produces muramyl dipeptide, which activates NOD2. NOD1 is activated by γ-glutamyl diaminopimelic acid (iE-DAP), a breakdown product of Gram-negative bacterial cell walls. Whether these ligands are recognized directly by NOD1 and NOD2 remains unclear. Activation of NOD1 and NOD2 induces aggregation, allowing CARD-dependent recruitment of the serine/threonine kinase RIP2, which associates with E3 ligases, including XIAP (X-linked inhibitor of apoptosis protein), cIAP1 (cellular inhibitor of apoptosis 1), and cIAP2. This recruited E3 ligase activity produces a polyubiquitin scaffold, as in TLR signaling, and the association of TAK1 and the IKK complex with this scaffold leads to the activation of NFκB, as shown in Fig. 3.14. In this pathway, RIP2 acts as a scaffold to recruit XIAP, and RIP2 kinase activity is not required for signaling.

3-11 Certain NLR proteins react to infection or cellular damage by forming an inflammasome that induces cell death and secretion of inflammatory cytokines.

Some NLR proteins respond to infection or, in some cases, cellular damage in the absence of infection by inducing the formation of a multiprotein complex known as an **inflammasome**. Inflammasomes serve as platforms for the activation of inflammatory caspases such as **caspase 1**, a protease that when activated induces the proteolytic cleavage and release of pro-inflammatory cytokines IL-1β and IL-18. Cleavage of these cytokines converts them into their active forms. Activated caspase 1 also cleaves **gasdermin D**, a cytosolic protein that, once cleaved, inserts into the plasma membrane and assembles into a pore (Fig. 3.20). This pore is required for exit of active IL-1β and IL-18 from the cell, as these cytokines lack signal peptides and are otherwise confined to the cytosol. The gasdermin D pore also induces a lytic form of cell death called **pyroptosis** ('fiery death'). While the induction of host-cell death in response to infection may seem counterproductive at first glance, pyroptosis exposes intracellular pathogens that otherwise hide within host cells (for example, macrophages). These pathogens are now visible and thus susceptible to killing by neutrophils and activated macrophages recruited by the inflammatory cytokines produced by inflammasome activation.

Certain NLR proteins function as PRRs by inducing inflammasome assembly after directly binding to molecules produced by pathogens. For example, **NAIPs (NLR family, apoptosis inhibitory proteins)** assemble into inflammasomes

Fig. 3.20 Inflammasomes activate inflammatory caspases, leading to secretion of pro-inflammatory cytokines and pyroptosis. The general steps of inflammasome activation and the downstream events after activation are shown for a 'generic' NLR protein. First panel: The NLR is in an inactive conformation in unstimulated cells. Second and third panels: Some NLRs detect pathogens directly while others respond to pathogen activities. NLR activation leads to a conformation change that enables oligomerization of the NLR and recruitment of the inflammatory protease caspase 1. In unstimulated cells caspase 1 is inactive, but binding to the assembled inflammasome activates its protease activity. Active caspase 1 cleaves pro-IL-1β, pro-IL-18, and gasdermin D, converting these proteins into their active forms. Fourth panel: Cleaved gasdermin D proteins form a pore in the plasma membrane, which allows release of IL-1β and IL-18. The loss of membrane integrity also induces lysis of cells. This form of cell death is called pyroptosis. Most cells require a separate priming step to induce expression of IL-1β or IL-18 (and in some cases inflammasome components themselves). This priming step, which can be achieved through TLR activation, may help prevent accidental inflammasome activation.

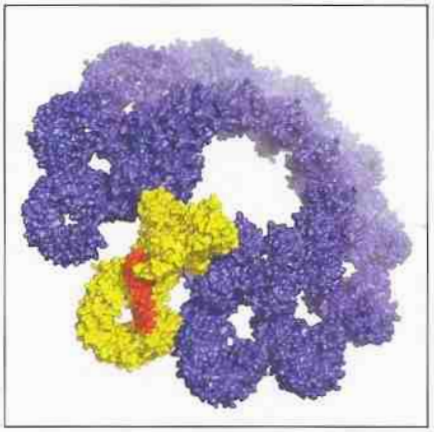

Fig. 3.21 NAIP5 and NLRC4 form an inflammasome upon flagellin recognition. A model of the structure of the NAIP5–NLRC4 inflammasome bound to flagellin. Note that NAIP5 (shown in yellow) directly contacts the D0 domain of flagellin (shown in red). This interaction induces a conformation change in NAIP5 that promotes interaction with multiple NLRC4 proteins (shown in blue) and assembly into an inflammasome. The CARDs of NLRC4 (not shown) form an inner ring and are responsible for the recruitment and activation of caspase 1.

with **NLRC4** after recognizing certain bacterial proteins that access the host cytosol. Mice encode a small family of NAIP proteins, each of which recognizes a distinct ligand. For example, **NAIP5** recognizes bacterial flagellin, whereas NAIP1 and **NAIP2** recognize distinct protein subunits of the **type III secretion system (T3SS)**, a needle-like macromolecular machine that bacterial pathogens use to inject proteins into host cells. Humans encode a single NAIP protein that has a broad specificity for flagellin and T3SS proteins. NAIP5 recognizes the highly conserved D0 domain of flagellin, which is distinct from the region of flagellin recognized by TLR-5. As a cell-surface receptor, TLR-5 can detect flagellin from potentially any extracellular flagellated bacterium, including harmless commensal species, whereas cytosolic NAIP5 will respond only to bacteria that have the capacity to invade or access the cytosol—typically only pathogenic species.

Structural analyses of the NAIP5–NLRC4 inflammasome bound to flagellin have confirmed that NAIP5 binds flagellin directly. This binding induces a conformational change in NAIP5, promoting interaction with NLRC4 and formation of an inflammasome (Fig. 3.21). NLRC4 contains an N-terminal CARD that, upon inflammasome assembly, interacts with the CARD present in caspase 1 to mediate its dimerization and activation. Active caspase 1 then cleaves multiple substrates, including the pro-forms of IL-1β, IL-18, and gasdermin D, as discussed earlier.

The importance of NAIP–NLRC4 inflammasomes for the host response to infection has been established by studies of cells or mice with disrupted NAIP or NLRC4 genes. Mice lacking NLRC4 are more susceptible to infection by numerous intracellular bacterial pathogens, including *Salmonella enterica*

ssp. *typhimurium* and *Legionella pneumophila*. NAIP and NLRC4 genes are highly expressed in intestinal epithelial cells. In these cells, inflammasome activation leads to pyroptotic cell death, which is accompanied by expulsion of the infected cell back into the intestinal lumen, which limits the ability of bacteria to establish infection.

While the NAIPs represent classic PRRs, other NLRs do not recognize pathogens directly but rather assemble inflammasomes in response to the consequences of infection, such as pathogen-induced disruptions of cellular structures. The most studied member of this subgroup of NLRs is **NLRP3** (also known as NALP3 or cryopyrin). In contrast to NLRC4, NLRP3 has a **pyrin** domain at its N terminus, hence its **NLRP** designation (NLRs with CARDs are designated NLRC). Pyrin domains are structurally related to CARDs and interact with other pyrin domains. Several seemingly unrelated triggers can induce NLRP3 activation: reduced intracellular potassium, the generation of reactive oxygen species (ROS), or the disruption of lysosomes (for example, via phagocytosis of crystalline material). It remains unclear how such diverse stimuli are sensed by this NLR, but each represents a potential consequence of infection. The loss of intracellular potassium through efflux can occur during infection with, for example, intracellular bacteria such as *Staphylococcus aureus* that produce pore-forming toxins. Also, the death of nearby cells during infection can release ATP into the extracellular space; this ATP can activate the **purinergic receptor P2X7**, which itself is a potassium channel, and allow K^+ ion efflux. As discussed earlier in this chapter, ROS are produced by phagocytes upon infection. Finally, a number of pathogens are known to disrupt or permeabilize the phagosomal membrane as a mechanism of escape or to manipulate the host cell.

While it is still not understood how NLRP3 senses such diverse changes to cellular homeostasis, structural and biochemical approaches have delineated the steps of NLRP3 inflammasome assembly. As mentioned earlier, NLRP3 lacks a CARD, so it cannot recruit caspase 1 directly. Instead, upon activation, NLRP3 oligomerizes, and this aggregation induces the pyrin domains of NLRP3 to interact with pyrin domains of another protein named **ASC** (also called PYCARD). ASC is an adaptor protein composed of an amino-terminal pyrin domain and a carboxyl-terminal CARD. Recruitment of ASC creates a platform for caspase 1 recruitment and activation, via CARD–CARD interactions, as described earlier for the NAIP–NLRC4 inflammasomes. Once caspase 1 is activated, the downstream events are similar for all inflammasomes.

NLRP1 is another NLR that assembles into an inflammasome in response to the activity of pathogens. Specifically, NLRP1 is partially degraded by several different bacterial enzymes; however, instead of inactivating NLRP1, this partial degradation releases a fragment of NLRP1 containing a CARD that assembles into an inflammasome that recruits and activates caspase 1. The best-understood example of this mechanism comes from studies of the **lethal factor protease**, a toxin secreted by the anthrax bacterium, *Bacillus anthracis*. Lethal factor enters into cells and promotes infection by cleaving MAP kinase kinases, which disrupts signaling and the ensuing immune response. However, lethal factor also cleaves NLRP1, leading to its partial degradation and inflammasome formation. Because responses downstream of caspase 1 are effective in preventing anthrax, it appears unlikely that *B. anthracis* evolved to activate NLRP1. Instead, NLRP1 appears to serve as a 'decoy' substrate for pathogen proteases and assembles into an inflammasome when such protease activity is detected.

Inflammasome activation can also be initiated by proteins other than NLRs. As discussed earlier for NLRs, some of these proteins detect pathogen-derived ligands while others sense the consequences of infection. As an example of the former, **AIM2 (absent in melanoma 2)**, a member of the **PYHIN** family of proteins, is activated by direct binding to cytosolic DNA. PYHIN proteins contain an N-terminal pyrin domain but lack the LRR domains present in the NLR

family. In place of LRR domains, PYHIN proteins have an HIN (hematopoietic expression, interferon-inducible nature, and nuclear localization) domain. The HIN domain of AIM2 recognizes the DNA genomes of pathogens and triggers caspase 1 activation through pyrin domain interactions with ASC. The protein **Pyrin** (not to be confused with the pyrin domain that is present in multiple proteins and was described earlier) is another inflammasome sensor protein with an N-terminal pyrin domain but no LRRs. Pyrin senses the inactivation of Rho GTPases, enzymes that regulate the cytoskeleton and cell motility (see Section 3-2). Kinases activated by RhoA phosphorylate specific residues in the Pyrin protein, and this phosphorylation keeps Pyrin in an inactive conformation. Certain pathogens, such as *Clostridium difficile*, produce toxins that inactivate RhoA, which correspondingly reduces phosphorylation of Pyrin and enables its activation. Activated Pyrin recruits ASC, leading to caspase 1 activation in a manner analogous to the other inflammasomes discussed above.

Many cell types, including most macrophages, must undergo a priming step before inflammasome activation can lead to release of inflammatory cytokines. This priming step induces the transcription and translation of the mRNAs that encode the pro-forms of IL-1β, IL-18, and other cytokines (see Fig. 3.20). In some cases, inflammasome components themselves (for example, NLRP3) are induced upon priming. TLR signaling can satisfy this priming step, which may help ensure that inflammasome activation proceeds primarily during infections. Priming is not always necessary, however, as some cells in tissues (for example, the intestine) express pro-IL-1 β and pro-IL-18 constitutively.

Caspase 11 (in mice) and **caspase 4** and **caspase 5** (in humans) are pro-inflammatory caspases that also function as cytosolic sensors of LPS. Once activated, these caspases are able to cleave and activate gasdermin D directly, leading to pyroptosis, but they do not appear to directly cleave the pro-forms of IL-1β and IL-18. However, once pyroptosis is initiated, K^+ efflux occurs via gasdermin D pores, resulting in NLRP3 activation, caspase 1 activation, and IL-1β and IL-18 processing and release. This response to LPS has been referred to as a 'non-canonical' inflammasome pathway. The ability of LPS to induce toxic shock in mice is due primarily to activation of caspase 11. TLR-4 is still involved, however, because caspase 11 requires TLR-4 signaling to be transcriptionally induced.

Inappropriate inflammasome activation has been associated with various diseases. **Gout** has been known for many years to cause inflammation in the cartilaginous tissues by the deposition of monosodium urate crystals, but how urate crystals caused inflammation was a mystery. Although the precise mechanism is still unclear, urate crystals are known to activate the NLRP3 inflammasome, which induces the inflammatory cytokines associated with the symptoms of gout. Mutations in NLRs can activate inflammasomes inappropriately, and they are the cause of some inherited **autoinflammatory diseases**, in which inflammation occurs in the absence of infection. Mutations in NLRP3 in humans are associated with hereditary periodic fever syndromes, such as **familial cold autoinflammatory syndrome** and **Muckle–Wells syndrome** (discussed in more detail in Chapter 13). Individuals with activating NLRC4 mutations have also been identified. Macrophages from individuals with these conditions show spontaneous production of inflammatory cytokines such as IL-1β and IL-18. We will discuss how pathogens can interfere with formation of the inflammasome in Chapter 13.

Hereditary Periodic Fever Syndromes

3-12 Activation of innate sensors in macrophages and dendritic cells triggers changes in gene expression that have far–reaching effects on the immune response.

Besides activating effector functions and cytokine production, another outcome of the activation of innate sensing pathways is the induction of **co-stimulatory molecules** on tissue dendritic cells and macrophages (see

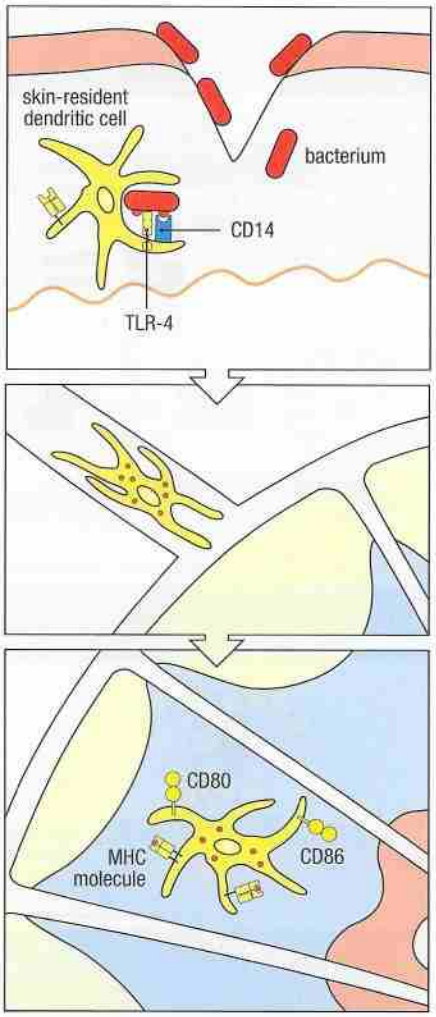

Fig. 3.22 Bacterial LPS induces changes in dendritic cells, stimulating them to migrate and to initiate adaptive immunity by activating T cells. Top panel: Immature dendritic cells in the skin are highly phagocytic and macropinocytic but lack the ability to activate T lymphocytes. Dendritic cells residing in the skin ingest microbes and their products and degrade them. During a bacterial infection, the dendritic cells are activated by various innate sensors, and the activation induces two types of changes. Second panel: The dendritic cells migrate out of the tissues into the lymphatic system and begin to mature. They lose the ability to ingest antigen but gain the ability to stimulate T cells. Third panel: In the regional lymph nodes, they become mature dendritic cells. They change the character of their cell-surface molecules, increasing the number of MHC molecules on their surface and the expression of the co-stimulatory molecules CD80 and CD86.

Section 1-15). We will describe these in more detail later in the book but mention them now because they provide an important link between innate and adaptive immune responses. Two important co-stimulatory molecules are the cell-surface proteins CD80 and CD86, which are induced on macrophages and tissue dendritic cells by innate sensors such as TLRs in response to pathogen recognition (Fig. 3.22). CD80 and CD86 are recognized by specific **co-stimulatory receptors** expressed by cells of the adaptive immune response, particularly CD4 T cells, and their activation is an important step in activating adaptive immune responses.

Substances such as LPS that induce co-stimulatory activity have been used for years in mixtures that are co-injected with protein antigens to enhance their immunogenicity. These substances are known as **adjuvants** (see Appendix I, Section A-1), and it was found empirically that the best adjuvants contain microbial components that induce macrophages and tissue dendritic cells to express co-stimulatory molecules and cytokines. We now know that the effect of these microbial components is due to activation of PRRs. As we shall see in Chapters 9 and 11, the cytokines produced in response to infections influence the functional character of the adaptive immune response that develops. In this way, the ability of the innate immune system to discriminate among different types of pathogens is used by the organism to ensure an appropriate module of the adaptive immune response is induced.

3-13 Toll signaling in *Drosophila* is downstream of a distinct set of pathogen-recognition molecules.

Before leaving innate sensing, we shall look briefly at how Toll, TLRs, and NODs are used in invertebrate innate immunity. Although Toll is central to defense against both bacterial and fungal pathogens in *Drosophila*, Toll itself is not a pattern-recognition receptor but is downstream of other proteins that detect pathogens (Fig. 3.23). In *Drosophila*, there are 13 genes encoding **peptidoglycan-recognition proteins (PGRPs)** that bind the peptidoglycan components of bacterial cell walls. Another family, the **Gram-negative binding proteins (GNBPs)**, recognizes LPS and β-(1,3)-linked glucans. GNBPs recognize Gram-negative bacteria and fungi rather than Gram-positive bacteria. The family members GNBP1 and PGRP-SA cooperate in the recognition of peptidoglycan from Gram-positive bacteria. They interact with a serine protease called **Grass**, which initiates a proteolytic cascade that terminates in the cleavage of the protein Spätzle. One of the cleaved fragments forms a homodimer that binds to Toll and induces its dimerization, which in turn stimulates the antimicrobial response. A fungus-specific recognition protein, GNBP3, also activates the proteolytic cascade, causing cleavage of Spätzle and activation of Toll.

In *Drosophila*, fat-body cells and hemocytes are phagocytic cells that act as part of the fly's immune system. When the Spätzle dimer binds to Toll, hemocytes synthesize and secrete antimicrobial peptides. The Toll signaling pathway in *Drosophila* activates a transcription factor called DIF, which is related to mammalian NFκB. DIF enters the nucleus and induces the transcription of genes for antimicrobial peptides such as drosomycin. Another

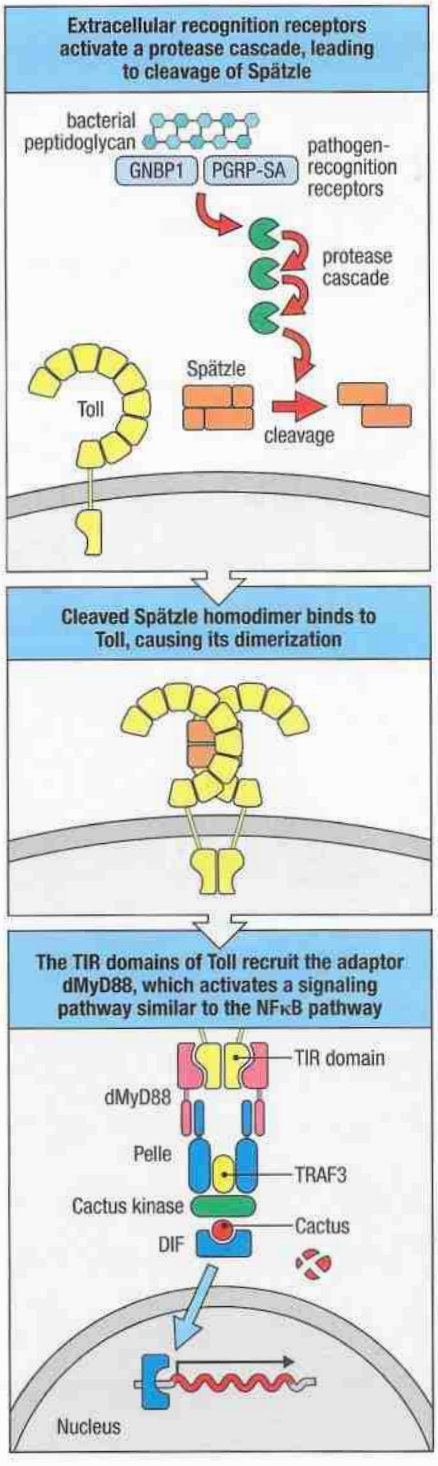

Fig. 3.23 *Drosophila* Toll is activated as a result of a proteolytic cascade initiated by pathogen recognition. The peptidoglycan-recognition protein PGRP-SA and the Gram-negative binding protein GNBP1 cooperate in the recognition of bacterial pathogens and activate the first protease in a protease cascade that leads to cleavage of the *Drosophila* protein Spätzle (first panel). Cleavage alters the conformation of Spätzle, enabling it to bind Toll and induce Toll dimerization (second panel). Toll's cytoplasmic TIR domains recruit the adaptor protein dMyD88 (third panel), which initiates a signaling pathway very similar to that leading to the release of NFκB from its cytoplasmic inhibitor in mammals. The *Drosophila* version of NFκB is the transcription factor DIF, which enters the nucleus and activates the transcription of genes encoding antimicrobial peptides. Fungal recognition also leads to cleavage of Spätzle and the production of antimicrobial peptides by this pathway.

Drosophila factor in the NFκB family, **Relish**, induces the production of antimicrobial peptides in response to the **Imd (immunodeficiency) signaling pathway**, which is triggered in *Drosophila* by particular PGRPs that recognize Gram-negative bacteria. Relish induces expression of the antimicrobial peptides diptericin, attacin, and cecropin, which are distinct from the peptides induced by Toll signaling. Thus, the Toll and Imd pathways activate effector mechanisms to eliminate infection by different kinds of pathogens. Four mammalian PGRP homologs have been identified but act differently than in *Drosophila*. One, PGLYRP-2, is secreted and functions as an amidase to hydrolyze bacterial peptidoglycans. The others are present in neutrophil granules and exert a bacteriostatic action through interactions with bacterial cell-wall peptidoglycan.

3-14 TLR and NOD genes have undergone extensive diversification in both invertebrates and some primitive chordates.

There are only about a dozen mammalian TLR genes, but some organisms have diversified their repertoire of innate recognition receptors, especially those containing LRR domains, to a much greater degree. The sea urchin *Strongylocentrotus purpuratus* has an unprecedented 222 different TLR genes, more than 200 NOD-like receptor genes, and more than 200 scavenger receptor genes in its genome. The sea urchin also has an increased number of proteins that are likely to be involved in signaling from these receptors, there being, for example, four genes that are similar to the single mammalian MyD88 gene. However, there is no apparent increase in the number of downstream targets, such as the family of NFκB transcription factors, suggesting that the ultimate outcome of TLR signaling in the sea urchin may be very similar to that in other organisms.

Sea urchin TLR genes fall into two broad categories. One is a small set of 11 divergent genes. The other is a large family of 211 genes, which show a high degree of sequence variation within particular LRR regions; this, together with the large number of pseudogenes in this family, indicates rapid evolutionary turnover, suggesting rapidly changing receptor specificities, in contrast with the few stable mammalian TLRs. Although the pathogen specificity of sea urchin TLRs is unknown, the hypervariability in the LRR domains could be used to generate a highly diversified pathogen-recognition system based on Toll-like receptors. A similar expansion of innate receptors has occurred in some chordates, the phylum to which vertebrates belong. Amphioxus (the lancelet) is a nonvertebrate chordate lacking an adaptive immune system. The amphioxus genome contains 71 TLRs, more than 100 NOD-like receptors, and more than 200 scavenger receptors. As we will see in Chapter 5, a primitive vertebrate lineage—the jawless fishes, which lack immunoglobulin-based and T cell–based adaptive immunity—uses somatic gene rearrangement of LRR-containing proteins to provide a version of adaptive immunity (see Section 5-18).

Summary.

Innate immune cells express several receptor systems that recognize microbes and induce rapid defenses as well as delayed cellular responses. Several scavenger and lectin-like receptors on neutrophils, macrophages, and dendritic cells help rapidly eliminate microbes through phagocytosis. G protein–coupled receptors for C5a (which can be produced by activation of the complement system's innate pathogen-recognition ability) and for the bacterial peptide fMLF synergize with phagocytic receptors in activating the NADPH oxidase in phagosomes to generate antimicrobial reactive oxygen intermediates. Toll-like receptors (TLRs) on the cell surface and in the membranes of endosomes detect microbes outside the cell and activate several host-defense signaling pathways. The NFκB and IRF pathways downstream of these receptors induce pro-inflammatory cytokines, including TNF-α, IL-1β, and IL-6, and antiviral cytokines including type I interferons. Other receptor families detect microbial infection in the cytosol. RIG-I and MDA-5 detect viral infection by sensing the presence of viral RNAs and activate the MAVS pathway, while cGAS senses cytosolic DNA and activates the STING pathway; both of these pathways induce type I interferons. NLR proteins detect pathogen products within the cytosol or sense changes to the cell due to pathogen infection. Some NLRs activate NFκB and induce the production of pro-inflammatory cytokines, while others form inflammasomes, leading to secretion of pro-inflammatory cytokines and pyroptotic cell death. The signaling pathways activated by all of these primary sensors of pathogens induce a variety of genes, including those for cytokines, chemokines, and co-stimulatory molecules that have essential roles in immediate defense and in directing the course of the adaptive immune response later in infection.

Consequences of innate immune activation.

We will now examine the responses of innate immunity induced as an immediate consequence of pathogen recognition by the sensors described in the first half of this chapter. We will focus on the major phagocytes—neutrophils, macrophages, and dendritic cells—and the cytokines they produce that induce and maintain inflammation. First, we will introduce the families of cytokines and chemokines that coordinate many cellular responses, such as the recruitment of neutrophils and other immune cells to sites of infection. We will discuss the various adhesion molecules that are induced on immune cells circulating in the blood and on endothelial cells of blood vessels to coordinate movement of cells out of the blood and into infected tissues. We will consider in some detail how macrophage-derived chemokines and cytokines promote the continued destruction of infecting microbes. This is achieved both by stimulating the production and recruitment of fresh phagocytes and by inducing another phase of the innate immune response—the acute-phase response—in which the liver produces proteins that act as opsonizing molecules, helping to augment the actions of complement. We will also look at the mechanism of action of antiviral interferons, the type I interferons, and finally examine the growing class of innate lymphoid cells, or ILCs, which include the NK cells that contribute to innate immune defense against viruses, other intracellular pathogens, and even cancerous cells. ILCs exert a diverse array of effector functions that contribute to a rapid innate immune response to infection. They respond to early cytokine signals provided by innate sensor cells and amplify the response by producing various types of effector cytokines. Some time after induction of the innate response, an adaptive response will ensue that uses many of the same effector mechanisms used by the innate immune system but targets them with much greater precision. The effector mechanisms described

here therefore serve as a primer for the focus on adaptive immunity in the later parts of this book.

3-15 Cytokines and their receptors fall into distinct families of structurally related proteins.

Cytokines are small proteins (about 25 kDa) that are released by various cells in the body, usually in response to an activating stimulus, and that induce responses through binding to specific receptors. Cytokines can act in an **autocrine** manner, affecting the behavior of the cell that releases the cytokine, or in a **paracrine** manner, affecting adjacent cells. Some cytokines are even stable enough to act in an **endocrine** manner, affecting distant cells, although this depends on their ability to enter the circulation and on their half-life in the blood. In an attempt to develop a standardized nomenclature for molecules secreted by, and acting on, leukocytes, many cytokines are called by the name **interleukin (IL)** followed by a number (for example, IL-1 or IL-2). However, not all cytokines are included in this system; thus, students of immunology are still faced with a somewhat confusing and difficult task. The cytokines are listed alphabetically, together with their receptors, in eAppendix III.

Cytokines can be grouped by structure into families—the IL-1 family, the hematopoietin superfamily, the interferons (described in Section 3-7), the TNF family, and chemokines—and their receptors can likewise be grouped (Fig. 3.24). The **IL-1 family** contains 11 members, notably IL-1α, IL-1β, IL-18, and IL-33. Most members of this family are produced as inactive proproteins that are cleaved (removing an amino-terminal peptide) to produce the mature cytokine. The exception to this rule is IL-1α, for which both the proprotein and its cleaved forms are biologically active. As discussed earlier (see Section 3-11), mature IL-1β and IL-18 are produced by macrophages through the action of caspase 1 in response to TLR signaling and inflammasome activation. The IL-1 family receptors have TIR domains in their cytoplasmic tails and signal by the NFκB pathway described earlier for TLRs. The IL-1 receptor functions in concert with a second transmembrane protein, the IL-1 receptor accessory protein (IL1RAP), which is required for IL-1 signal transduction.

The **hematopoietin superfamily** of cytokines is quite large and includes non-immune-system growth and differentiation factors, such as erythropoietin (which stimulates red blood cell development), as well as interleukins with roles in innate immunity and adaptive immunity. IL-6 is a member of this superfamily, as is the cytokine GM-CSF, which stimulates the production of new monocytes and granulocytes in the bone marrow. Many of the soluble cytokines made by activated T cells are members of the hematopoietin superfamily. The receptors for the hematopoietin cytokines are tyrosine kinase–associated receptors that form dimers when their cytokine ligand binds. Dimerization initiates intracellular signaling from the tyrosine kinases associated with the cytoplasmic domains of the receptor. Some types of cytokine receptors are composed of two identical subunits, but others have two different subunits. An important feature of cytokine signaling is the large variety of different receptor subunit combinations that occur.

These cytokines and their receptors can also be further divided into subfamilies characterized by functional similarities and genetic linkage. For instance, IL-3, IL-4, IL-5, IL-13, and GM-CSF are related structurally, their genes are closely linked in the genome, and they are often produced together by the same kinds of cells. In addition, they bind to closely related receptors, which belong to the family of **class I cytokine receptors**. The IL-3, IL-5, and GM-CSF receptors form a subgroup that shares a **common β chain (β_c)**. Another subgroup of class I cytokine receptors is defined by a **common γ chain (γ_c)** of the IL-2 receptor. This chain is shared by receptors for the cytokines IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 and is encoded by a gene located on the X chromosome. Mutations

Homodimeric receptors		Receptors for erythropoietin and growth hormone
Heterodimeric receptors with a common chain		Receptors for IL-3, IL-5, GM-CSF share a common chain, CD131 or β_c (common β chain)
		Receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 share a common chain, CD132 or γ_c (common γ chain). IL-2 receptor also has a third chain, a high-affinity subunit IL-2Rα (CD25)
Heterodimeric receptors (no common chain)		IL-1 family receptors
		Receptors for IL-13, IFN-α, IFN-β, IFN-γ, IL-10
TNF receptor family		Tumor necrosis factor (TNF) receptors I and II, CD40, Fas (Apo1, CD95), CD30, CD27, nerve growth factor receptor
Chemokine receptor family		CCR1–10, CXCR1–5, XCR1, CX3CR1

Fig. 3.24 Cytokine receptors belong to families of receptor proteins, each with a distinctive structure. Many cytokines signal through receptors of the hematopoietin receptor superfamily, named after its first member, the erythropoietin receptor. The hematopoietin receptor superfamily includes homodimeric and heterodimeric receptors, which are subdivided into families on the basis of protein sequence and structure. Examples of these are given in the first three rows. Heterodimeric class I cytokine receptors have an α chain that often defines the ligand specificity of the receptor; they may share with other receptors a common β or γ chain that confers the intracellular signaling function. Heterodimeric class II cytokine receptors have no common chain and include receptors for interferons or interferon-like cytokines. Many cytokine receptors signal through the JAK–STAT pathway. The IL-1 family receptors have extracellular immunoglobulin domains and signal as dimers through TIR domains in their cytoplasmic tails and through MyD88. Other families of cytokine receptors are the tumor necrosis factor receptor (TNFR) family and the chemokine receptor family, the latter belonging to the very large family of G protein–coupled receptors. The ligands of the TNFR family act as trimers and may be associated with the cell membrane rather than being secreted.

that inactivate γ_c cause an **X-linked severe combined immune deficiency (X-linked SCID)** because of inactivation of the signaling pathways for several cytokines—IL-7, IL-15, and IL-2—that are required for normal lymphocyte development (see Section 13-2). More distantly related, the receptor for IFN-γ is a member of a small family of heterodimeric cytokine receptors with some similarities to the hematopoietin receptor superfamily. These so-called **class II cytokine receptors** (also known as interferon receptors) include the receptors for IFN-α and IFN-β and the IL-10 receptor. The hematopoietin and interferon receptors all signal through the JAK–STAT pathway described in the next section and activate different combinations of STATs with different effects.

X-linked Severe Combined Immune Deficiency

The **TNF family**, of which TNF-α is the prototype, contains more than 17 cytokines with important functions in adaptive immunity and innate immunity. Unlike most of the other immunologically important cytokines, many members of the TNF family are transmembrane proteins, a characteristic that gives them distinct properties and limits their range of action. Some, however, can be released from the membrane in some circumstances. They are usually found as homotrimers of a membrane-bound subunit, although

some heterotrimers consisting of different subunits also occur. TNF-α (sometimes called simply TNF) is initially expressed as a trimeric membrane-bound cytokine but can be released from the membrane. The effects of TNF-α are mediated by either of two **TNF receptors**. TNF receptor I (TNFR-I) is expressed on a wide range of cells, including endothelial cells and macrophages, whereas TNFR-II is expressed largely by lymphocytes. The receptors for cytokines of the TNF family are structurally unrelated to the receptors described above and also have to cluster to become activated. Because TNF family cytokines are produced as trimers, the binding of these cytokines induces the clustering of three identical receptor subunits. The signaling pathway activated by these receptors is described in Chapter 7, where we see that signaling uses members of the TRAF family to activate the so-called non-canonical NFκB pathway.

Members of the chemokine receptor family are listed in eAppendix IV, along with the chemokines they recognize. These receptors have a seven-transmembrane structure and signal by interacting with G proteins as described in Section 3-2.

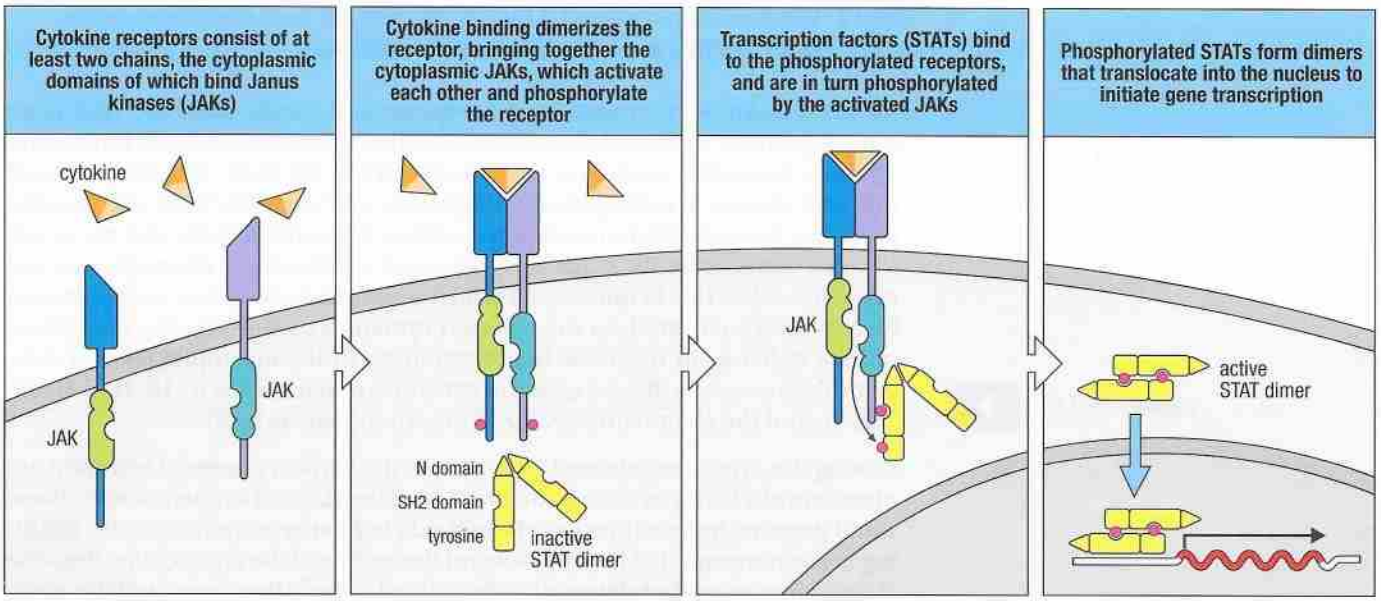
3-16 Cytokine receptors of the hematopoietin superfamily are associated with the JAK family of tyrosine kinases, which activate STAT transcription factors.

The signaling chains of the hematopoietin superfamily of cytokine receptors are noncovalently associated with protein tyrosine kinases of the **Janus kinase (JAK) family**—so called because they have two tandem kinase-like domains and thus resemble the two-headed mythical Roman god Janus. There are four members of the JAK family: Jak1, Jak2, Jak3, and Tyk2. Because mice deficient for individual JAK family members show different phenotypes, each kinase must have a distinct function. For example, Jak3 is used by γ_c for signaling by several of the cytokines described above. Mutations that inactivate Jak3 cause a form of **SCID** that is not X-linked.

ANIMATION 3.7

The dimerization or clustering of receptor signaling chains brings the JAKs into close proximity, causing phosphorylation of each JAK on a tyrosine residue that stimulates its kinase activity. The activated JAKs then phosphorylate their associated receptors on specific tyrosine residues. This phosphotyrosine, and the specific amino acid sequence surrounding it, creates a binding site that is recognized by **SH2 domains** found in other proteins, in particular members of a family of transcription factors known as **signal transducers and activators of transcription (STATs)** (Fig. 3.25).

There are seven STATs (1–4, 5a, 5b, and 6), which reside in the cytoplasm in an inactive form until activated by cytokine receptors. Before activation, most STATs form homodimers, due to a specific homotypic interaction between domains present at the amino termini of the individual STAT monomers. The receptor specificity of each STAT is determined by the recognition of the distinctive phosphotyrosine sequence on each activated receptor by the different SH2 domains within the various STAT proteins. Recruitment of a STAT to the activated receptor brings the STAT close to an activated JAK, which can then phosphorylate the conserved tyrosine residue in the carboxyl terminus of each of the STATs. This leads to a rearrangement of the STAT dimer, in which the phosphotyrosine of each STAT monomer binds to the SH2 domain of the other STAT monomer, forming a configuration that can bind DNA with high affinity. Activated STATs predominantly form homodimers, with a cytokine typically activating one type of STAT. For example, IFN-γ activates STAT1 and generates STAT1 homodimers, whereas IL-4 activates STAT6, generating STAT6 homodimers. Other cytokine receptors can activate several STATs, and some STAT heterodimers can be formed, such as STAT1–STAT2 heterodimers formed downstream of the receptor for



Cytokine receptors consist of at least two chains, the cytoplasmic domains of which bind Janus kinases (JAKs)
Cytokine binding dimerizes the receptor, bringing together the cytoplasmic JAKs, which activate each other and phosphorylate the receptor
Transcription factors (STATs) bind to the phosphorylated receptors, and are in turn phosphorylated by the activated JAKs

active STAT dimer

Fig. 3.25 Many cytokine receptors signal using a rapid pathway called the JAK–STAT pathway. First panel: Many cytokines act via receptors that are associated with cytoplasmic Janus kinases (JAKs). The receptor consists of at least two chains, each associated with a specific JAK. Second panel: Binding of ligand brings the two chains together, allowing the JAKs to phosphorylate and activate each other, and then to phosphorylate (red dots) specific tyrosines in the receptor tails. Each member of the STAT (signal transducer and activator of transcription) family of proteins has an N-terminal domain that homodimerizes STAT monomers in the cytosol before activation and an SH2 domain that binds to a tyrosine-phosphorylated cytokine receptor tail. Third panel: Upon binding, the STAT homodimers are phosphorylated on a conserved tyrosine residue in their carboxyl terminus by JAKs. Fourth panel: After phosphorylation, the STAT dimer reconfigures into a dimer that is stabilized by the SH2 domain of one monomer binding to a phosphotyrosine residue on the other monomer. They then translocate to the nucleus, where they bind to and activate the transcription of a variety of genes important for adaptive immunity.

IFN-α and IFN-β. The phosphorylated STAT dimer enters the nucleus, where it acts as a transcription factor to initiate the expression of selected genes that can regulate growth, differentiation, and/or survival of particular subsets of lymphocytes.

Because signaling by these receptors depends on tyrosine phosphorylation, dephosphorylation of the receptor complex by **tyrosine phosphatases** is one way that cells can terminate signaling. A variety of tyrosine phosphatases have been implicated in the dephosphorylation of cytokine receptors, JAKs, and STATs. These include the nonreceptor tyrosine phosphatases SHP-1 and SHP-2 (encoded by *PTPN6* and *PTPN11*) and the transmembrane receptor tyrosine phosphatase **CD45**, which is expressed as multiple isoforms on many hematopoietic cells. Cytokine signaling can also be terminated by negative feedback involving specific inhibitors that are induced by cytokine activation. The **suppressor of cytokine signaling (SOCS)** proteins are a class of inhibitors that terminate the signaling of many cytokine and hormone receptors. SOCS proteins contain an SH2 domain that can recruit them to the phosphorylated JAK protein or receptor, and they can inhibit JAK activity directly, or compete for the receptor, and direct the ubiquitination and subsequent degradation of JAKs and STATs. SOCS proteins are induced by STAT activation and thus inhibit receptor signaling after the cytokine has had its effect. Their importance can be seen in SOCS1-deficient mice, which develop a multiorgan inflammatory infiltrate caused by increased signaling from interferon receptors, γ_c-containing receptors, and TLRs. Another class of inhibitory proteins, the **protein inhibitors of activated STAT (PIAS)**, regulate the response to cytokines, as well as other biological pathways, by promoting the degradation of pathway components.

3-17 Chemokines released by macrophages and dendritic cells recruit effector cells to sites of infection.

All the cytokines produced by macrophages in innate immune responses have important local and systemic effects that contribute to both innate and adaptive immunity, and these are summarized in Fig. 3.26. The recognition of different classes of pathogens by phagocytes and dendritic cells may involve signaling through different receptors, such as the various TLRs, and can result in some variation in the cytokines expressed by stimulated macrophages and dendritic cells. This is one way in which appropriate immune responses can be selectively activated, as the released cytokines orchestrate the next phase of host defense. In response to activation by PRRs, macrophages and dendritic cells secrete a diverse group of cytokines that includes IL-1β, IL-6, IL-12, TNF-α, and the chemokine CXCL8 (formerly known as IL-8).

ANIMATION 3.8

Among the cytokines released by tissues in the earliest phases of infection are members of a family of chemoattractant cytokines known as chemokines. These small proteins induce directed **chemotaxis** in nearby responsive cells, resulting in the movement of the cells toward the source of the chemokine. Because chemokines were first detected in functional assays, they were initially given a variety of names, which are listed along with their standardized nomenclature in eAppendix IV. All the chemokines are related in amino acid sequence, and their receptors are G protein–coupled receptors (see Section 3-2). The signaling pathway stimulated by chemokines causes changes in cell adhesiveness and changes in the cell's cytoskeleton that lead to directed migration. Chemokines can be produced and released by many different types of cells, not only those of the immune system. In the immune system they function mainly as chemoattractants for leukocytes, recruiting monocytes, neutrophils, and other effector cells of innate immunity from the blood into sites of

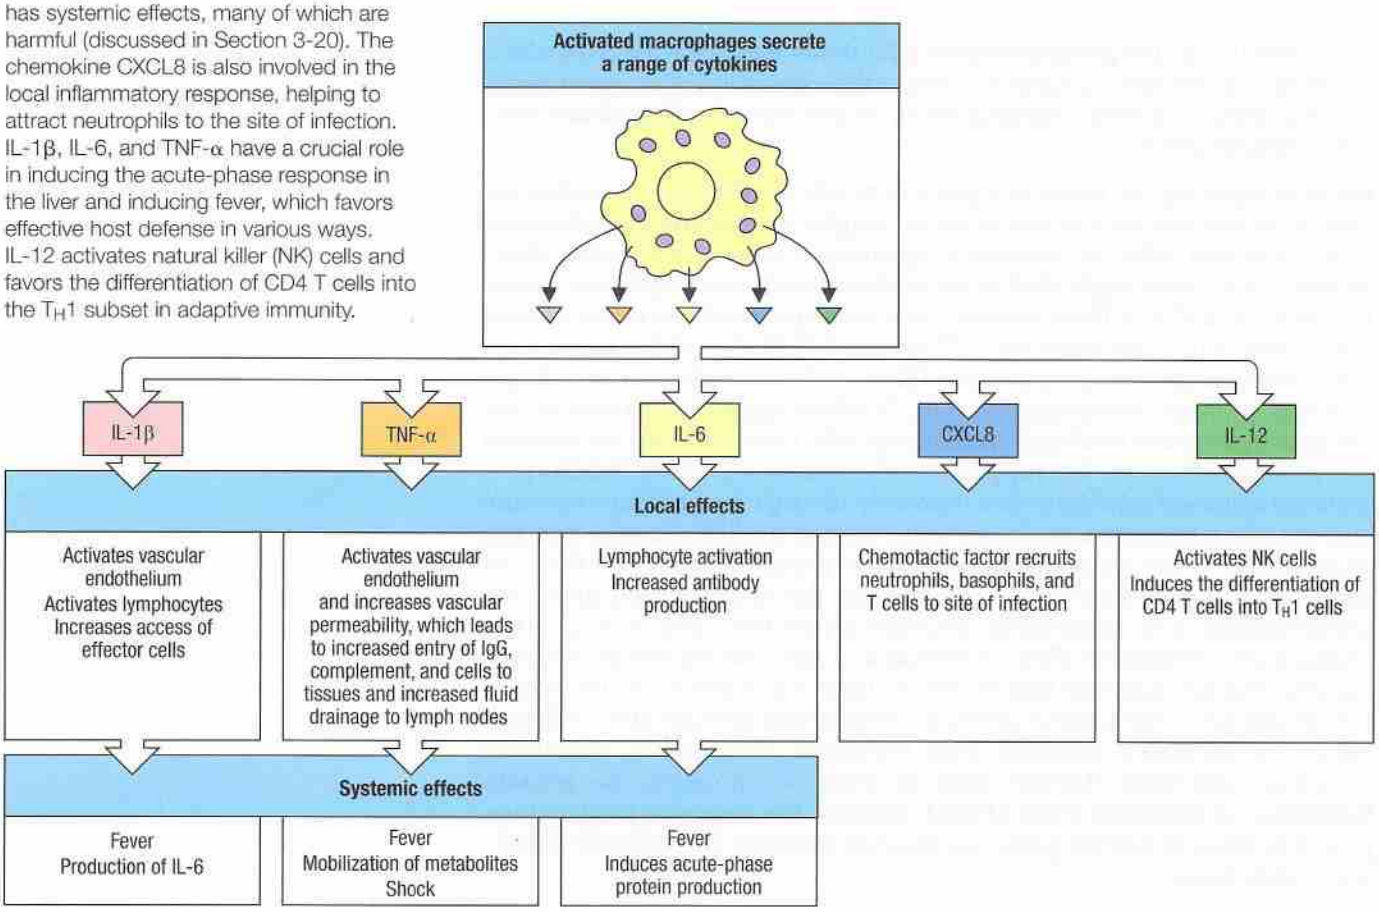

Fig. 3.26 Important cytokines and chemokines secreted by dendritic cells and macrophages in response to bacterial products include IL-1β, IL-6, CXCL8, IL-12, and TNF-α. TNF-α is an inducer of a local inflammatory response that helps to contain infections. It also has systemic effects, many of which are harmful (discussed in Section 3-20). The chemokine CXCL8 is also involved in the local inflammatory response, helping to attract neutrophils to the site of infection. IL-1β, IL-6, and TNF-α have a crucial role in inducing the acute-phase response in the liver and inducing fever, which favors effective host defense in various ways. IL-12 activates natural killer (NK) cells and favors the differentiation of CD4 T cells into the T_H1 subset in adaptive immunity.

infection. They also guide lymphocytes in adaptive immunity, as we will learn in Chapters 9–11. Some chemokines also function in lymphocyte development and migration and in angiogenesis (the growth of new blood vessels). There are more than 50 known chemokines, and this striking multiplicity may reflect their importance in delivering cells to their correct locations, which seems to be their main function in the case of lymphocytes. Some of the chemokines that are produced by or that affect human innate immune cells are listed in Fig. 3.27, along with their properties.

Chemokines fall mainly into two related but distinct groups. **CC chemokines** have two adjacent cysteine residues near the amino terminus, whereas in **CXC chemokines** the corresponding two cysteine residues are separated by a single amino acid. The CC chemokines promote the migration of monocytes, lymphocytes, and other cell types. One example relevant to innate immunity is CCL2, which attracts monocytes through the receptor CCR2B, inducing their migration from the bloodstream to become tissue macrophages. In contrast, neutrophil migration is promoted by CXC chemokines. CXCL8, acting through CXCR2, mobilizes neutrophils from bone marrow and induces them to leave the blood and migrate into the surrounding tissues. CCL2 and CXCL8 therefore have similar but complementary functions in the innate immune response, attracting monocytes and neutrophils, respectively.

The role of chemokines in cell recruitment is twofold. First, they act on the leukocyte as it rolls along endothelial cells at sites of inflammation, converting this rolling into stable binding by triggering a change of conformation in the adhesion molecules known as leukocyte integrins. These conformational changes enable integrins to bind strongly to their ligands on the endothelial

Class	Chemokine	Produced by	Receptors	Cells attracted	Major effects
CXC	CXCL8 (IL-8)	Monocytes Macrophages Fibroblasts Epithelial cells Endothelial cells	CXCR1 CXCR2	Neutrophils Naive T cells	Mobilizes, activates, and degranulates neutrophils Angiogenesis
	CXCL7 (PBP, β-TG, NAP-2)	Platelets	CXCR2	Neutrophils	Activates neutrophils Clot resorption Angiogenesis
	CXCL1 (GROα) CXCL2 (GROβ) CXCL3 (GROγ)	Monocytes Fibroblasts Endothelium	CXCR2	Neutrophils Naive T cells Fibroblasts	Activates neutrophils Fibroplasia Angiogenesis
CC	CCL3 (MIP-1α)	Monocytes T cells Mast cells Fibroblasts	CCR1, 3, 5	Monocytes NK and T cells Basophils Dendritic cells	Competes with HIV-1 Antiviral defense Promotes T_H1 immunity
	CCL4 (MIP-1β)	Monocytes Macrophages Neutrophils Endothelium	CCR1, 3, 5	Monocytes NK and T cells Dendritic cells	Competes with HIV-1
	CCL2 (MCP-1)	Monocytes Macrophages Fibroblasts Keratinocytes	CCR2B	Monocytes NK and T cells Basophils Dendritic cells	Activates macrophages Basophil histamine release Promotes T_H2 immunity
	CCL5 (RANTES)	T cells Endothelium Platelets	CCR1, 3, 5	Monocytes NK and T cells Basophils Eosinophils Dendritic cells	Degranulates basophils Activates T cells Chronic inflammation
CXXXC (CX_3C)	CX3CL1 (Fractalkine)	Monocytes Endothelium Microglial cells	CX_3CR1	Monocytes T cells	Leukocyte–endothelial adhesion Brain inflammation

Fig. 3.27 Properties of selected human chemokines. Chemokines fall mainly into two related but distinct groups: the CC chemokines, which have two adjacent cysteine residues near the amino terminus; and the CXC chemokines, in which the equivalent cysteine residues are separated by a single amino acid. In humans, the genes for CC chemokines are mostly clustered in one region of chromosome 4. Genes for CXC chemokines are found mainly in a cluster on chromosome 17. The two groups of chemokines act on different sets of receptors, all of which are G protein–coupled receptors. CC chemokines bind to receptors designated CCR1–10. CXC chemokines bind to receptors designated CXCR1–7. Different receptors are expressed on different cell types, and so a particular chemokine can be used to attract a particular cell type. In general, CXC chemokines with a Glu-Leu-Arg tripeptide motif immediately before the first cysteine promote the migration of neutrophils. CXCL8 is an example of this type. Most of the other CXC chemokines, including those that interact with receptors CXCR3, 4, and 5, lack this motif. Fractalkine is unusual in several respects: it has three amino acid residues between the two cysteines, and it exists in two forms, one that is tethered to the membrane of the endothelial and epithelial cells that express it, where it serves as an adhesion protein, and a soluble form that is released from the cell surface and acts as a chemoattractant for a wide range of cell types. A more comprehensive list of chemokines and their receptors is given in eAppendix IV.

ANIMATION 3.9

cells, which allows the leukocyte to cross the blood vessel walls by squeezing between the endothelial cells. Second, the chemokine directs the migration of the leukocyte along a gradient of chemokine molecules bound to the extracellular matrix and the surfaces of endothelial cells. This gradient increases in concentration toward the site of infection.

Chemokines are produced by a wide variety of cell types in response to bacterial products, viruses, and agents that cause physical damage, such as silica, alum, or the urate crystals that occur in gout. Complement fragments, such as C3a and C5a, and fMLF bacterial peptides also act as chemoattractants for neutrophils. Thus, infection or physical damage to tissues induces the production of chemokine gradients that can direct phagocytes to the sites where they are needed. Neutrophils arrive rapidly in large numbers at a site of infection. The recruitment of monocytes occurs simultaneously, but they accumulate more slowly at the site of infection, perhaps because they are less abundant in the circulation. The complement fragment C5a and the chemokines CXCL8 and CCL2 activate their respective target cells, so that not only are neutrophils and monocytes brought to potential sites of infection, but also, in the process, they are armed to deal with the pathogens they encounter there. In particular, the signaling induced by C5a or CXCL8 in neutrophils serves to augment the respiratory burst that generates oxygen radicals and nitric oxide and to induce the neutrophils to release their stored antimicrobial granule contents (see Section 3-2).

Chemokines do not act alone in cell recruitment. They require the action of vasoactive mediators that bring leukocytes close to the blood vessel wall (see Section 3-3) and cytokines such as TNF-α to induce the necessary adhesion molecules on endothelial cells. We will return to the chemokines in later chapters, where they are discussed in the context of the adaptive immune response. Now, however, we turn to the molecules that enable leukocytes to adhere to the endothelium, and we shall then describe step by step the extravasation process by which monocytes and neutrophils enter infected sites.

3-18 Cell-adhesion molecules control interactions between leukocytes and endothelial cells during an inflammatory response.

The recruitment of activated phagocytes to sites of infection is one of the most important functions of innate immunity. Recruitment occurs as part of the inflammatory response and is mediated by cell-adhesion molecules that are induced on the surface of the endothelial cells of local blood vessels. Here we consider those functions that participate in the recruitment of inflammatory cells in the hours to days after the establishment of an infection.

ANIMATION 3.10

As with the complement components, a significant barrier to understanding the functions of cell-adhesion molecules is their nomenclature. Most adhesion molecules, especially those on leukocytes, which are relatively easy to analyze functionally, were originally named after the effects of specific monoclonal antibodies directed against them. Their names therefore bear no relation to their structural class. For instance, the **leukocyte functional antigens** LFA-1, LFA-2, and LFA-3 are actually members of two different protein families. In Fig. 3.28, the adhesion molecules relevant to innate immunity are grouped according to their molecular structure, which is shown in schematic form alongside their different names, sites of expression, and ligands. Three structural families of adhesion molecules are important for leukocyte recruitment. The **selectins** are membrane glycoproteins with a distal lectin-like domain that binds specific carbohydrate groups. Members of this family are induced on activated endothelium and initiate endothelium–leukocyte interactions by binding to fucosylated oligosaccharide ligands on passing leukocytes (see Fig. 3.28).

		Name	Tissue distribution	Ligand
Selectins Bind carbohydrates. Initiate leukocyte–endothelial interaction	P-selectin	P-selectin (PADGEM, CD62P)	Activated endothelium and platelets	PSGL-1, sialyl-Lewis^X
		E-selectin (ELAM-1, CD62E)	Activated endothelium	Sialyl-Lewis^X
Integrins Bind to cell-adhesion molecules and extracellular matrix. Strong adhesion	LFA-1	$\alpha_L\beta_2$ (LFA-1, CD11a:CD18)	Monocytes, T cells, macrophages, neutrophils, dendritic cells, NK cells	ICAM-1, ICAM-2
		$\alpha_M\beta_2$ (CR3, Mac-1, CD11b:CD18)	Neutrophils, monocytes, macrophages, NK cells	ICAM-1, iC3b, fibrinogen
		$\alpha_x\beta_2$ (CR4, p150.95, CD11c:CD18)	Dendritic cells, macrophages, neutrophils, NK cells	iC3b
		$\alpha_5\beta_1$ (VLA-5, CD49d:CD29)	Monocytes, macrophages	Fibronectin
Immunoglobulin superfamily Various roles in cell adhesion. Ligand for integrins	ICAM-1	ICAM-1 (CD54)	Activated endothelium, activated leukocytes	LFA-1, Mac-1
		ICAM-2 (CD102)	Resting endothelium, dendritic cells	LFA-1
		VCAM-1 (CD106)	Activated endothelium	VLA-4
		PECAM (CD31)	Activated leukocytes, endothelial cell–cell junctions	CD31

Fig. 3.28 Adhesion molecules involved in leukocyte interactions. Three structural families of adhesion molecules have a role in leukocyte migration, homing, and cell–cell interactions: the selectins, the integrins, and proteins of the immunoglobulin superfamily. The figure shows schematic representations of an example from each family, a list of other family members that participate in leukocyte interactions, their cellular distribution, and their ligand in adhesive interactions. The family members shown here are limited to those that participate in inflammation and other innate immune mechanisms. The same molecules and others participate in adaptive immunity and will be considered in Chapters 9 and 11. The nomenclature of the different molecules in these families is confusing because it often reflects the way in which the molecules were first identified rather than their related structural characteristics. Alternative names for each of the adhesion molecules are given in parentheses. Sulfated sialyl-Lewis^X, which is recognized by P-selectin and E-selectin, is an oligosaccharide present on the cell-surface glycoproteins of circulating leukocytes.

The next step in leukocyte recruitment depends on tighter adhesion, which is due to the binding of **intercellular adhesion molecules (ICAMs)** on the endothelium to heterodimeric proteins of the **integrin** family on leukocytes. ICAMs are single-pass membrane proteins that belong to the large superfamily of **immunoglobulin-like proteins**, which contain protein domains similar to those of immunoglobulins. The extracellular regions of ICAMs are composed of several immunoglobulin-like domains. An integrin molecule is composed of two transmembrane protein chains, α and β, of which there are numerous different types. Subsets of integrins have a common β chain partnered with different α chains. The leukocyte integrins important for extravasation are **LFA-1** ($\alpha_L\beta_2$, also known as **CD11a:CD18**) and **CR3** ($\alpha_M\beta_2$, complement receptor 3, also known as **CD11b:CD18** or Mac-1). We described CR3 in Section 2-13 as a receptor for iC3b, but it also binds other ligands. Both LFA-1 and CR3 bind to ICAM-1 (Fig. 3.29). Even in the absence of infection, circulating monocytes are continually leaving the blood and entering certain tissues, such as the intestine, where they become resident macrophages. LFA-1 also binds to ICAM-2. To navigate out of the blood vessel, monocytes may adhere to ICAM-2, which is expressed at low levels by unactivated endothelium. CR3 also binds to fibrinogen and factor X, both substrates of the coagulation cascade.

Strong adhesion between leukocytes and endothelial cells is promoted by the induction of ICAM-1 on inflamed endothelium together with a conformational change in LFA-1 and CR3 that occurs on the leukocyte. Integrins can switch between an 'active' state, in which they bind strongly to their ligands, and an 'inactive' state, in which binding is easily broken. This enables cells to make and break integrin-mediated adhesions in response to signals received by the cell either through the integrin itself or through other receptors. In the

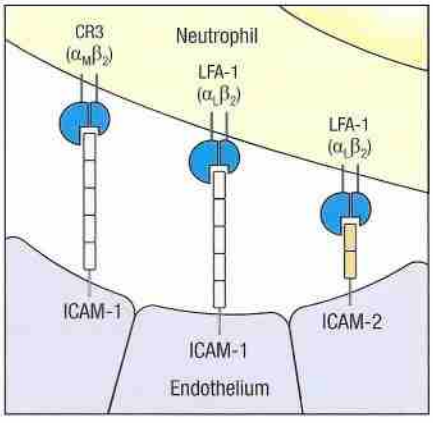

Fig. 3.29 Phagocyte adhesion to vascular endothelium is mediated by integrins. When vascular endothelium is activated by inflammatory mediators it expresses two adhesion molecules, namely ICAM-1 and ICAM-2. These are ligands for integrins expressed by phagocytes—ICAM-1 for $\alpha_M\beta_2$ (also called CR3, Mac-1, or CD11b:CD18), and ICAM-1 and ICAM-2 for $\alpha_L\beta_2$ (also called LFA-1 or CD11a:CD18).

activated state, an integrin molecule is linked via the intracellular protein **talin** to the actin cytoskeleton. In the case of migrating leukocytes, chemokines binding to their receptors on the leukocyte generate intracellular signals that cause talin to bind to the cytoplasmic tails of the β chains of LFA-1 and CR3, forcing the integrin extracellular regions to assume an active binding conformation. The importance of leukocyte integrin function in inflammatory-cell recruitment is illustrated by **leukocyte adhesion deficiencies (LADs)**, which can be caused by defects in the integrins themselves or in the proteins required for modulating adhesion. People with these diseases suffer from recurrent bacterial infections and impaired healing of wounds.

Leukocyte Adhesion Deficiency

Endothelial activation is driven by macrophage-produced cytokines, particularly TNF-α, which induce the rapid externalization of granules called **Weibel–Palade bodies** in the endothelial cells. These granules contain preformed **P-selectin**, which appears on the surfaces of local endothelial cells just minutes after macrophages have responded to the presence of microbes by producing TNF-α. Shortly after P-selectin gets to the cell surface, mRNA encoding **E-selectin** is synthesized, and within 2 hours the endothelial cells are expressing mainly E-selectin. Both P-selectin and E-selectin interact with **sulfated sialyl-Lewis^X**, a sulfated form of a carbohydrate structure that is also an important blood group antigen. Sulfated sialyl-Lewis^X is present on the surface of neutrophils, and its interactions with P-selectin and E-selectin are important for neutrophil rolling on the endothelium. Mutations in enzymes involved in its synthesis, such as fucosyltransferase, cause defective sialyl-Lewis^X expression that results in an immunodeficiency, **leukocyte adhesion deficiency type 2**.

Integrins are also convenient cell-surface markers for distinguishing different cell types. Dendritic cells, macrophages, and monocytes express different integrin α chains and thus display distinct β2 integrins on their surface. The predominant leukocyte integrin on conventional dendritic cells is $\alpha_X\beta_2$, also known as **CD11c:CD18** or complement receptor 4 (**CR4**) (see Fig. 3.28). This integrin is a receptor for the complement C3 cleavage product iC3b, fibrinogen, and ICAM-1. In contrast to conventional dendritic cells, most monocytes and macrophages express low levels of CD11c and predominantly express the integrin $\alpha_M\beta_2$ (CD11b:CD18; CR3). However, patterns of integrin expression can vary, with some tissue macrophages, such as those in the lung, expressing high levels of CD11c:CD18. In the mouse, the two major branches of conventional dendritic cells can be distinguished by expression of CD11b:CD18: one branch characterized by high expression of CD11b:CD18, and a second branch that lacks CD11b:CD18. Plasmacytoid dendritic cells (pDCs) express lower levels of CD11c but can be distinguished from conventional dendritic cells using other markers; human pDCs express the C-type lectin **BDCA-2 (blood dendritic cell antigen 2)**, and mouse pDCs express **BST2 (bone marrow stromal antigen 2)**, neither of which is expressed by conventional dendritic cells.

3-19 Neutrophils make up the first wave of cells that cross the blood vessel wall to enter an inflamed tissue.

The migration of leukocytes out of blood vessels, the process known as extravasation, occurs in response to signals generated at sites of infection. Under normal conditions, leukocytes travel in the center of small blood vessels, where blood flow is fastest. Within sites of inflammation, the vessels are dilated and the consequent slower blood flow allows leukocytes to interact in large numbers with the vascular endothelium. During an inflammatory response, the induction of adhesion molecules on the endothelial cells of blood vessels within the infected tissue, as well as changes in the adhesion molecules expressed on leukocytes, recruits large numbers of circulating leukocytes to the site of infection. We will describe this process with regard to monocytes and neutrophils (Fig. 3.30).

ANIMATION 3.11

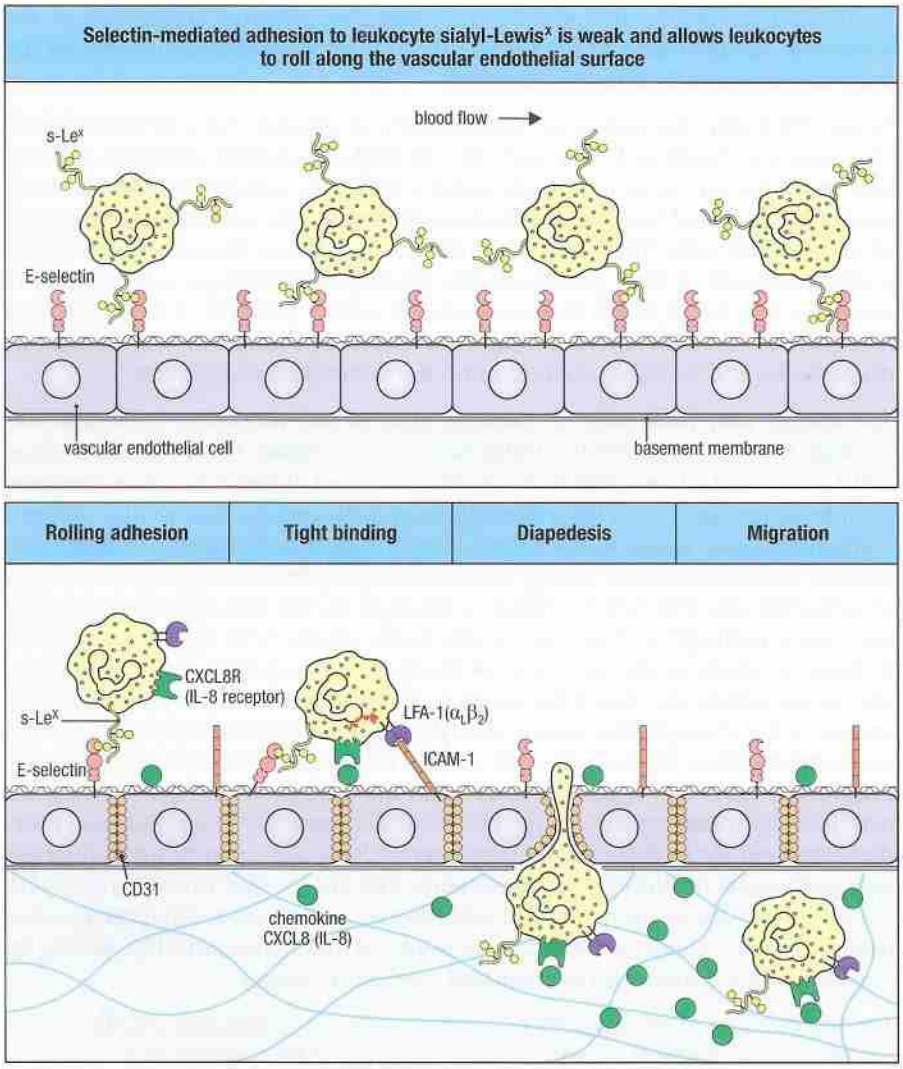

Fig. 3.30 Neutrophils leave the blood and migrate to sites of infection in a multistep process involving adhesive interactions that are regulated by macrophage-derived cytokines and chemokines. Top panel: The first step involves the reversible binding of a neutrophil to vascular endothelium through interactions between selectins induced on the endothelium and their carbohydrate ligands on the neutrophil, shown here for E-selectin and its ligand, the sialyl-Lewis^X moiety (s-Le^X). This interaction cannot anchor the cells against the shearing force of the flow of blood, and thus they roll along the endothelium, continually making and breaking contact. Bottom panel: The binding does, however, eventually trigger stronger interactions, which result only when binding of a chemokine such as CXCL8 to its specific receptor on the neutrophil triggers the activation of the integrins LFA-1 and CR3 (Mac-1; not shown). Inflammatory cytokines such as TNF-α are also necessary to induce the expression of adhesion molecules such as ICAM-1 and ICAM-2, the ligands for these integrins, on the vascular endothelium. Tight binding between ICAM-1 and the integrins arrests the rolling and allows the neutrophil to squeeze between the endothelial cells forming the wall of the blood vessel (that is, to extravasate). The leukocyte integrins LFA-1 and CR3 are required for extravasation and for migration toward chemoattractants. Adhesion between molecules of CD31, expressed on both the neutrophil and the junction of the endothelial cells, is also thought to contribute to extravasation. The neutrophil also needs to traverse the basement membrane; it penetrates this with the aid of a matrix metalloproteinase enzyme, MMP-9, that it expresses at the cell surface. Finally, the neutrophil migrates along a concentration gradient of chemokines (shown here as CXCL8) secreted by cells at the site of infection.

Extravasation proceeds in four stages. In the first, induction of selectins enables leukocyte rolling along the endothelium. P-selectin appears on endothelial cell surfaces within a few minutes of exposure to leukotriene B4, C5a, or histamine, which is released from mast cells in response to C5a. P-selectin can also be induced by TNF-α or LPS, and both of these induce synthesis of E-selectin, which appears on the endothelial cell surface a few hours later. When the sulfated sialyl-Lewis^X on monocytes and neutrophils contacts these exposed P- and E-selectins, these cells adhere reversibly to the vessel wall and begin to 'roll' along endothelium (see Fig. 3.30, top panel), permitting stronger interactions of the next step in leukocyte migration. Neutrophils are particularly efficient at rolling along endothelium, even under flow rates that prevent rolling by other cells. Such **shear-resistant rolling** by neutrophils uses long extensions of plasma membrane, termed **slings**, that bind the endothelium and wrap around the cell as it rolls, serving to tether the cell firmly to the endothelium and to promote rapid entry to sites of infection.

The second step depends on interactions between the leukocyte integrins LFA-1 and CR3 and adhesion molecules such as ICAM-1 (which can be induced on endothelial cells by TNF-α) or ICAM-2 on endothelium (see Fig. 3.30, bottom panel). LFA-1 and CR3 normally bind their ligands only weakly, but CXCL8 (or other chemokines), bound to proteoglycans on the surface of endothelial cells, binds to specific chemokine receptors on the leukocyte and signals the cell to trigger a conformational change in LFA-1 and CR3 on

ANIMATION 3.12

ANIMATION 3.13

the rolling leukocyte; this greatly increases the adhesive properties of the leukocyte, as discussed in Section 3-18. The cell then attaches firmly to the endothelium, and its rolling is arrested.

In the third step the leukocyte extravasates, or crosses the endothelial wall. This step also involves LFA-1 and CR3, as well as a further adhesive interaction involving an immunoglobulin-related molecule called **PECAM**, or **CD31**, which is expressed both on the leukocyte and at the intercellular junctions of endothelial cells. These interactions enable cells to squeeze between the endothelial cells. It then penetrates the basement membrane with the aid of enzymes that break down the extracellular matrix proteins of the basement membrane. The movement through the basement membrane is known as **diapedesis**, and it enables cells to enter the subendothelial tissues.

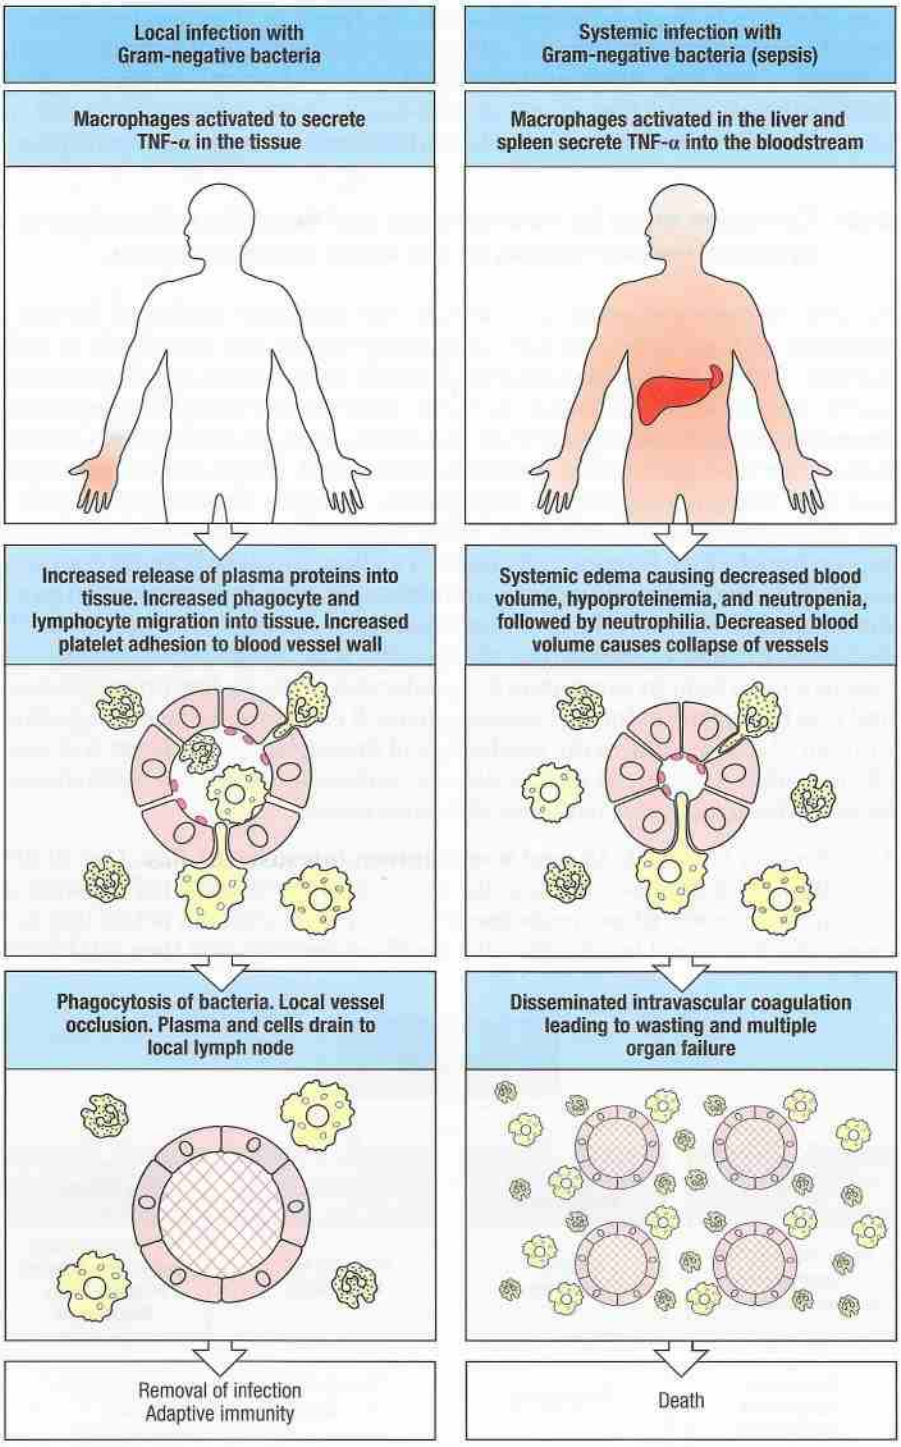
The fourth and final step in extravasation is the migration of leukocytes through the tissues under the influence of chemokines. Chemokines such as CXCL8 and CCL2 (see Section 3-17) are produced at the site of infection and bind to proteoglycans in the extracellular matrix and on endothelial cell surfaces. In this way, a matrix-associated concentration gradient of chemokines is formed on a solid surface along which the leukocyte can migrate to the focus of infection (see Fig. 3.30). CXCL8 is released by the macrophages that first encounter pathogens; it recruits neutrophils, which enter the infected tissue in large numbers in the early part of the induced response. Their influx usually peaks within the first 6 hours of an inflammatory response. Monocytes are recruited through the action of CCL2 and accumulate more slowly than neutrophils. Once in the inflamed tissue, neutrophils are able to eliminate many pathogens by phagocytosis. In an innate immune response, neutrophils use their complement receptors and the direct pattern-recognition receptors discussed earlier in this chapter (see Section 3-1) to recognize and phagocytose pathogens or pathogen components directly or after opsonization with complement (see Section 2-13). In addition, as we will see in Chapter 10, neutrophils act as phagocytic effectors in humoral adaptive immunity, taking up antibody-coated microbes by means of specific receptors.

The importance of neutrophils in immune defense is dramatically illustrated by diseases or medical treatments that severely reduce neutrophil numbers. Individuals suffering this affliction are said to have **neutropenia**, and they are highly susceptible to deadly infection with a wide range of pathogens and commensal organisms. Restoring neutrophil levels in such individuals by transfusion of neutrophil-rich blood fractions or by stimulating their production with specific growth factors largely corrects this susceptibility.

3-20 TNF-α is an important cytokine that triggers local containment of infection but induces shock when released systemically.

TNF-α acting on endothelial cells stimulates the expression of adhesion molecules and aids the extravasation of cells such as monocytes and neutrophils. Another important action of TNF-α is to stimulate endothelial cells to express proteins that trigger blood clotting in the local small vessels, occluding them and cutting off blood flow. This can be important in preventing the pathogen from entering the bloodstream and spreading through the blood to organs all over the body. The importance of TNF-α in the containment of local infection is illustrated by experiments in which rabbits were infected locally with a bacterium. Normally, the infection would be contained at the site of the inoculation; if, however, an injection of anti-TNF-α antibody was also given to block the action of TNF-α, the infection spread via the blood to other organs. In parallel, the fluid that has leaked into the tissue in the early phases of an infection carries the pathogen, usually enclosed in dendritic cells, via the lymph to the regional lymph nodes, where an adaptive immune response can be initiated.

Once an infection has spread to the bloodstream, however, the same mechanisms by which TNF-α so effectively contains local infection instead become catastrophic (Fig. 3.31). Although produced as a membrane-associated cytokine, TNF-α can be cleaved by a protease, **TACE (TNF–α–converting enzyme**, which is encoded by the ADAM17 gene), and released from the membrane as a soluble cytokine. The presence of infection in the bloodstream, or sepsis, is accompanied by a massive release of soluble TNF-α from macrophages in the liver, spleen, and other sites throughout the body. The systemic release of TNF-α into the bloodstream causes vasodilation, which leads to a loss of blood pressure and increased vascular permeability; this in turn



Local infection with Gram-negative bacteria
Macrophages activated to secrete TNF-α in the tissue
Increased release of plasma proteins into tissue. Increased phagocyte and lymphocyte migration into tissue. Increased platelet adhesion to blood vessel wall
Phagocytosis of bacteria. Local vessel occlusion. Plasma and cells drain to local lymph node
Removal of infection Adaptive immunity
Systemic infection with Gram-negative bacteria (sepsis)
Macrophages activated in the liver and spleen secrete TNF-α into the bloodstream
Systemic edema causing decreased blood volume, hypoproteinemia, and neutropenia, followed by neutrophilia. Decreased blood volume causes collapse of vessels
Disseminated intravascular coagulation leading to wasting and multiple organ failure
Death

Fig. 3.31 The release of TNF-α by macrophages induces local protective effects, but TNF-α can be damaging when released systemically. The panels on the left show the causes and consequences of local release of TNF-α, and the panels on the right show the causes and consequences of systemic release. In both cases, TNF-α acts on blood vessels, especially venules, to increase blood flow and vascular permeability to fluid, proteins, and cells, and to increase endothelial adhesiveness for leukocytes and platelets (center row). Local release thus allows an influx of fluid, cells, and proteins into the infected tissue, where they participate in host defense. Later, blood clots form in the small vessels (bottom left panel), preventing spread of infection via the blood, and the accumulated fluid and cells drain to regional lymph nodes, where an adaptive immune response is initiated. When there is a systemic infection, or sepsis, with bacteria that elicit TNF-α production, TNF-α is released into the blood by macrophages in the liver and spleen and acts in a similar way on all small blood vessels in the body (bottom right panel). The result is shock, disseminated intravascular coagulation with depletion of clotting factors, and consequent bleeding, multiple organ failure, and frequently death.

leads to a loss of plasma volume and eventually to shock, known in this case as septic shock because the underlying cause is a bacterial infection. The TNF-α released in septic shock also triggers blood clotting in small vessels throughout the body—known as **disseminated intravascular coagulation (DIC)**—which leads to the massive consumption of clotting proteins, so that the individual's blood cannot clot appropriately. Disseminated intravascular coagulation frequently leads to the failure of vital organs such as the kidneys, liver, heart, and lungs, which are quickly compromised by the failure of normal blood perfusion; consequently, septic shock has a very high mortality rate.

Blockade of TNF-α activity, either with specific antibodies or with soluble proteins that mimic the receptor, is a successful treatment for several inflammatory disorders, including rheumatoid arthritis. However, these treatments have been found to reactivate tuberculosis in some apparently well individuals with evidence of previous infection (as demonstrated by skin test), which is a direct demonstration of the importance of TNF-α in keeping infection local and in check. The efficacy of TNF-α blockade as a treatment for sepsis remains unclear.

3-21 Cytokines made by macrophages and dendritic cells induce a systemic reaction known as the acute-phase response.

As well as their important local effects, the cytokines produced by macrophages and dendritic cells have long-range effects that contribute to host defense. One of these is the elevation of body temperature, which is caused mainly by TNF-α, IL-1β, and IL-6. These cytokines are termed **endogenous pyrogens** because they cause fever and derive from an endogenous source rather than from bacterial components such as LPS, which also induces fever and is an **exogenous pyrogen**. Endogenous pyrogens cause fever by inducing the synthesis of prostaglandin E2 by the enzyme cyclooxygenase-2, the expression of which is induced by these cytokines. Prostaglandin E2 then acts on the hypothalamus, resulting in an increase in both heat production from the catabolism of brown fat and heat retention from vasoconstriction, which decreases the loss of excess heat through the skin. Exogenous pyrogens are able to induce fever by promoting the production of the endogenous pyrogens and also by directly inducing cyclooxygenase-2 as a consequence of signaling through TLR-4, leading to the production of prostaglandin E2. Fever is generally considered beneficial to host defense, although the precise mechanisms by which fever facilitates pathogen clearance remain unclear.

The effects of TNF-α, IL-1β, and IL-6 are summarized in Fig. 3.32. One of the most important of these occurs in the liver and is the initiation of a response known as the **acute-phase response** (Fig. 3.33). The cytokines act on hepatocytes, which respond by changing the profile of proteins that they synthesize

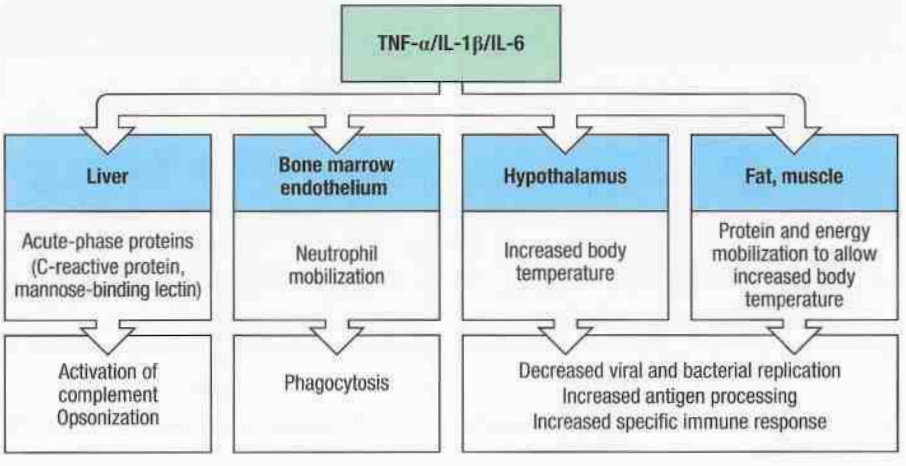


Fig. 3.32 The cytokines TNF-α, IL 1β, and IL-6 have a wide spectrum of biological activities that help to coordinate the body's responses to infection. TNF-α, IL-1β, and IL-6 activate hepatocytes to synthesize acute-phase proteins and activate bone marrow endothelium to release neutrophils. The acute-phase proteins act as opsonins, whereas the disposal of opsonized pathogens is augmented by the enhanced recruitment of neutrophils from the bone marrow. TNF-α, IL-1β, and IL-6 are also endogenous pyrogens, raising body temperature, which is believed to help in eliminating infections. A major effect of these cytokines is to induce synthesis of prostaglandin E2, which acts on the hypothalamus, altering the body's temperature regulation, and on muscle and fat cells, altering energy mobilization to increase the body temperature. At higher temperatures, bacterial and viral replication is less efficient, whereas the adaptive immune response operates more efficiently.

Serum amyloid protein

Fig. 3.33 The acute-phase response produces molecules that bind pathogens but not host cells. Acute-phase proteins are produced by liver cells in response to cytokines released by macrophages in the presence of bacteria (top panel). They include serum amyloid protein (SAP) (in mice but not humans), C-reactive protein (CRP), fibrinogen, and mannose-binding lectin (MBL). CRP binds phosphocholine on certain bacterial and fungal surfaces but does not recognize it in the form in which it is found in host-cell membranes (middle panel). SAP and CRP are homologous in structure; both are pentraxins, forming five-membered discs, as shown for SAP (lower panel). SAP both acts as an opsonin in its own right and activates the classical complement pathway by binding C1q to augment opsonization. MBL is a member of the collectin family, which also includes the pulmonary surfactant proteins SP-A and SP-D. Like CRP, MBL can act as an opsonin in its own right, as can SP-A and SP-D.

and secrete into the blood. In the acute-phase response, blood levels of some proteins go down, whereas levels of others increase markedly. The proteins induced by TNF-α, IL-1β, and IL-6 are called the **acute-phase proteins**. Several of these are of particular interest because they mimic the action of antibodies, but unlike antibodies they have broad specificity for pathogen-associated molecular patterns and depend only on the presence of cytokines for their production.

One acute-phase protein, the **C-reactive protein**, is a member of the **pentraxin** protein family, so called because the proteins are formed from five identical subunits. C-reactive protein is yet another example of a multipronged pathogen-recognition molecule, and it binds to the phosphocholine portion of certain bacterial and fungal cell-wall lipopolysaccharides. Phosphocholine is also found in mammalian cell-membrane phospholipids, but it cannot be bound by C-reactive protein. When C-reactive protein binds to a bacterium, it not only is able to opsonize the bacterium but can also activate the complement cascade by binding to C1q, the first component of the classical pathway of complement activation (see Section 2-7). The interaction with C1q involves the collagen-like parts of C1q rather than the globular heads that make contact with pathogen surfaces, but the same cascade of reactions is initiated.

Mannose-binding lectin (MBL) is another acute-phase protein; it serves as an innate recognition molecule that can activate the lectin pathway of complement (see Section 2-6). MBL is present at low levels in the blood of healthy individuals, but it is produced in increased amounts during the acute-phase response. By recognizing mannose residues on microbial surfaces, MBL can act as an opsonin that is recognized by monocytes, which do not express the macrophage mannose receptor. Two other proteins with opsonizing properties that are also produced in increased amounts during an acute-phase response are the **surfactant proteins A and D (SP-A and SP-D)**. These are produced by the liver and a variety of epithelia. They are, for example, found along with macrophages in the alveolar fluid of the lung, where they are secreted by pneumocytes, and are important in promoting the phagocytosis of opportunistic respiratory pathogens such as *Pneumocystis jirovecii* (formerly known as *P. carinii*), one of the main causes of pneumonia in individuals with AIDS.

Thus, within a day or two, the acute-phase response provides the host with several proteins with the functional properties of antibodies but able to bind a broad range of pathogens. However, unlike antibodies, which we describe in Chapters 4 and 10, acute-phase proteins have no structural diversity and are made in response to any stimulus that triggers the release of TNF-α, IL-1β, and IL-6. Therefore, unlike antibodies, their synthesis is not specifically induced and targeted.

A final, distant effect of the cytokines produced by macrophages is to induce **leukocytosis**, an increase in the numbers of circulating neutrophils. The neutrophils come from two sources: the bone marrow, from which mature leukocytes are released in increased numbers; and sites in blood vessels, where they are attached loosely to endothelial cells. Thus, the effects of these cytokines

contribute to the control of infection while the adaptive immune response is being developed.

3-22 Interferons induced by viral infection make several contributions to host defense.

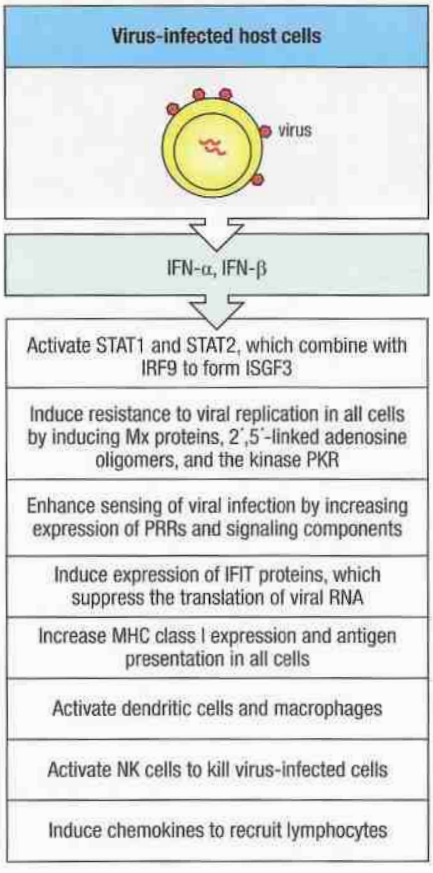
Interferon-γ Receptor Deficiency

Viral infection induces the production of interferons, originally named because of their ability to interfere with viral replication in previously uninfected tissue culture cells. Interferons have a similar role *in vivo*, blocking the spread of viruses to uninfected cells. There are numerous genes encoding antiviral, or type I, interferons. Best understood are the IFN-α family of 12 closely related human genes and IFN-β, the product of a single gene; less well studied are IFN-κ, IFN-ε, and IFN-ω. **IFN-γ** is the sole **type II interferon**.

Type III interferons are a newly classified IFN family composed of the products of three **IFN-λ** genes, also known as IL-28A, IL-28B, and IL-29, which bind a heterodimeric **IFN-λ receptor** composed of a unique IL-28Rα subunit and the β subunit of the IL-10 receptor. While receptors for type I interferons and IFN-γ are widespread in their tissue distribution, type III receptors are more restricted. For example, they are not expressed by fibroblasts but are expressed on epithelial cells.

Type I interferons are inducible and are synthesized by many cell types after infection by diverse viruses. Almost all types of cells can produce IFN-α and IFN-β in response to activation of several innate sensors. For example, type I interferons are induced by RLRs and cGAS-STING signaling (see Sections 3-8 and 3-9). However, some immune cells seem to be specialized for this task. In Section 3-1 we introduced the plasmacytoid dendritic cell (pDC). Also called **interferon-producing cells (IPCs)** or **natural interferon-producing cells**, human plasmacytoid dendritic cells were initially recognized as rare peripheral blood cells that accumulate in peripheral lymphoid tissues during a viral infection and make abundant type I interferons (IFN-α and IFN-β)—up to 1000 times more than that made by other cell types. This abundant production of type I interferons may result from the efficient coupling of viral recognition by TLRs to the pathways of interferon production (see Section 3-7). Plasmacytoid dendritic cells express a subset of TLRs that includes TLR-7 and TLR-9, which are endosomal sensors of viral RNA and DNA (see Fig. 3.11). The requirement for TLR-9 in sensing infections caused by DNA viruses has been demonstrated, for example, by the inability of TLR-9–deficient plasmacytoid dendritic cells to generate type I interferons in response to herpes simplex virus.

Interferons help defend against viral infection in several ways (Fig. 3.34). IFN-β induces an antiviral state in cells, which includes making cells more likely to produce IFN-α in response to PRR triggering, thus amplifying the interferon response. IFN-α and IFN-β bind to a common cell-surface receptor, known as the **interferon-α receptor (IFNAR)**, which uses the JAK and STAT pathways described in Section 3-16. IFNAR uses the kinases Tyk2 and Jak1 to activate the factors **STAT1 and STAT2**, which can interact with **IRF9** and form a complex called **ISGF3**, which binds to the promoters of many **interferon-stimulated genes (ISGs)**. The induction of ISGs induces a state of resistance



Virus-infected host cells
virus
IFN-α, IFN-β
Activate STAT1 and STAT2, which combine with IRF9 to form ISGF3
Induce resistance to viral replication in all cells by inducing Mx proteins, 2′,5′-linked adenosine oligomers, and the kinase PKR
Enhance sensing of viral infection by increasing expression of PRRs and signaling components
Induce expression of IFIT proteins, which suppress the translation of viral RNA
Increase MHC class I expression and antigen presentation in all cells
Activate dendritic cells and macrophages
Activate NK cells to kill virus-infected cells
Induce chemokines to recruit lymphocytes

Fig. 3.34 Interferons are antiviral proteins produced by cells in response to viral infection. The interferons IFN-α and IFN-β promote antiviral immunity through multiple mechanisms. They induce resistance to viral replication in uninfected cells by activating genes that cause the destruction of mRNA and inhibit the translation of viral proteins and some host proteins. The products of these genes include the Mx proteins, oligoadenylate synthetase, PKR, and IFIT proteins. Interferons can also induce MHC class I expression in most cell types in the body, thus enhancing their resistance to NK cells; they may also induce increased synthesis of MHC class I molecules in cells that are newly infected by virus, thus making them more susceptible to being killed by CD8 cytotoxic T cells (see Chapter 9). In addition, interferons activate NK cells, which then selectively kill virus-infected cells.

to viral replication in all cells. Many of the genes involved in nucleic-acid sensing and signaling are ISGs, including the genes for RIG-I, MDA-5, IRF7, and STING, such that cells exposed to interferons have a heightened ability to recognize viral nucleic acids.

ISGs exert antiviral activities through a variety of mechanisms. One ISG encodes the enzyme **oligoadenylate synthetase**, which polymerizes ATP into 2′,5′-linked oligomers (whereas nucleotides in nucleic acids are normally linked 3′,5′). These 2′,5′-linked oligomers serve as second messengers and activate an endoribonuclease that then degrades viral RNA (note the parallels to cGAMP activation of STING, described in Section 3-9). Another ISG-encoded protein induced by IFN-α and IFN-β is a dsRNA-dependent protein kinase called **PKR**. This serine/threonine kinase phosphorylates the α subunit of eukaryotic initiation factor 2 (eIF2), thus suppressing protein translation and contributing to the inhibition of viral replication. **Mx (myxoma resistant) proteins** are also ISG-encoded proteins induced by type I interferons. Humans and wild mice have two highly similar proteins, Mx1 and Mx2, which are GTPases belonging to the dynamin protein family, but how they interfere with viral replication is not understood.

The **IFIT (IFN-induced protein with tetratricoid repeats)** family of ISG-encoded proteins contains four human and three mouse proteins that function in restraining the translation of viral RNA into proteins. **IFIT1 and IFIT2** can both suppress the translation of normal capped mRNAs by binding to subunits of the **eukaryotic initiation factor 3 (eIF3)** complex, which prevents eIF3 from interacting with eIF2 to form the 43S pre-initiation complex (Fig. 3.35). This action may be responsible in part for the reduction in cellular

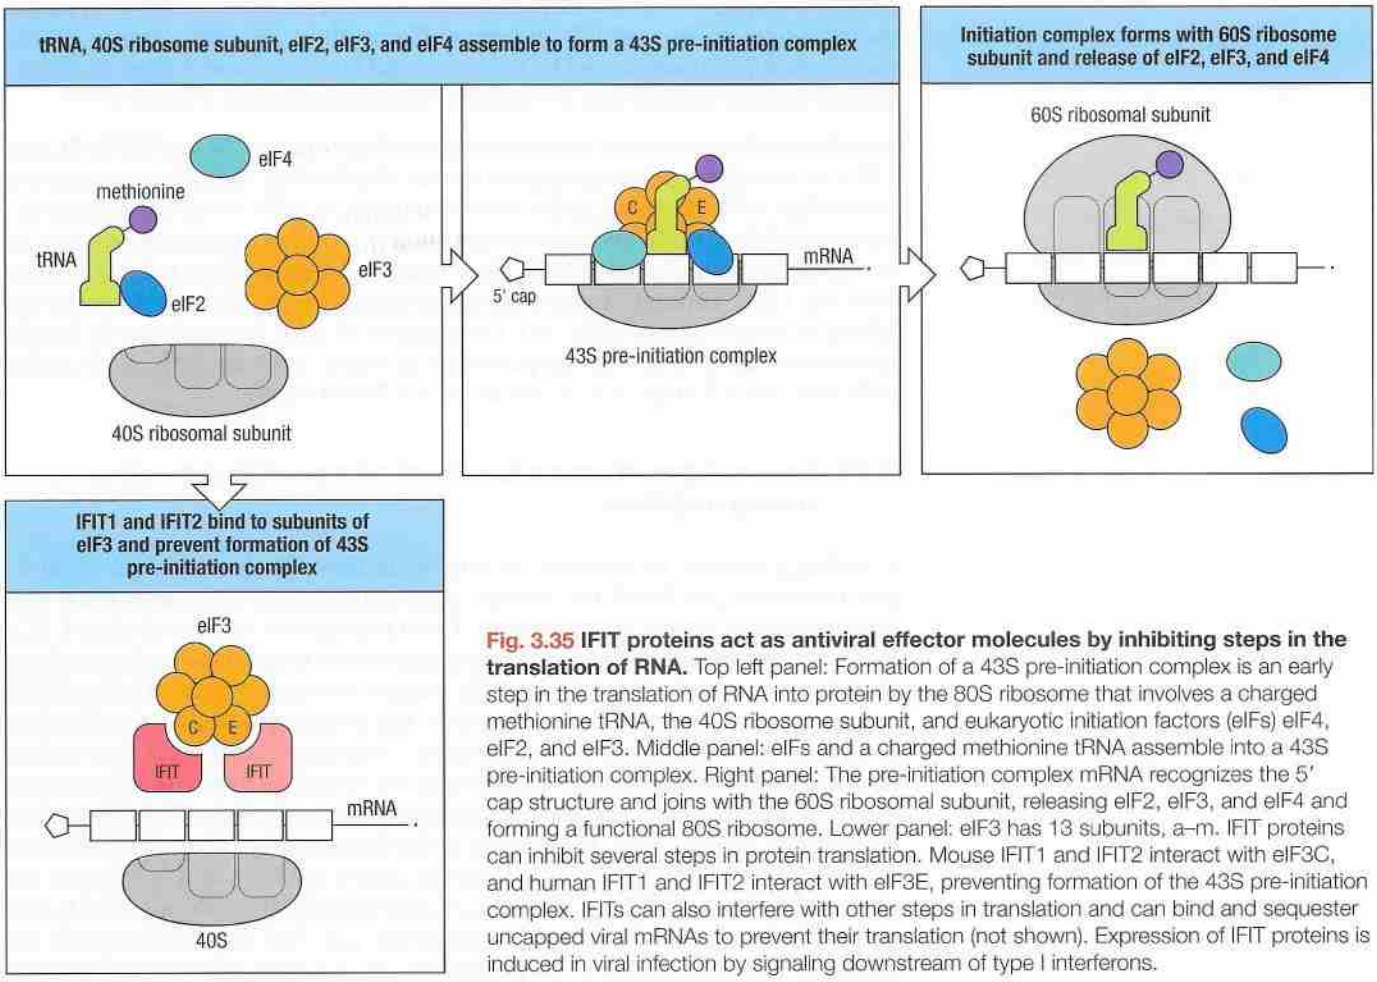


Fig. 3.35 IFIT proteins act as antiviral effector molecules by inhibiting steps in the translation of RNA. Top left panel: Formation of a 43S pre-initiation complex is an early step in the translation of RNA into protein by the 80S ribosome that involves a charged methionine tRNA, the 40S ribosome subunit, and eukaryotic initiation factors (eIFs) eIF4, eIF2, and eIF3. Middle panel: eIFs and a charged methionine tRNA assemble into a 43S pre-initiation complex. Right panel: The pre-initiation complex mRNA recognizes the 5′ cap structure and joins with the 60S ribosomal subunit, releasing eIF2, eIF3, and eIF4 and forming a functional 80S ribosome. Lower panel: eIF3 has 13 subunits, a–m. IFIT proteins can inhibit several steps in protein translation. Mouse IFIT1 and IFIT2 interact with eIF3C, and human IFIT1 and IFIT2 interact with eIF3E, preventing formation of the 43S pre-initiation complex. IFITs can also interfere with other steps in translation and can bind and sequester uncapped viral mRNAs to prevent their translation (not shown). Expression of IFIT proteins is induced in viral infection by signaling downstream of type I interferons.

proliferation induced by type I interferons. Mice lacking IFIT1 or IFIT2 show increased susceptibility to infection by certain viruses, such as vesicular stomatitis virus.

Another function of IFIT1 is to suppress translation of viral RNA that lacks a normal host modification of the 5′ cap. Recall that the normal mammalian 5′ cap is initiated by linking a 7-methylguanosine nucleotide to the first ribose sugar of the mRNA by a 5′,5′-linked triphosphate bridge to produce a structure called cap-0. This structure is further modified by cytoplasmic methylation of the 2′ hydroxyl groups on the first and second ribose sugars of the RNA. Methylation of the first ribose sugar produces a structure called cap-1; methylation of the second generates cap-2. IFIT1 has a high affinity for cap-0 but much lower affinity for cap-1 and cap-2. Some viruses, such as Sindbis virus (family Togaviridae), lack 2′-*O*-methylation and therefore are restricted by this action of IFIT1. Many viruses, such as West Nile virus and SARS coronavirus, have acquired a **2′-*O*-methyltransferase (MTase)** that produces cap-1 or cap-2 on their viral transcripts. These viruses can thus evade restriction by IFIT1.

Members of the **interferon-induced transmembrane protein (IFITM)** family are expressed at a basal level on many types of tissues but are strongly induced by type I interferons. There are four functional IFITM genes in humans and in mice, and these encode proteins that have two transmembrane domains and are localized to various vesicular compartments of the cell. IFITM proteins act to inhibit, or restrict, viruses at early steps of infection. Although the molecular details are unclear, **IFITM1** appears to interfere with the fusion of viral membranes with the membrane of the lysosome, which is required for introducing some viral genomes into the cytoplasm. Viruses that must undergo this fusion event in lysosomes, such as the Ebola virus, are restricted by IFITM1. Similarly, **IFITM3** interferes with membrane fusion in late endosomes, and so restricts the influenza A virus, which undergoes fusion there. The importance of this mechanism is demonstrated by the increased viral load and higher mortality in mice lacking IFITM3 that are infected with the influenza A virus.

Interferons also stimulate production of the chemokines CXCL9, CXCL10, and CXCL11, which recruit lymphocytes to sites of infection. They also increase the expression of MHC class I molecules on all types of cells, which facilitates recognition of virally infected cells by cytotoxic T lymphocytes via the display of viral peptides complexed to MHC class I molecules on the infected cell surface (see Fig. 1.30). Through these effects, interferons indirectly help promote the killing of virus-infected cells by CD8 cytotoxic T cells. Another way in which interferons act is to activate populations of innate immune cells, such as NK cells, that can kill virus-infected cells, as described below.

3-23 Several types of innate lymphoid cells provide protection in early infection.

A defining feature of adaptive immunity is the clonal expression of antigen receptors, produced by somatic gene rearrangements, that provide the extraordinarily diverse specificities of T and B lymphocytes (see Section 1-11). However, for several decades, immunologists have recognized cells with lymphoid characteristics that lack specific antigen receptors. **Natural killer (NK) cells** have been known the longest, but in the past several years other distinct groups of such cells have been identified. Collectively, these are now called **innate lymphoid cells (ILCs)** and include NK cells (Fig. 3.36). ILCs develop in the bone marrow from the same **common lymphoid progenitor (CLP)** that gives rise to B and T cells. Expression of the transcription factor Id2 (inhibitor of DNA binding 2) in the CLP represses B- and T-cell fates and is required for the development of all ILCs. ILCs are identified by the absence of T- and B-cell antigen receptor and co-receptor complexes, but they express receptors for common γ-chain cytokines. They migrate from the bone marrow and take up

The major categories of innate lymphoid cells (ILCs) and their properties			
Innate lymphoid subgroup	**Inducing cytokines**	**Effector molecules produced**	**Function**
NK cells	IL-12, IL-18, type I IFN	IFN-γ, perforin, granzyme	Immunity against viruses, intracellular pathogens
ILC1	IL-12, IL-18	IFN-γ	Defense against viruses, intracellular pathogens
ILC2	IL-25, IL-33, TSLP	IL-5, IL-13, amphiregulin, IL-4	Expulsion of extracellular parasites, tissue repair
ILC3 (LTi cells)	IL-1β, IL-23	IL-17, IL-22	Immunity to extracellular bacteria

Fig. 3.36 The major categories of innate lymphoid cells (ILCs) and their properties.

residence in lymphoid tissues and peripheral organs, notably the dermis, liver, small intestine, adipose tissue, and lung.

ILCs function in innate immunity as effector cells that amplify the signals delivered by innate recognition. They are stimulated by cytokines produced by other innate cells, such as macrophages or dendritic cells, or by nonimmune cells, such as epithelial cells, that have been activated by innate sensors of microbial infection or cellular damage. Three major subgroups of ILCs are defined, largely on the basis of the types of cytokines that each produces. **Group 1 ILCs (ILC1s)** generate IFN-γ in response to activation by certain cytokines, in particular IL-12 and IL-18, made by dendritic cells and macrophages, and they function in protection against infection by viruses or intracellular pathogens. NK cells are now considered to be a type of ILC. ILC1s and NK cells are closely related but have distinct functional properties and differ in the cytokines and transcription factors required for their development. For example, both NK and ILC1 cells require the transcription factors Id2 and **Nfil3** for their development, but ILC1s also require the transcription factor PLZF whereas NK cells do not. NK cells require the cytokine IL-15, while liver ILC1 cells require the cytokine IL-7 and the transcription factor **Tbet**. Functionally, NK cells are more similar to CD8 T cells, while ILC1s resemble more closely the T_H1 subset of CD4 T cells (see Section 3-24). NK cells can be found within tissues, but they also circulate through the blood, while ILC1 cells appear to be largely noncirculating tissue-resident cells. In the mouse, conventional NK cells express the integrin α2 (CD49b), while ILC1 cells, for example in the liver, lack CD49b but express the surface protein CD49a.

Group 2 ILCs (ILC2s) produce the cytokines IL-4, IL-5, and IL-13 in response to various cytokines, particularly **thymic stromal lymphopoietin (TSLP)**, IL-25, and IL-33. ILC2 cytokines function in promoting mucosal and barrier immunity and aid in protection against parasites. ILC2s also produce amphiregulin, an EGF family member that induces epithelial cell proliferation and differentiation, which facilitates repair of damaged tissues.

Group 3 ILCs (ILC3s) respond to the cytokines IL-1β and IL-23 and produce several cytokines, including IL-17 and IL-22, which increase defenses against extracellular bacteria and fungi. IL-17 functions by stimulating the production of chemokines that recruit neutrophils, while IL-22 acts directly on epithelial cells to stimulate the production of antimicrobial peptides such as RegIIIγ (see Section 2-4).

The classification of ILC subtypes and the analysis of their development and function is still an active area, and studies to define the relative importance of these cells in immune responses are ongoing. The ILC subgroups identified so far appear to be highly parallel in structure to the subsets of effector CD8 and CD4 T cells that were defined over the past three decades. The transcription factors that control the development of different ILC subsets seem, for now at least, to be the same as those that control the corresponding T-cell subsets.

Because of these similarities, we will postpone a detailed description of ILC development until Chapter 9, where we will cover this topic along with the development of T-cell subsets.

3-24 NK cells are activated by type I interferon and macrophage-derived cytokines.

NK cells are larger than naive T and B cells, have distinctive cytoplasmic granules containing cytotoxic proteins, and were functionally identified by their ability to kill certain tumor cell lines *in vitro* without the need for prior immunization. NK cells kill cells by releasing their cytotoxic granules, which are similar to those of cytotoxic T cells and have the same effects (discussed in Chapter 9). In brief, the contents of cytotoxic granules, which contain granzymes and the pore-forming protein perforin, are released onto the surface of the target cell and penetrate the cell membrane and induce programmed cell death. However, unlike T cells, killing by NK cells is triggered by germline-encoded receptors that recognize molecules on the surface of infected or malignantly transformed cells. A second pathway used by NK cells to kill target cells involves the TNF family member known as **TRAIL (tumor necrosis factor–related apoptosis-inducing ligand)**. NK cells express TRAIL on their cell surface. TRAIL interacts with two TNFR superfamily 'death' receptors, **DR4 and DR5** (encoded by *TNFSF10A* and *TNFSF10B*), that are expressed by many types of cells. When NK cells recognize a target cell, TRAIL stimulates DR4 and DR5 to activate the pro-enzyme **caspase 8**, which leads to apoptosis. In contrast to pyroptosis, induced by caspase 1 after inflammasome activation (see Section 3-11), apoptosis is not associated with production of inflammatory cytokines. We will discuss more details of the mechanisms of caspase-induced apoptosis when we discuss killing by cytotoxic T cells in Chapter 9. Finally, NK cells express Fc receptors (see Section 1-20); binding of antibodies to these receptors activates NK cells to release their cytotoxic granules, a process known as **antibody-dependent cell-mediated cytotoxicity, or ADCC**, to which we will return in Chapter 10.

Virus titer
1 2 3 4 5 6 7 8 9 10
time after viral infection (days)

Fig. 3.37 Natural killer cells (NK cells) are an early component of the host response to virus infection. Experiments in mice have shown that IFN-α, IFN-β, and the cytokines TNF-α and IL-12 are produced first after viral infection, and are followed by a wave of NK cells, which together control virus replication via IFN-α secretion and cytotoxicity but do not eliminate the virus. Virus elimination is accomplished when virus-specific CD8 T cells and neutralizing antibodies are produced. Without NK cells, the levels of some viruses are much higher in the early days of the infection, and the infection can be lethal unless treated vigorously with antiviral compounds.

The ability of NK cells to kill target cells can be enhanced by interferons or certain cytokines. NK cells that can kill sensitive targets can be isolated from uninfected individuals, but this activity is increased 20- to 100-fold when NK cells are exposed to IFN-α and IFN-β or to IL-12, a cytokine produced by dendritic cells and macrophages during infection by many types of pathogens. Activated NK cells serve to contain virus infections while the adaptive immune response is generating antigen-specific cytotoxic T cells and neutralizing antibodies that can clear the infection (Fig. 3.37). A clue to the physiological function of NK cells in humans comes from rare individuals deficient in these cells, who are frequently susceptible to herpesvirus infection. For example, a selective NK-cell deficiency results from mutations in the human MCM4 (minichromosome maintenance-deficient 4) protein, which is associated with predisposition to viral infections. Similarly, depletion of NK cells in mice, either by antibody or genetically, results in susceptibility to a number of viruses, including herpesviruses.

IL-12, produced by activated macrophages and dendritic cells, acts in synergy with the cytokine IL-18 to stimulate NK cells to secrete large amounts of IFN-γ. This IFN-γ is crucial in controlling certain infections because it precedes the production of IFN-γ by activated CD8 cytotoxic T cells. IFN-γ, whose receptor activates only the STAT1 transcription factor, is quite distinct functionally from the antiviral type I interferons IFN-α and IFN-β and is not directly induced by viral infection. The production of IFN-γ by NK cells early in an immune response can directly activate macrophages to enhance their capacity to kill pathogens, augmenting innate immunity. IFN-γ also influences adaptive immunity through actions on dendritic cells and by regulating the

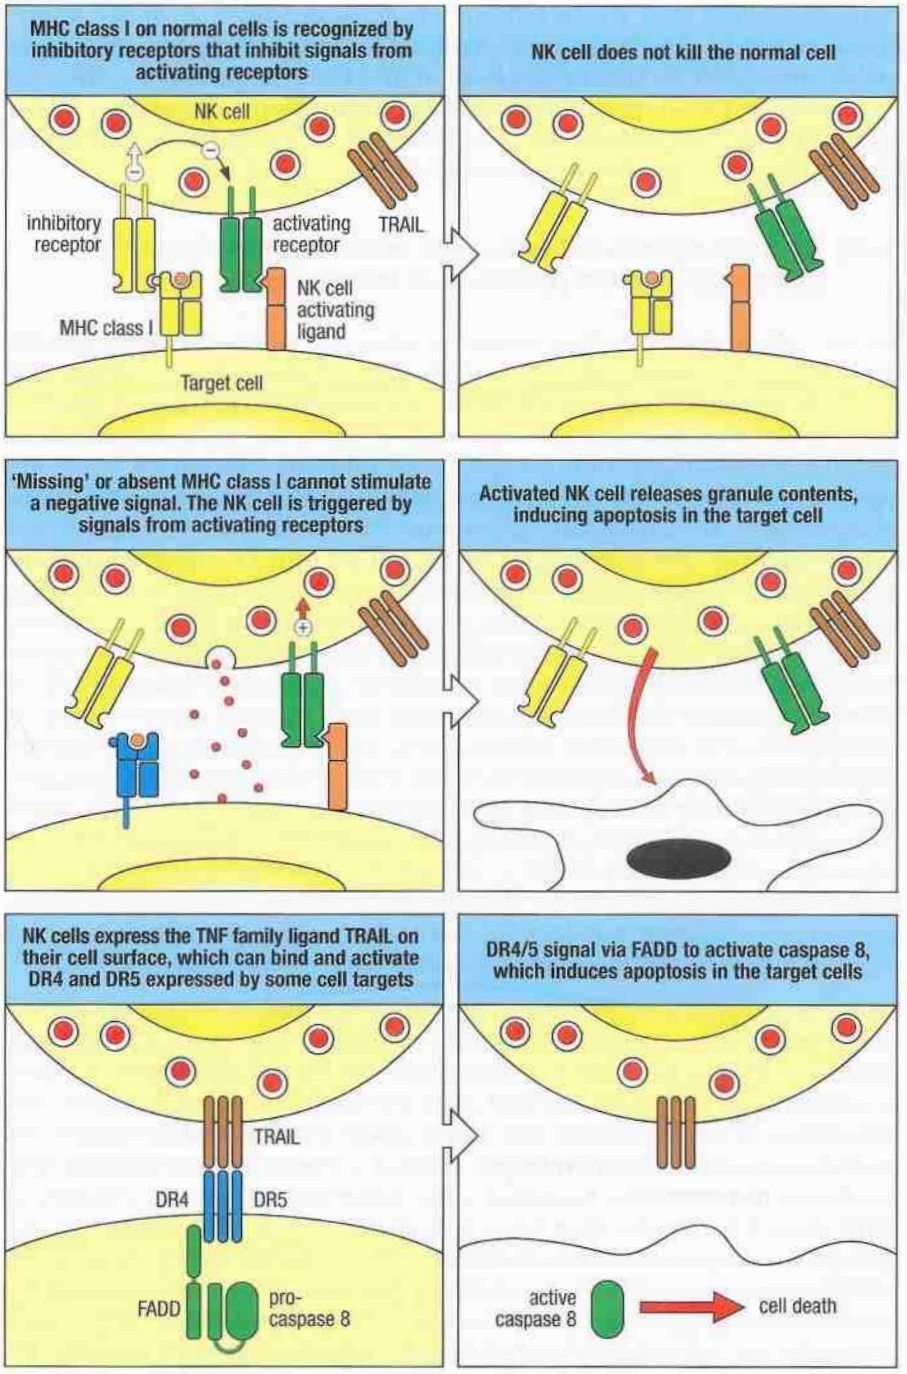
differentiation of CD4 T cells into the pro-inflammatory T_H1 subset, which produces IFN-γ. Accordingly, mice deficient for the gene encoding IFN-γ are highly susceptible to viruses and intracellular bacterial pathogens. NK cells also produce TNF-α, **granulocyte–macrophage colony-stimulating factor (GM-CSF)**, and the chemokines CCL3 (MIP-1α), CCL4, and CCL5 (RANTES), which act to recruit and activate macrophages.

3-25 NK cells express activating and inhibitory receptors to distinguish between healthy and infected cells.

For NK cells to defend against viruses or other pathogens, they must be able to distinguish infected cells from uninfected healthy cells. To do this, NK cells use a mechanism distinct from the mechanism of pathogen recognition used by T or B cells. An individual NK cell expresses various combinations of germline-encoded **activating receptors** and **inhibitory receptors**. While the exact details are not clear in every case, it is thought that the overall balance of signaling by these receptors determines whether an NK cell engages and kills a target cell. The receptors on an NK cell are tuned to detect changes in expression of various surface proteins on a target cell, referred to as '**dysregulated self**.' The activating receptors generally recognize cell-surface proteins that are induced on target cells by infection or stress, such as malignant transformation. These induced proteins are referred to as '**stress-induced self**.' A number of cellular perturbations, including DNA damage, signals related to proliferation, and heat shock–related stress, can lead to induction of ligands for activating receptors. Signaling by innate sensors (for example, TLRs) is also capable of inducing such ligands. When activating receptors on NK cells detect stress-induced self ligands, signaling is initiated in the NK cell that results in release of cytokines, such as IFN-γ, and killing of the stimulating cell through the release of cytotoxic granules. However, engagement of activating receptors is not always sufficient to induce NK-cell activation; negative signals imposed by inhibitory receptors must either be lost or overcome, as discussed below.

Inhibitory receptors on NK cells recognize surface molecules that are constitutively expressed at high levels by most healthy cells. As such, NK cells that encounter healthy cells receive signals that inhibit the signals downstream of activating receptors and prevent their activation. However, infection, cellular stress, or transformation can lead to down-regulation of the ligands for inhibitory receptors. The loss of these molecules is referred to as '**missing self**.' Inhibitory receptors can recognize other molecules, but those recognizing **MHC class I molecules** have been best characterized. MHC molecules are glycoproteins expressed on nearly all cells of the body. We will discuss the role of MHC proteins in antigen presentation to T cells in Chapter 6, but for now we need only to introduce the two main classes of MHC molecules. MHC class I molecules are expressed on most of the cells of the body (except, notably, red blood cells), whereas the expression of **MHC class II molecules** is far more restricted, largely to immune cells.

Inhibitory receptors that recognize MHC class I molecules function to prevent NK cells from killing normal host cells. The greater the number of MHC class I molecules on a cell surface, the better protected that cell is against attack by NK cells. Interferons induce expression of MHC class I molecules and protect uninfected host cells from being killed by NK cells, while also activating NK cells to kill virus-infected cells. Viruses and some other intracellular pathogens can cause down-regulation of MHC class I molecules as a strategy to prevent the display of antigens as peptides to T cells, also discussed in Chapter 13. MHC class I molecules are often similarly down-regulated in cancerous cells. Importantly, NK cells are able to sense this reduction in expression of MHC class I molecules through reduced signaling from their inhibitory receptors. Reduction in MHC class I expression is an example of 'missing self' and



MHC class I on normal cells is recognized by inhibitory receptors that inhibit signals from activating receptors

cell death

Fig. 3.38 Killing by NK cells depends on the balance between activating and inhibitory signals. NK cells have several different activating receptors that signal the NK to kill the bound cell. However, NK cells are prevented from a wholesale attack by another set of inhibitory receptors that recognize MHC class I molecules (which are present on almost all cell types) and that inhibit signaling by the activating receptors. Up-regulation of ligands for activating receptors can overrule this inhibition. Alternatively, activation can occur when inhibitory signals are lost, such as when viruses inhibit MHC class I expression or alter its conformation so as to avoid recognition by CD8 T cells. NK cells may also kill target cells through their expression of the TNF family member TRAIL, which binds to TNFR members DR4 and DR5 expressed by some types of cells. DR4 and DR5 signal through FADD, an adaptor that activates pro-caspase 8, leading to induction of apoptosis of the target cell.

increases the chance that an NK cell will kill the target cell. It is thought that the balance of signals from 'stress-induced self' and 'missing self' determines whether an individual NK cell will be triggered to kill a particular target cell (Fig. 3.38). Thus, receptors expressed on NK cells integrate the signals from two types of surface receptors, which together control an NK cell's cytotoxic activity and cytokine production.

3-26 NK-cell receptors belong to several structural families.

The receptors that regulate the activity of NK cells fall into several large families that contain a number of other cell-surface receptors in addition to NK receptors (Fig. 3.39). Members of the family of **killer cell immunoglobulin-like**

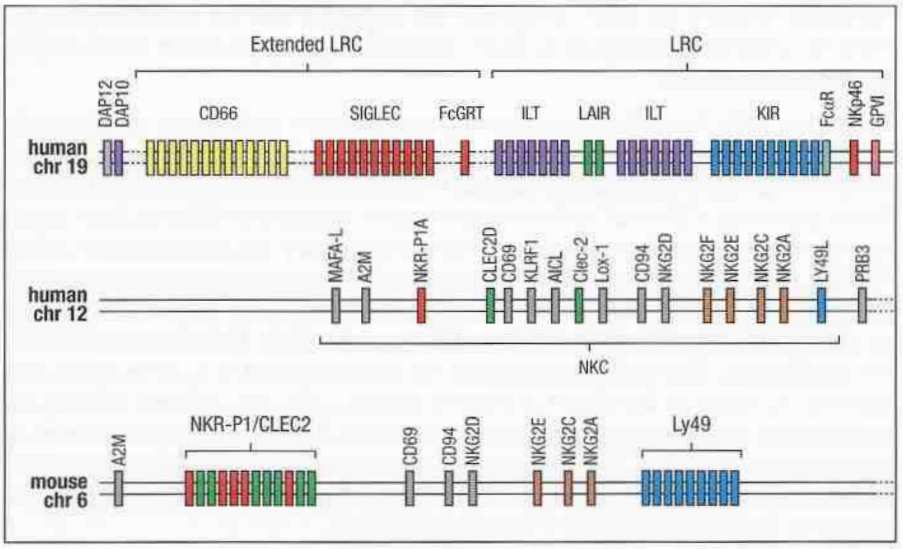

Fig. 3.39 The genes that encode NK receptors fall into two large families. The first, the leukocyte receptor complex (LRC), comprises a large cluster of genes encoding a family of proteins composed of immunoglobulin-like domains. These include the killer cell immunoglobulin-like receptors (KIRs) expressed by NK cells, the ILT (immunoglobulin-like transcript) class, and the leukocyte-associated immunoglobulin-like receptor (LAIR) gene families. The sialic acid–binding Ig-like lectins (SIGLECs) and members of the CD66 family are located nearby. In humans, this complex is located on chromosome 19. The second gene cluster is called the NK receptor complex (NKC) and encodes killer cell lectin-like receptors (KLRs), a receptor family that includes the NKG2 proteins and CD94, with which some NKG2 molecules pair to form a functional receptor. This complex is located on human chromosome 12. The corresponding locus in mice is located on chromosome 6 and also contains the expanded family of Ly49 genes. Some NK receptor genes are found outside these major gene clusters.

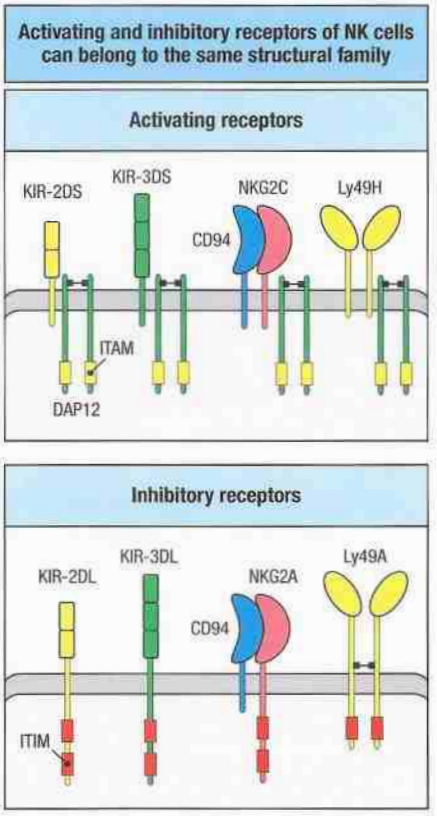

Fig. 3.40 The structural families of NK receptors encode both activating and inhibitory receptors. The families of killer cell immunoglobulin-like receptors (KIRs) and killer cell lectin-like receptors (KLRs and Ly49 receptors) have members that send activating signals to the NK cell (upper panel) and others that send inhibitory signals to the NK cell (lower panel). KIR family members are designated according to the number of immunoglobulin-like domains they possess and by the length of their cytoplasmic tails. Activating KIRs have short cytoplasmic tails and bear the designation 'S.' These associate with the signaling protein DAP12 via a charged amino acid residue in the transmembrane region. The cytoplasmic tails of DAP12 contain amino acid motifs called ITAMs, which are involved in signaling. NKG2 receptors belong to the KLR family, and, whether activating or inhibitory, form heterodimers with another C-type lectin–like family member, CD94. The inhibitory KIRs have longer cytoplasmic tails and are designated 'L.' Inhibitory KIR and Ly49 family members do not associate constitutively with adaptor proteins but contain a signaling motif called an ITIM, which, when phosphorylated, is recognized by inhibitory phosphatases.

receptors (KIRs) have differing numbers of immunoglobulin domains. Some, such as KIR-2D, have two immunoglobulin domains, whereas others, such as KIR-3D, have three. The KIR genes form part of a larger cluster of immunoglobulin-like receptor genes known as the **leukocyte receptor complex (LRC)**. Another family, the **killer cell lectin-like receptors (KLRs)** are C-type lectin–like proteins whose genes reside in a gene cluster called the **NK receptor complex (NKC)**. Mice lack KIR genes and instead predominantly express **Ly49 receptors**, encoded in the NKC on mouse chromosome 6, to control their NK-cell activity. These receptors can be activating or inhibitory and are highly polymorphic between different strains of mice. By contrast, humans lack functional Ly49 genes and rely on KIRs encoded in the LRC to control their NK-cell activity. An important feature of the NK-cell population is that any given NK cell expresses only a subset of the receptors in its potential repertoire, and so not all NK cells in an individual are identical.

Activating and inhibitory receptors are present within the same structural family. Whether a KIR or Ly49 protein is activating or inhibitory depends on the presence or absence of particular signaling motifs in its cytoplasmic domain. Inhibitory KIRs and Ly49s have long cytoplasmic tails that contain an **immunoreceptor tyrosine-based inhibition motif (ITIM)**. The consensus amino acid sequence for the ITIM is V/I/LxYxxL/V, where 'x' stands for any amino acid. For example, the cytoplasmic tails of the inhibitory receptors KIR-2DL and KIR-3DL each contain two ITIMs (Fig. 3.40). When ligands associate with an inhibitory KIR, the tyrosine in its ITIM becomes phosphorylated by the action of **Src family protein tyrosine kinases**. When phosphorylated, the ITIM can then bind the intracellular protein tyrosine phosphatases **SHP-1** (Src homology region 2–containing protein tyrosine phosphatase-1) and **SHP-2**, which become localized near the cell membrane. These phosphatases inhibit

signaling induced by other receptors (for example, the NK activating receptors) by removing phosphates from tyrosine residues on other intracellular signaling molecules.

Activating KIRs have short cytoplasmic tails and are designated, for example, as KIR-2DS and KIR-3DS (see Fig. 3.40). In mice, activating Ly49 proteins similarly have a short cytoplasmic tail that contains no signaling domain. Instead, these activating KIRs and Ly49 receptors have a charged residue in their transmembrane regions that associates with an accessory signaling protein called **DAP12**. DAP12 is a transmembrane protein that contains an immunoreceptor tyrosine-based activation motif (ITAM) with consensus sequence Yxx[L/I] x_{6-9}Yxx[L/I]) in its cytoplasmic tail and forms a disulfide-linked homodimer in the membrane. When a ligand binds to an activating KIR or Ly49 receptor, the tyrosine residues in the ITAM of DAP12 become phosphorylated, turning on intracellular signaling pathways that activate the NK cell and lead to release of the cytotoxic granules. The phosphorylated ITAMs bind and activate intracellular tyrosine kinases such as Syk or ZAP-70, leading to further signaling events similar to those described for T cells in Chapter 7.

The KLR family also has both activating and inhibitory members. In mice, inhibitory Ly49 receptors have an ITIM in their cytoplasmic tail that recruits SHP-1. The latter's importance is shown by the failure of Ly49 to inhibit NK activation upon binding to MHC class I in mice carrying the **motheaten** mutation, which inactivates SHP-1 protein. In humans and mice, NK cells express a heterodimer of two different C-type lectin–like receptors, **CD94** and **NKG2**. This heterodimer interacts with nonpolymorphic MHC class I–like molecules, including HLA-E in humans and Qa1 in mice. HLA-E and Qa1 are unusual in that instead of binding peptides derived from pathogens, they bind fragments of the **signal peptide** derived from other MHC class I molecules during processing in the endoplasmic reticulum. This enables CD94:NKG2 to detect the presence of several different MHC class I variants, whose expression may be targeted by viruses, and kill cells in which overall MHC molecule expression is diminished. In humans there are four closely related NKG2 family proteins, NKG2A, C, E, and F (encoded by *KLRC1–4*), and a more distantly related protein, NKG2D (encoded by *KLRK1*). Of these, for example, NKG2A contains an ITIM and is inhibitory, whereas NKG2C has a charged transmembrane residue, associates with DAP12, and is activating (see Fig. 3.40). NKG2D is also activating but quite distinct from the other NKG2 receptors, and we will discuss it separately in the next section.

The overall response of NK cells to differences in MHC expression is further complicated by the extensive polymorphism of KIR genes, with different numbers of activating and inhibitory KIR genes being found in different people. The responsiveness of NK cells is thought to be tuned by their ability to recognize inhibitory ligands during their development. This process, referred to as licensing or education, is likely to underlie the effect of NK cells as a barrier to transplantation, because the NK cells educated in the environment of the recipient may fail to recognize the same inhibitory ligands on donor cells. A similar phenomenon may occur during pregnancy, because of differences between fetal and maternal MHC molecules (see Section 15-26). The advantage of such extensive KIR polymorphism is not yet clear, and some genetic epidemiologic studies even suggest an association between certain alleles of KIR genes and earlier onset (although not absolute frequency) of rheumatoid arthritis. The KIR gene cluster is not present in mice, but some species, including some primates, contain genes of both the KIR and KLR families. This might suggest that both gene clusters are relatively ancient and that for some reason, one or the other gene cluster was lost by mice and humans.

Signaling by the inhibitory NK receptors suppresses the killing activity and cytokine production of NK cells. This means NK cells will not kill healthy, genetically identical cells with normal expression of MHC class I molecules,

such as the other cells of the body. Virus-infected cells, however, can become susceptible to being killed by NK cells by a variety of mechanisms. First, some viruses inhibit all protein synthesis in their host cells, so that synthesis of MHC class I proteins would be blocked in infected cells, even while their production in uninfected cells is being stimulated by the actions of type I interferons. The reduced level of MHC class I expression in infected cells would make them correspondingly less able to inhibit NK cells through their MHC-specific receptors, and they would become more susceptible to being killed. Second, many viruses can selectively prevent the export of MHC class I molecules to the cell surface or induce their degradation once there. This might allow the infected cell to evade recognition by cytotoxic T cells but would make it susceptible to being killed by NK cells. Virally infected cells can still be killed by NK cells even if the cells do not down-regulate MHC, provided that ligands for activating receptors are induced. However, some viruses target ligands for the activating receptors on NK cells, thwarting NK-cell recognition and killing of virus-infected cells.

3-27 NK cells express activating receptors that recognize ligands induced on infected cells or tumor cells.

In addition to the KIRs and KLRs, which have a role in sensing the level of MHC class I proteins present on other cells, NK cells also express receptors that more directly sense the presence of infection or other perturbations in a cell. Activating receptors for the recognition of infected cells, tumor cells, and cells injured by physical or chemical damage include the **natural cytotoxicity receptors (NCRs)** NKp30, NKp44, and NKp46, which are immunoglobulin-like receptors, and the C-type lectin–like family members **Ly49H** and **NKG2D** (Fig. 3.41). Among NCRs, only NKp46 is conserved in humans and in mice, and it is the most selective marker of NK cells across mammalian species. The ligands recognized by the NCRs are still being defined, but some evidence suggests that they recognize viral proteins. Ly49H is an activating receptor that recognizes the viral protein m157, an MHC class I–like structure encoded by the murine cytomegalovirus. The ligand for NKp30 is a protein named B7-H6, a member of the B7 family of co-stimulatory proteins, further described in Chapters 7 and 9.

NKG2D has a specialized role in activating NK cells. NKG2A, NKG2C, NKG2E, and NKG2F form heterodimers with CD94 and bind the MHC class I molecule HLA-E. In contrast, two NKG2D molecules form a homodimer that binds to several MHC class I–like molecules that are induced by various types of cellular stress. These include the MIC molecules **MIC-A and MIC-B** and the **RAET1** family of proteins, which are similar to the α_1 and α_2 domains of MHC class I molecules (Fig. 3.42). The RAET1 family has 10 members, three of which were initially characterized as ligands for the **cytomegalovirus UL16 protein** and are also called **UL16-binding proteins, or ULBPs**. Mice do not have equivalents of the MIC molecules; however, the ligands for mouse NKG2D have a very similar structure to that of the RAET1 proteins and are probably orthologs of them. In fact, these ligands were first identified in mice as the **RAE1 (retinoic acid early inducible 1) protein family** and also include related proteins H60 and MULT1 (see Fig. 6.26). We will return to these MHC-like molecules when we discuss the structure of the MHC molecule in Chapter 6.

The ligands for NKG2D are expressed in response to cellular or metabolic stress, and so are up-regulated on cells infected with intracellular bacteria and most viruses, as well as on incipient tumor cells that have become malignantly transformed. Thus, recognition by NKG2D acts as a generalized alarm signal to the immune system. In addition to expression by a subset of NK cells, NKG2D is expressed by various T cells, including all CD8 T cells and some γδ T cells and invariant NKT cells (described in Chapter 8). In these

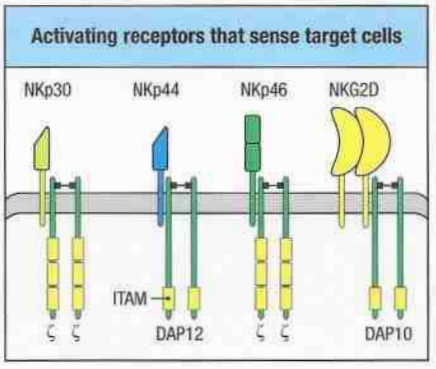

Fig. 3.41 Activating receptors of NK cells include the natural cytotoxicity receptors and NKG2D. The natural cytotoxicity receptors are immunoglobulin-like proteins. NKp30 and NKp44, for example, have an extracellular domain that resembles a single variable domain of an immunoglobulin molecule. NKp30 and NKp46 activate the NK cell through their association with homodimers of the CD3ζ chain or the Fc receptor γ chain (not shown). These signaling proteins also associate with other types of receptors that are described in Chapter 7. NKp44 activates the NK cell through its association with homodimers of DAP12. NKp46 resembles the KIR-2D molecules in having two domains that resemble the constant domains of an immunoglobulin molecule. NKG2D is a member of the C-type lectin–like family and forms a homodimer that associates with DAP10. In mice, an alternatively spliced form of NKG2D also associates with DAP12 (not shown).

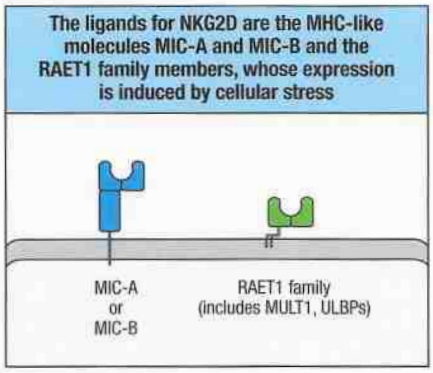

The ligands for NKG2D are the MHC-like molecules MIC-A and MIC-B and the RAET1 family members, whose expression is induced by cellular stress
MIC-A or MIC-B
RAET1 family (includes MULT1, ULBPs)

Fig. 3.42 The ligands for the activating NK receptor NKG2D are proteins that are expressed in conditions of cellular stress. Ligands for NKG2D are induced on epithelial and other cells by stress, such as DNA damage, cellular transformation, or infection. The MIC proteins MIC-A and MIC-B are MHC-like molecules. RAET1 family members, including the subset designated as UL16-binding proteins (ULBPs), also resemble a portion of an MHC class I molecule—the α_1 and α_2 domains—and most (but not all) are attached to the cell via a glycosylphosphatidylinositol linkage. Unlike MHC class I molecules, the NKG2D ligands do not bind processed peptides.

cells, recognition of NKG2D ligands provides a potent co-stimulatory signal that enhances their effector functions.

NKG2D differs from other activating receptors on NK cells in the signaling pathway it engages within the cell. The other activating receptors are associated intracellularly with signaling proteins such as the CD3ζ chain, the Fc receptor γ chain, and DAP12, which all contain ITAMs. In contrast, NKG2D binds a different adaptor protein, **DAP10**, which does not contain an ITAM sequence and instead activates the intracellular lipid kinase **phosphatidylinositol 3-kinase (PI 3-kinase)**, initiating a different series of intracellular signaling events in the NK cell (see Section 7-4). Generally, PI 3-kinase is considered to enhance the survival of cells in which it is activated, thereby augmenting the cell's overall effector activity. In NK cells, activation of PI 3-kinase is directly linked to the induction of cytotoxic activity. In mice, the workings of NKG2D are more complicated, because mouse NKG2D is produced in two alternatively spliced forms, one of which binds DAP12 and DAP10, whereas the other binds only DAP10. Mouse NKG2D can thus activate both signaling pathways, whereas human NKG2D seems to signal only through DAP10 to activate the PI 3-kinase pathway. Finally, NK cells express several receptors from the **SLAM (signaling lymphocyte activation molecule)** family, including **2B4**, which recognizes the cell-surface molecule **CD48** expressed by many cells including NK cells. Interactions between 2B4 and CD48 on nearby NK cells can release signals that promote survival and proliferation through **SAP (SLAM-associated protein)** and the Src kinase Fyn.

Summary.

Triggering of innate sensors on various cells—neutrophils, macrophages, and dendritic cells in particular—not only activates these cells' individual effector functions but also stimulates the release of pro-inflammatory chemokines and cytokines that act together to recruit more phagocytic cells to the site of infection. Especially prominent is the early recruitment of neutrophils and monocytes. Furthermore, cytokines released by tissue phagocytic cells can induce more systemic effects, including fever and the production of acute-phase response proteins, such as mannose-binding lectin, C-reactive protein, fibrinogen, and pulmonary surfactant proteins, which add to a general state of augmented innate immunity. These cytokines also mobilize antigen-presenting cells that induce the adaptive immune response. The innate immune system has at its service several recently recognized subtypes of innate lymphoid cells to join the ranks of the long-recognized NK cells. ILCs exhibit specialized effector activity in response to different signals and act to amplify the strength of the innate response. The production of interferons in response to viral infections serves to inhibit viral replication and to activate NK cells. These in turn can distinguish healthy cells from those that are infected by virus or that are transformed or stressed in some way on the basis of expression of MHC class I molecules and MHC-related molecules that are ligands for some NK receptors. As we will see later in the book, cytokines, chemokines, phagocytic cells, and NK cells are all effector mechanisms that are also employed in the adaptive immune response, which uses variable receptors to target specific pathogen antigens.

Summary to Chapter 3.

Innate immunity uses a variety of effector mechanisms to detect infection and eliminate pathogens or to hold them in check until an adaptive immune response develops. These effector mechanisms are all regulated by germline-encoded receptors on many types of cells that can detect molecules of microbial origin or that sense pathogen-induced changes to host cells. The

induced responses of the innate immune system are based on several distinct components. After the initial barriers—the body's epithelia and the soluble antimicrobial molecules described in Chapter 2—have been breached, the most important innate defenses rely on tissue macrophages and other tissue-resident sensor cells, such as dendritic cells and ILCs. Macrophages provide a double service: they mediate rapid cellular defense at the borders of infection through phagocytosis and antimicrobial actions, and they also use their various innate sensors to activate the process of inflammation, which involves recruiting additional cells to sites of infection. Innate sensors activate signaling pathways that lead to the production of pro-inflammatory and antiviral cytokines, which in turn stimulate innate effector responses while also helping to initiate an adaptive immune response. The uncovering of the pathogen-sensing mechanisms described in this chapter is still extremely active. It is providing new insights into human autoinflammatory conditions such as lupus, Crohn's disease, and gout. Indeed, the induction of powerful effector mechanisms by innate immune recognition based on germline-encoded receptors clearly has some dangers. It is a double-edged sword, as is illustrated by the effects of the cytokine TNF-α—beneficial when released locally, but disastrous when produced systemically. This illustrates the evolutionary knife edge along which all innate mechanisms of host defense travel. The innate immune system can be viewed as a defense system that mainly frustrates the establishment of a focus of infection; however, even when it proves limited in fulfilling this function, it has already set in motion the initiation of the adaptive immune response, which forms an essential part of human defenses against infection.

Discussion Questions

3.1 The innate immune system uses multiple strategies to identify pathogens.

a. Give examples of each strategy.

b. What are the advantages or disadvantages of these different strategies?

3.2 What is the significance of nonclonal expression of pattern-recognition receptors?

3.3 There are a number of cases in which multiple innate immune receptors recognize the same ligand. List some examples. Why might multiple receptors evolve to recognize the same ligand?

3.4 Signaling cascades involving multiple adaptors and numerous intermediate steps seem unnecessarily complex. Why might they have evolved in this way?

3.5 Many signaling cascades used in innate immunity involve the interactions of proteins via specific protein domains. Name the kinds of interaction domains used in TLR signaling. How are the domains of the intermediates used to propagate signals? Also answer this question for RLR and NLR proteins.

3.6 Describe the ways in which interferons interfere with viral replication. Why doesn't the host produce interferons all the time, as a way of preventing viral infection?

3.7 How is it that NK cells can recognize both infected cells and cancerous cells?

3.8 Throughout the chapter we discuss how inappropriate activation of the innate immune system can lead to disease. Select two examples and describe how the inappropriate activation occurs.

6 Antigen Presentation to T Lymphocytes

Antigen Recognition by B-cell and T-cell Receptors

4

IN THIS CHAPTER

The structure of a typical antibody molecule.

Structural variation in immunoglobulin constant regions.

The interaction of the antibody molecule with specific antigen.

Antigen recognition by T cells.

Innate immune responses are the body's initial defense against infection, but these work only to control pathogens that have certain molecular patterns or that induce interferons and other nonspecific defenses. To effectively fight the wide range of pathogens an individual will encounter, the lymphocytes of the adaptive immune system have evolved to recognize a great variety of different **antigens** from bacteria, viruses, and other disease-causing organisms. An antigen is any molecule or part of a molecule that is specifically recognized by the highly specialized recognition proteins of lymphocytes. On B cells these proteins are the **immunoglobulins (Igs)**, which these cells produce in a vast range of antigen specificities, each B cell producing immunoglobulins of a single specificity (see Section 1-12). A membrane-bound form of immunoglobulin on the B-cell surface serves as the cell's receptor for antigen and is known as the **B-cell receptor (BCR)**. A secreted form of immunoglobulin of the same antigen specificity is the **antibody** produced by terminally differentiated B cells—plasmablasts and plasma cells. The secretion of antibodies, which bind pathogens or their toxic products in the extracellular spaces of the body (see Fig. 1.28), is the main effector function of B cells in adaptive immunity.

Antibodies were the first proteins involved in specific immune recognition to be characterized and are understood in great detail. The antibody molecule has two separate functions: one is to bind specifically to the pathogen or its products that have elicited the immune response; the other is to recruit other cells and molecules to destroy the pathogen once antibody has bound. For example, binding by antibodies can neutralize viruses and mark pathogens for destruction by phagocytes and complement, as described in Chapters 2 and 3. Recognition and effector functions are structurally separated in the antibody molecule, one part of which specifically binds to the antigen whereas the other engages the elimination mechanisms. The antigen-binding region varies extensively among antibody molecules and is known as the **variable region**, or **V region**. The variability of antibody molecules allows each antibody to bind a different specific antigen, and the total repertoire of antibodies made by a single individual is large enough to ensure that virtually any structure can be recognized. The region of the antibody molecule that engages the

effector functions of the immune system does not vary in the same way and is known as the **constant region**, or **C region**. It comes in five main forms, called **isotypes**, each of which is specialized for activating different effector mechanisms. The membrane-bound B-cell receptor does not have these effector functions, because the C region remains inserted in the membrane of the B cell. The function of the B-cell receptor is to recognize and bind antigen via the V regions exposed on the surface of the cell, thus transmitting a signal that activates the B cell, leading to clonal expansion and antibody production. To this end, the B-cell receptor is associated with a set of intracellular signaling proteins, which will be described in Chapter 7. Antibodies have become an important class of drug due to their highly specific activities, and we return to discuss their therapeutic uses in Chapter 16.

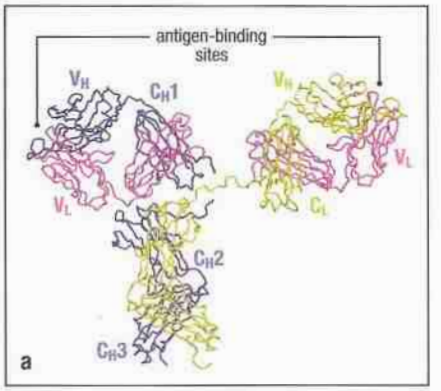
The antigen-recognition molecules of T cells are made solely as membrane-bound proteins, which are associated with an intracellular signaling complex and function only to signal T cells for activation. These **T-cell receptors (TCRs)** are related to immunoglobulins both in their protein structure—having both V and C regions—and in the genetic mechanism that produces their great variability, which is discussed in Chapter 5. The T-cell receptor differs from the B-cell receptor in an important way, however: it does not recognize and bind antigen by itself but instead recognizes short peptide fragments of protein antigens that are presented to it by proteins known as **MHC molecules** on the surface of host cells.

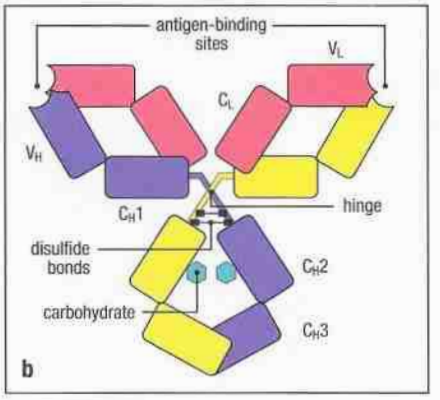
The MHC molecules are transmembrane glycoproteins encoded in the large cluster of genes known as the **major histocompatibility complex (MHC)**. The most striking structural feature of MHC molecules is a cleft in the extracellular face of the molecule in which peptides can be bound. MHC molecules are highly **polymorphic**—each type of MHC molecule occurs in many different versions—within the population. These are encoded by slightly different versions of individual genes called **alleles**. Most people are therefore heterozygous for the MHC molecules; that is, they express two different alleles for each type of MHC molecule, thus increasing the range of pathogen-derived peptides and self peptides that can be bound. T-cell receptors recognize features of both the peptide antigen and the MHC molecule to which it is bound. This introduces an extra dimension to antigen recognition by T cells, known as **MHC restriction** because any given T-cell receptor is specific for a particular peptide bound to a particular MHC molecule.

In this chapter, we focus on the structure and antigen-binding properties of immunoglobulins and T-cell receptors. Although B cells and T cells recognize foreign molecules in separate distinct fashions, the receptor molecules they use for this task are very similar in structure. We will see how this basic structure can accommodate great variability in antigen specificity, and how it enables immunoglobulins and T-cell receptors to perform their functions as the antigen-recognition molecules of the adaptive immune response. With this foundation, we will return to discuss the impact of MHC polymorphism on T-cell antigen recognition and T-cell development in Chapters 6 and 8, respectively.

The structure of a typical antibody molecule.

Antibodies are the secreted form of the B-cell receptor. Because they are soluble and secreted into the blood in large quantities, antibodies are easily obtained and easily studied. For this reason, most of what we know about the B-cell receptor comes from the study of antibodies.





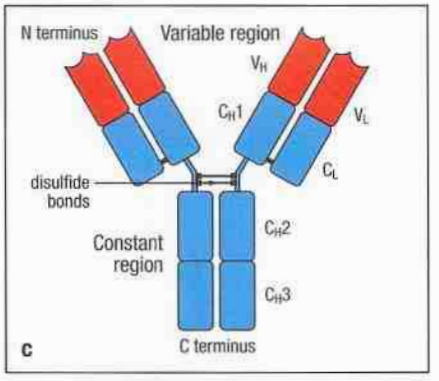


Fig. 4.1 Structure of an antibody molecule. In panel a, the X-ray crystallographic structure of an IgG antibody is illustrated as a ribbon diagram of the backbones of the polypeptide chains. The two heavy chains are shown in yellow and purple. The two light chains are both shown in red. Three globular regions form an approximate Y shape. The two antigen-binding sites are at the tips of the arms, which are tethered at their other end to the trunk of the Y by a flexible hinge region. The light-chain variable (V_L) and constant (C_L) regions are indicated. The heavy-chain variable region (V_H) and V_L together form the antigen-binding site of the antibody. In panel b, a schematic representation of the same structure denotes each immunoglobulin domain as a separate rectangle. The hinge that tethers each heavy chain's first constant domain (C_H1) to its second (C_H2) is illustrated by a thin purple or yellow line, respectively. The antigen-binding sites are indicated by concave regions in V_L and V_H. Positions of carbohydrate modifications and disulfide linkages are indicated. In panel c, a more simplified schematic is shown that will be used throughout this book with the variable region in red and the constant region in blue. C terminus, carboxyl terminus; N terminus, amino terminus.

Antibody molecules are roughly Y-shaped, as represented in Fig. 4.1 using three different schematic styles. This part of the chapter will explain how this structure is formed and allows the antibody molecule to perform its dual tasks of binding to a wide variety of antigens while also binding to effector molecules and to cells that destroy the antigen. Each of these tasks is performed by different parts of the molecule. The ends of the two arms of the Y—the V regions—are involved in antigen binding, and they vary in their detailed structure between different antibody molecules. The stem of the Y—the C region—is far less variable and is the part that interacts with effector molecules and cells. There are five different **classes** of immunoglobulins, distinguished in their being constructed from C regions that have different structures and properties. These are known as **immunoglobulin M (IgM)**, **immunoglobulin D (IgD)**, **immunoglobulin G (IgG)**, **immunoglobulin A (IgA)**, and **immunoglobulin E (IgE)**.

All antibodies are constructed in the same way from paired heavy and light polypeptide chains, and the generic term immunoglobulin is used for all such proteins. More subtle differences confined to the V region account for the specificity of antigen binding. We will use the IgG antibody molecule as an example to describe the general structural features of immunoglobulins.

4-1 IgG antibodies consist of four polypeptide chains.

IgG antibodies are large molecules with a molecular mass of approximately 150 kDa and are composed of two different kinds of polypeptide chains. One, of approximately 50 kDa, is called the **heavy** or **H chain**, and the other, of 25 kDa, is the **light** or **L chain** (Fig. 4.2). Each IgG molecule consists of two heavy chains and two light chains. The two heavy chains are linked to each other by disulfide bonds, and each heavy chain is linked to a light chain by a disulfide bond. In any given immunoglobulin molecule, the two heavy chains and the two light chains are identical, giving an antibody molecule two identical antigen-binding sites. This gives the antibody the ability to bind simultaneously to two identical antigens on a surface, thereby increasing the total strength of the interaction, which is called its **avidity**. The strength of the interaction between a single antigen-binding site and its antigen is called its **affinity**.

Two types of light chains, **lambda (λ)** and **kappa (κ)**, are found in antibodies. A given immunoglobulin has either κ chains or λ chains, never one of each. No

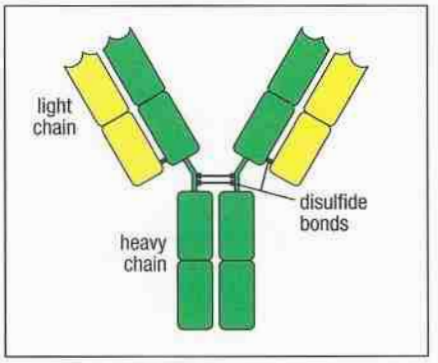

Fig. 4.2 Immunoglobulin molecules are composed of two types of protein chains: heavy chains and light chains. Each immunoglobulin molecule is made up of two hinged heavy chains (green) and two light chains (yellow) joined by disulfide bonds so that each heavy chain is linked to a light chain and the two heavy chains are linked together.

functional difference has been found between antibodies having λ or κ light chains, and either type of light chain can be found in antibodies of any of the five major classes. The ratio of the two types of light chains varies from species to species. In mice, the average κ to λ ratio is 20:1, whereas in humans it is 2:1 and in cattle it is 1:20. The reason for this variation is unknown. Distortions of this ratio can sometimes be used to detect the abnormal proliferation of a B-cell clone, because all progeny of a particular B cell will express an identical light chain. For example, an abnormally high level of λ light chains in a person might indicate the presence of a B-cell tumor that is producing λ chains.

Figure 4.2 depicts a typical IgG molecule; however, not all antibodies in the body are IgG. In addition to IgG, there are four other classes of antibodies that differ in the structures of their heavy chains. These different classes of antibodies are known as isotypes, and they include IgM, IgD, IgG, IgA, and IgE. We will first consider IgG as a typical antibody molecule and then return to discuss the structural and functional properties of the different heavy-chain isotypes in Section 4-6.

The structure of a B-cell antigen receptor on the surface of a B cell is identical to that of its corresponding antibody except for a small portion of the carboxyl terminus of the heavy-chain C region. In the B-cell receptor, the carboxyl terminus is a hydrophobic amino acid sequence that anchors the molecule in the membrane, whereas in the antibody it is a hydrophilic sequence that allows secretion.

4-2 Immunoglobulin heavy and light chains are composed of constant and variable regions.

The amino acid sequences of many immunoglobulin heavy and light chains have been determined and reveal two important features of antibody molecules. First, each chain consists of a series of similar, although not identical, sequences, each about 110 amino acids long. Each of these repeats corresponds to a discrete, compactly folded region of protein known as an **immunoglobulin domain**, or **Ig domain**. The light chain consists of two Ig domains, whereas the heavy chain of the IgG antibody contains four Ig domains (see Fig. 4.2). This suggests that the immunoglobulin chains have evolved by repeated duplication of ancestral gene segments corresponding to a single Ig domain.

The second important feature is that the amino-terminal amino acid sequences of the heavy and light chains vary greatly between different antibodies. The variability is limited to approximately the first 110 amino acids, corresponding to the first Ig domain, whereas the remaining domains are constant between immunoglobulin chains of the same isotype. The amino-terminal **variable Ig domains (V domains)** of the heavy and light chains (V_H and V_L, respectively) together make up the V region of the antibody and determine its antigen-binding specificity, whereas the **constant Ig domains (C domains)** of the heavy and light chains (C_H and C_L, respectively) make up the C region (see Fig. 4.1). The multiple heavy-chain C domains are numbered from the amino-terminal end to the carboxyl terminus; for example, C_H1, C_H2, and so on.

4-3 The domains of an immunoglobulin molecule have similar structures.

Immunoglobulin heavy and light chains are composed of a series of Ig domains that have a similar overall structure. Within this basic structure, there are distinct differences between V and C domains that are illustrated for the light chain in Fig. 4.3. Each V or C domain is constructed from two **β sheets**. A β sheet is built from several **β strands**, which are regions of protein where several consecutive polypeptides have their peptide backbone bonds arranged

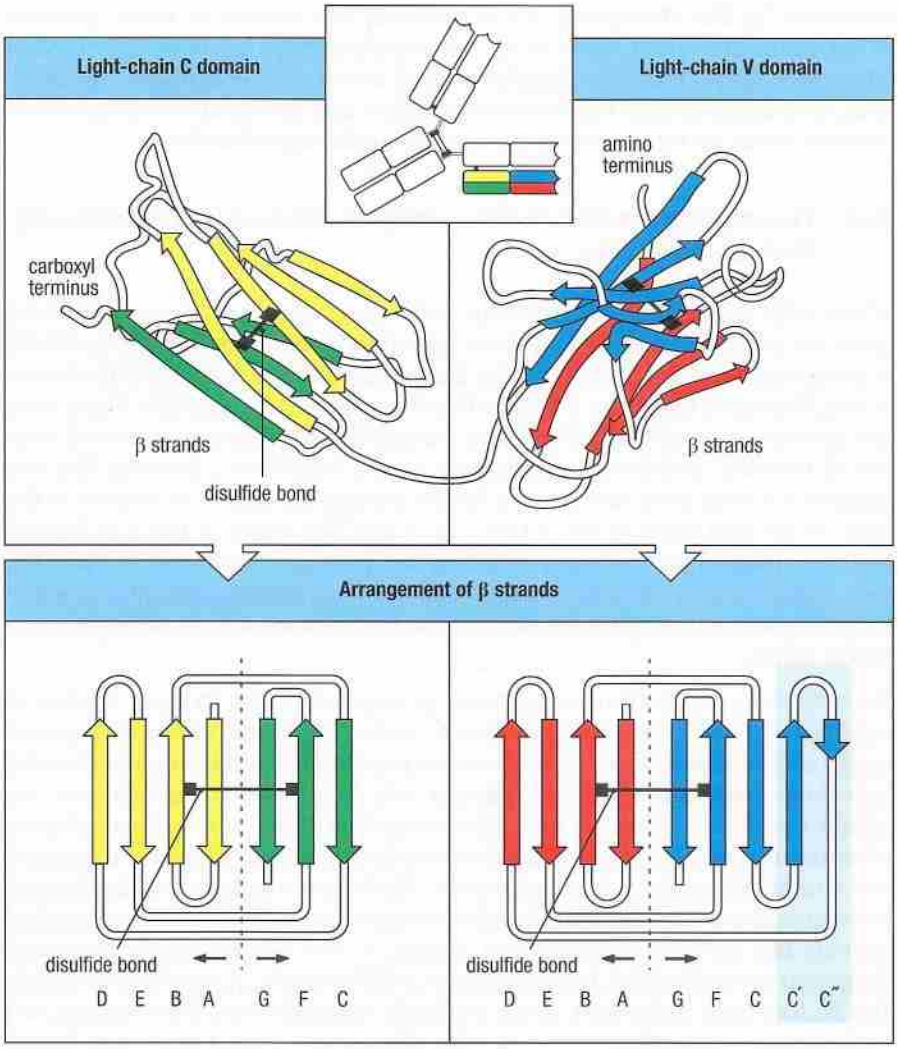

Fig. 4.3 The structure of immunoglobulin constant and variable domains. The upper panels show schematically the folding pattern of the constant (C) and variable (V) domains of an immunoglobulin light chain. Each domain is a barrel-shaped structure in which strands of polypeptide chain (β strands) running in opposite directions (antiparallel) pack together to form two β sheets (shown in yellow and green for the C domain and red and blue for the V domain), which are held together by a disulfide bond. The way in which the polypeptide chain folds to give the final structure can be seen more clearly when the sheets are opened out, as shown in the lower panels. The β strands are lettered sequentially with respect to the order of their occurrence in the amino acid sequence of the domains; the order in each β sheet is characteristic of immunoglobulin domains. The β strands C′ and C″ that are found in the V domains but not in the C domains are indicated by a blue-shaded background. The characteristic four-strand plus three-strand (C-region type domain) or four-strand plus five-strand (V-region type domain) arrangements are typical immunoglobulin superfamily domain building blocks, found in a whole range of other proteins as well as antibodies and T-cell receptors.

in an extended, or flat, conformation. β strands in proteins are sometimes shown as 'ribbons with an arrow' to indicate the direction of the polypeptide backbone (see Fig. 4.3). β strands can pack together in a side-by-side manner, being stabilized laterally by two or three backbone hydrogen bonds between adjacent strands. This arrangement is called a β sheet. The Ig domain has two β sheets that are folded onto each other, like two pieces of bread, into a structure called a β **sandwich**, and are covalently linked by a disulfide bond between cysteine residues from each β sheet. This distinctive structure is known as the **immunoglobulin fold**.

The similarities and differences between V and C domains can be seen in the bottom panels of Fig. 4.3. Here, the Ig domains have been opened out to show how their respective polypeptide chains fold to create each of the β sheets and how each polypeptide chain forms flexible loops between adjacent β strands as it turns to change direction. The main difference between the V and C domains is that the V domain is larger and contains extra β strands, called C′ and C″. In the V domain, the flexible loops formed between some of the β strands contribute to the antigen-binding site of the immunoglobulin molecule.

Many of the amino acids that are common to the C and V domains are present in the core of the immunoglobulin fold and are essential for its stability. Other proteins with sequences similar to those of immunoglobulins have been found to have domains with a similar structure, called **immunoglobulin-like**

domains (Ig-like domains). These domains are present in many proteins of the immune system, such as the KIRs expressed by NK cells described in Chapter 3. They are also frequently involved in cell–cell recognition and adhesion, and together with the immunoglobulins and the T-cell receptors, these proteins make up the extensive **immunoglobulin superfamily**.

4-4 The antibody molecule can readily be cleaved into functionally distinct fragments.

When fully assembled, an antibody molecule comprises three equal-sized globular portions, with its two arms joined to its trunk by a flexible stretch of polypeptide chain known as the **hinge region** (see Fig. 4.1b). Each arm of this Y-shaped structure is formed by the association of a light chain with the amino-terminal half of a heavy chain; the V_H domain is paired with the V_L domain, and the C_H1 domain is paired with the C_L domain. The two antigen-binding sites are formed by the paired V_H and V_L domains at the ends of the two arms of the Y (see Fig. 4.1b). The trunk of the Y is formed by the pairing of the carboxyl-terminal halves of the two heavy chains. The C_H3 domains pair with each other but the C_H2 domains do not interact. Carbohydrate side chains attached to the C_H2 domains lie between the two heavy chains.

Proteolytic enzymes (proteases) were an important tool in early studies of antibody structure, and it is valuable to review the terminology they generated. Limited digestion with the protease papain cleaves antibody molecules into three fragments (Fig. 4.4). **Papain** cuts the antibody molecule on the amino-terminal side of the disulfide bonds that link the two heavy chains, releasing the two arms of the antibody molecule as two identical fragments that contain the antigen-binding activity. These are called the **Fab fragments**, for fragment antigen binding. The other fragment contains no antigen-binding activity, but because it crystallized readily, it was named the **Fc fragment** (fragment crystallizable). It corresponds to the paired C_H2 and C_H3 domains. The Fc fragment is the part of the antibody molecule that does not interact with antigen, but rather interacts with effector molecules and cells, and it differs between heavy-chain isotypes. Another protease, **pepsin**, cuts on the carboxyl-terminal side of the disulfide bonds (see Fig. 4.4). This produces a fragment, the **$F(ab')_2$ fragment**, in which the two antigen-binding arms of the antibody molecule remain linked. Pepsin cuts the remaining part of the heavy chain into several small fragments. The $F(ab')_2$ fragment has exactly the same antigen-binding characteristics as the original antibody but is unable to interact with any effector molecule, such as C1q or Fc receptors, and can be used experimentally to separate the antigen-binding functions from the antibody's other effector functions.

Many antibody-related molecules can be constructed using genetic engineering techniques, and many antibodies and antibody-related molecules are being used therapeutically to treat a variety of diseases. We will return to this topic in Chapter 16, where we discuss the various therapeutic uses of antibodies that have been developed over the past two decades.

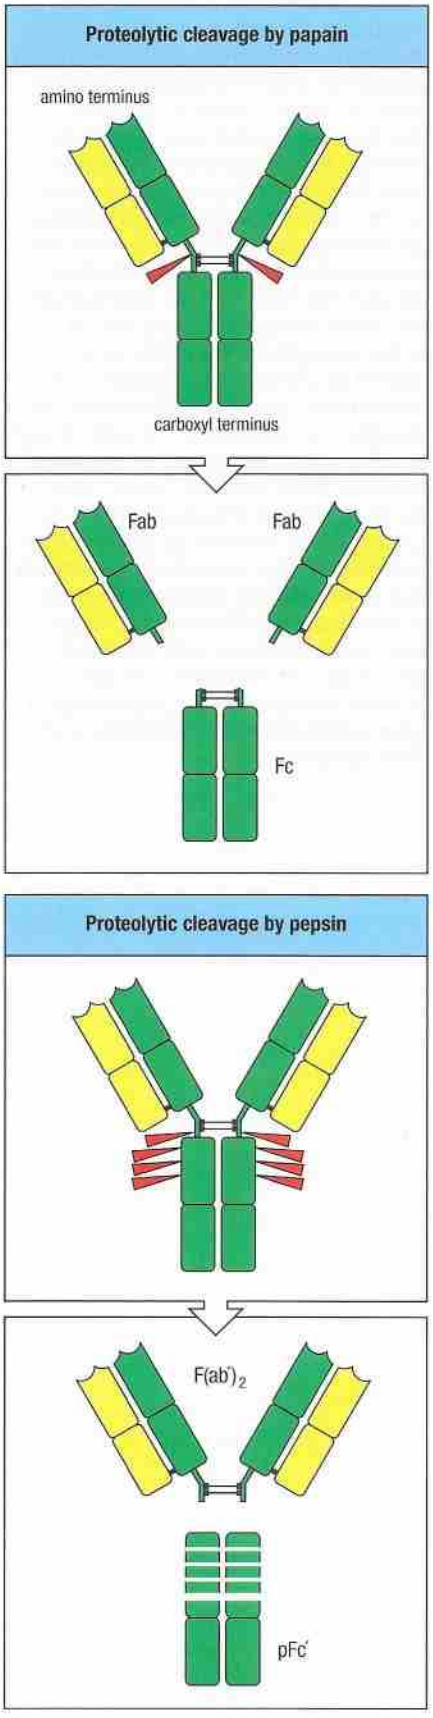

Fig. 4.4 The Y-shaped immunoglobulin molecule can be dissected by partial digestion with proteases. Upper panels: Papain cleaves the immunoglobulin molecule into three pieces, two Fab fragments and one Fc fragment. The Fab fragment contains the V regions and binds antigen. The Fc fragment is crystallizable and contains C regions. Lower panels: Pepsin cleaves immunoglobulin to yield one $F(ab')_2$ fragment and many small pieces of the Fc fragment, the largest of which is called the pFc' fragment. $F(ab')_2$ is written with a prime because it contains a few more amino acids than Fab, including the cysteines that form the disulfide bonds.

4-5 The hinge region of the immunoglobulin molecule allows flexibility in binding to multiple antigens.

The hinge region between the Fc and Fab portions of the IgG molecule allows for some degree of independent movement of the two Fab arms. For example, in the antibody molecule shown in Fig. 4.1a, not only are the two hinge regions clearly bent differently, but the angle between the V and C domains in each of the two Fab arms is also different. This range of motion has led to the junction between the V and C domains being referred to as a 'molecular ball-and-socket joint.' This flexibility can be revealed by studies of antibodies bound to small antigens known as **haptens**. These are molecules of various types that are typically about the size of a tyrosine side chain. Although haptens are specifically recognized by antibody, they can stimulate the production of anti-hapten antibodies only when linked to a protein (see Appendix I, Section A-1). Two identical hapten molecules joined by a short flexible region can link two or more anti-hapten antibodies, forming dimers, trimers, tetramers, and so on, which can be seen by electron microscopy (Fig. 4.5). The shapes formed by these complexes show that antibody molecules are flexible at the hinge region. Some flexibility is also found at the junction between the V and C domains, allowing bending and rotation of the V domain relative to the C domain. Flexibility at both the hinge and the V-C junction enables the two arms of an antibody molecule to bind to sites some distance apart, such as the repeating sites on bacterial cell-wall polysaccharides. Flexibility at the hinge also enables antibodies to interact with the antibody-binding proteins that mediate immune effector mechanisms.

Summary.

The IgG antibody molecule is made up of four polypeptide chains, comprising two identical light chains and two identical heavy chains, and can be thought of as forming a flexible Y-shaped structure. Each of the four chains has a variable (V) region at its amino terminus, which contributes to the antigen-binding site, and a constant (C) region. The light chains are bound to the heavy chains by many noncovalent interactions and by disulfide bonds, and the V regions of the heavy and light chains pair in each arm of the Y to generate two identical

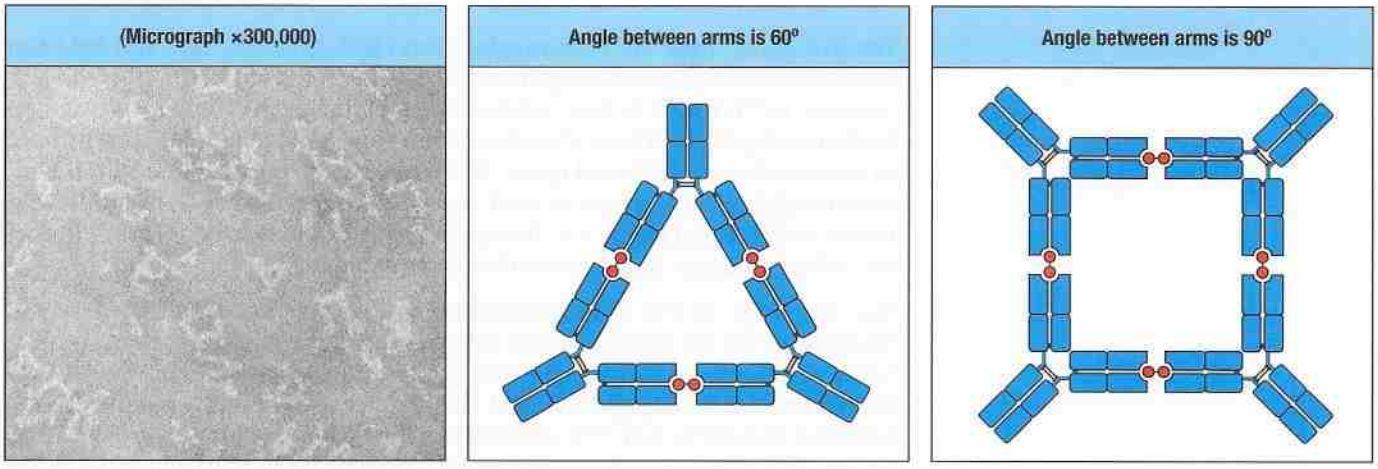

Fig. 4.5 Antibody arms are joined by a flexible hinge. An antigen consisting of two hapten molecules (red balls in diagrams) that can cross-link two antigen-binding sites is used to create antigen:antibody complexes, which can be seen in the electron micrograph. Linear, triangular, and square forms are seen, with short projections or spikes. Limited pepsin digestion removes these spikes (not shown in the figure), which therefore correspond to the Fc portion of the antibody; the $F(ab')_2$ pieces remain cross-linked by antigen. The interpretation of some of the complexes is shown in the diagrams. The angle between the arms of the antibody molecules varies. In the triangular forms, this angle is 60°, whereas it is 90° in the square forms, showing that the connections between the arms are flexible.

antigen-binding sites, which lie at the tips of the arms of the Y. The possession of two antigen-binding sites allows antibody molecules to cross-link antigens and to bind them much more stably and with higher avidity. The trunk of the Y, also called the Fc fragment, is composed of the carboxyl-terminal domains of the heavy chains, and it is these domains that determine the antibody's isotype. Joining the arms of the Y to the trunk are the flexible hinge regions. The Fc fragment and hinge regions differ in antibodies of different isotypes. Different isotypes have different properties and therefore differ in their interactions with effector molecules and cell types. However, the overall organization of the domains is similar in all isotypes.

Structural variation in immunoglobulin constant regions.

The class or isotype of an antibody is defined by the structure of its heavy-chain constant region. The differences between the antibody isotypes determine the effector functions of the antibody once it has bound antigen. There are five main heavy-chain isotypes, IgM, IgD, IgG, IgA, and IgE, some of which have several subtypes. These heavy-chain proteins are denoted by the lowercase Greek letters μ, δ, γ, α, and ϵ, respectively. For example, the constant region of IgM is denoted by C_μ. IgG is by far the most abundant immunoglobulin in serum. The distinctive functional properties of the different classes of antibodies are conferred by the carboxyl-terminal part of the heavy chain, where this chain is not associated with the light chain. In spite of these differences, the general structural features of all the isotypes are similar, particularly with respect to antigen binding. In this part of the chapter, we will consider the structural differences of the antibody isotypes and the specialized properties of each isotype. For IgM and IgA, individual antibodies form multimers that are secreted from cells. IgM forms pentamers, and IgA forms dimers. This feature aids in binding to repetitive structures, such as those on the surfaces of bacteria or viruses.

4-6 Different classes of immunoglobulins are distinguished by the structure of their heavy-chain constant regions.

The five main classes of immunoglobulins (IgM, IgD, IgG, IgE, and IgA) can occur as transmembrane antigen receptors or secreted antibodies (Fig. 4.6). In humans, IgG is found as four subclasses (IgG1, IgG2, IgG3, and IgG4), named by decreasing order of their abundance in serum, and IgA antibodies are found as two subclasses (IgA1 and IgA2). The heavy chains are encoded by different immunoglobulin C_H genes located in a gene cluster that is 3′ of the J_H segments as illustrated in Fig. 4.6. The major physical and functional properties of the different classes of human antibody are listed in Fig. 4.7.

The functions of the immunoglobulin classes are discussed in detail in Chapter 10, in the context of the humoral immune response; here, we just touch on them briefly. IgM is the first class of immunoglobulin produced after activation of a B cell, and the IgM antibody is secreted as a pentamer (see Section 4-8 and Fig. 4.8). This accounts for the high molecular mass of IgM and the fact that it is normally present in the bloodstream but not in tissues. Being a pentamer also increases the avidity of IgM for antigens before its affinity is increased through the process of affinity maturation.

IgG isotypes produced during an immune response are found in the bloodstream and in the extracellular spaces in tissues. IgM and most IgG isotypes can interact with the complement component C1 to activate the classical complement pathway (described in Section 2-7). IgA and IgE do not activate

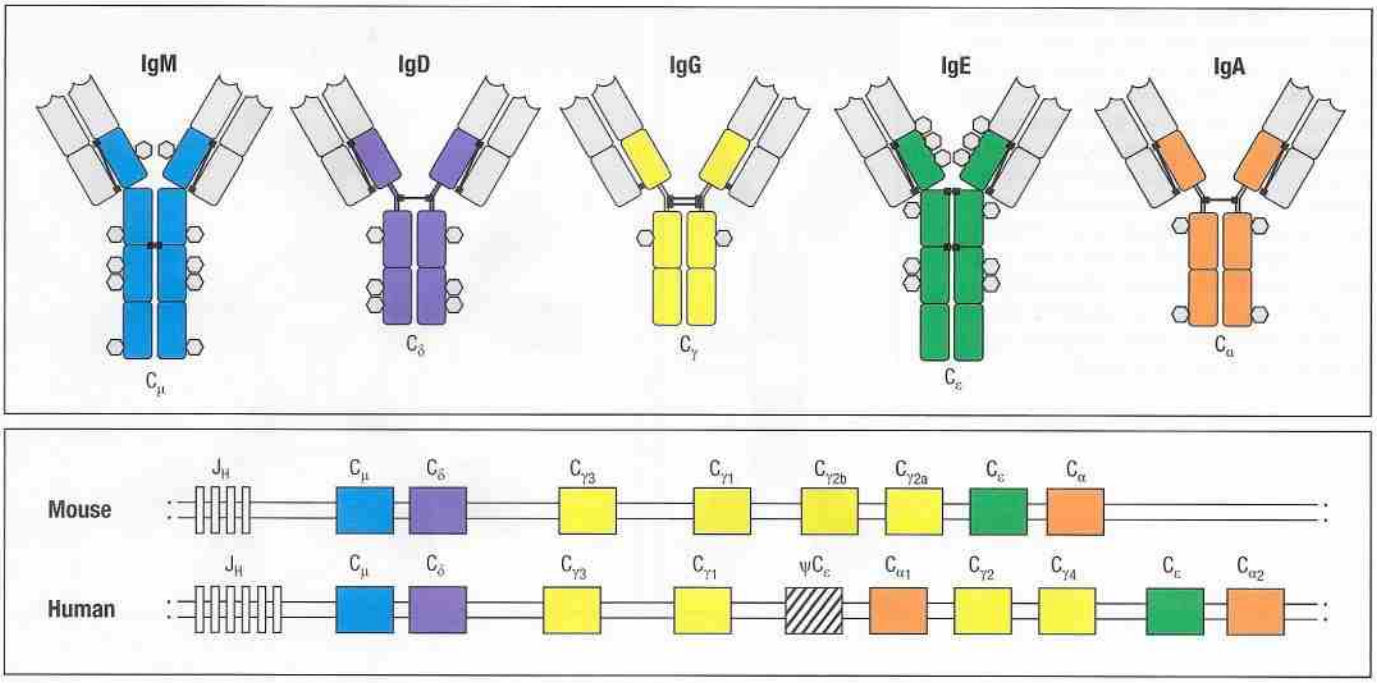

Fig. 4.6 The immunoglobulin isotypes are encoded by a cluster of immunoglobulin heavy-chain C-region genes. The general structure of the main immunoglobulin isotypes (upper panel) is indicated, with each rectangle denoting an immunoglobulin domain. These isotypes are encoded by separate heavy-chain C-region genes arranged in a cluster in both mouse and human (lower panel). The constant region of the heavy chain for each isotype is indicated by the same color as the C-region gene segment that encodes it. IgM and IgE lack a hinge region, but each contains an extra heavy-chain domain. Note the differences in the number and location of the disulfide bonds (heavy black lines) linking the chains. The isotypes also differ in the distribution of *N*-linked carbohydrate groups, shown as hexagons. In humans, the gene cluster shows evidence of evolutionary duplication of a unit consisting of two γ genes, an ε gene, and an α gene. One of the ε genes is a nonfunctional gene, called a pseudogene (ψC_ε); hence only one subtype of IgE is expressed. For simplicity, other pseudogenes are not illustrated, and the exon details within each C gene are not shown. The classes of immunoglobulins found in mice are called IgM, IgD, IgG1, IgG2a, IgG2b, IgG3, IgA, and IgE.

	Immunoglobulin								
	IgG1	IgG2	IgG3	IgG4	IgM	IgA1	IgA2	IgD	IgE
Heavy chain	γ_1	γ_2	γ_3	γ_4	μ	α_1	α_2	δ	ε
Molecular mass (kDa)	146	146	165	146	970	160	160	184	188
Serum level (mean adult mg/ml)	9	3	1	0.5	1.5	3.0	0.5	0.03	5×10^{-5}
Half-life in serum (days)	21	20	7	21	10	6	6	3	2
Classical pathway of complement activation	++	+	+++	−	++++	−	−	−	−
Alternative pathway of complement activation	−	−	−	−	−	+	−	−	−
Placental transfer	+++	+	++	−/+	−	−	−	−	−
Binding to macrophage and phagocyte Fc receptors	+	−	+	−/+	−	+	+	−	+
High-affinity binding to mast cells and basophils	−	−	−	−	−	−	−	−	+++
Reactivity with staphylococcal Protein A	+	+	−/+	+	−	−	−	−	−

Fig. 4.7 The physical and functional properties of the human immunoglobulin isotypes. IgM is so called because of its size: although monomeric IgM is only 190 kDa, it normally forms pentamers, known as macroglobulin (hence the M), of very large molecular mass (see Fig. 4.8). IgA dimerizes to give an approximate molecular mass of around 390 kDa in secretions. IgE antibody is associated with immediate-type hypersensitivity. When fixed to tissue mast cells, IgE has a much longer half-life than its half-life in serum shown here. The relative activities of the various isotypes are compared for several functions, ranging from inactive (–) to most active (++++).

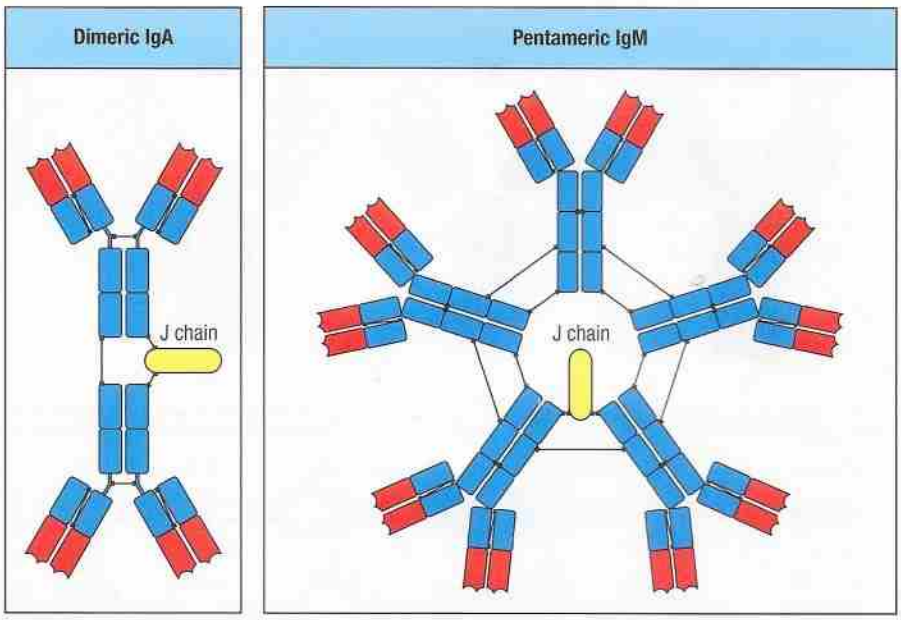

Fig. 4.8 The IgM and IgA molecules can form multimers. IgM and IgA are usually synthesized as multimers in association with an additional polypeptide chain, the J chain. In dimeric IgA (left panel), the monomers have disulfide bonds to the J chain as well as to each other. In pentameric IgM (right panel), the monomers are cross-linked by disulfide bonds to each other and to the J chain. IgM can also form hexamers that lack a J chain (not shown). IgM and IgA in secretions also contain a 'secretory piece,' a part of the receptor that transports the Igs through the cell via transcytosis.

the complement. IgA can be found in the bloodstream, but it also acts in the defense of mucosal surfaces; it is secreted into the gut and respiratory tract and also into mother's milk. IgE is particularly involved in defense against multicellular parasites (for example, schistosomes), but it is also the antibody involved in common allergic diseases such as allergic asthma. IgG and IgE are always monomers, but IgA can be secreted as either a monomer or a dimer (see Fig. 4.8).

Sequence differences in the constant regions of the immunoglobulin heavy chains produce the distinct characteristics of each antibody isotype. These characteristics include the number and location of interchain disulfide bonds, the number of attached carbohydrate groups, the number of C domains, and the length of the hinge region (see Fig. 4.6). IgM and IgE heavy chains contain an extra C domain that replaces the hinge region found in γ, δ, and α chains. The absence of the hinge region does not mean that IgM and IgE molecules lack flexibility; electron micrographs of IgM molecules binding to ligands show that the Fab arms can bend relative to the Fc portion. However, such a difference in structure may have functional consequences that are not yet characterized. Different isotypes and subtypes also differ in their ability to engage various effector functions, as described next.

4-7 The constant region confers functional specialization on the antibody.

Antibodies can protect the body in a variety of ways. In some cases it is enough for the antibody simply to bind antigen. For instance, by binding tightly to a toxin or virus, an antibody can prevent it from recognizing its receptor on a host cell (see Fig. 1.28). The antibody V regions are sufficient for this activity. The C region is essential, however, for recruiting the help of other cells and molecules to destroy and dispose of pathogens to which the antibody has bound.

The Fc region contains C-region domains of the heavy chain and has three main effector functions: Fc-receptor binding, complement activation, and regulation of secretion. First, the Fc region of certain isotypes binds to specialized Fc receptors expressed by immune effector cells. Fcγ receptors expressed on the surface of macrophages and neutrophils bind the Fc portions of IgG1 and IgG3 antibodies, facilitating the phagocytosis of pathogens coated with these antibodies. The Fc region of IgE binds to a high-affinity Fcϵ receptor

on mast cells, basophils, and activated eosinophils, triggering the release of inflammatory mediators in response to antigens. We will return to this topic in Chapter 10.

Second, the Fc regions in antigen:antibody complexes can bind to the C1q complement protein (see Section 2-7) and initiate the classical complement cascade, which recruits and activates phagocytes to engulf and destroy pathogens. Third, the Fc portion can deliver antibodies to places they would not reach without active transport. These include transport of IgA into mucous secretions, tears, and breast milk, and the transfer of IgG from the pregnant mother into the fetal blood circulation. In both cases, the Fc portion of IgA or IgG engages a specific receptor, the poly-Ig receptor (pIgR) or the neonatal Fc receptor (FcRn), respectively, which actively transports the immunoglobulin through cells to reach different body compartments. Podocytes, a specialized cell type in the kidney glomerulus, express FcRn to help remove IgG that has been filtered from the blood and accumulated at the glomerular basement membrane.

The role of the Fc portion in these effector functions has been demonstrated by studying immunoglobulins that have had one or more Fc domains cleaved off enzymatically or modified genetically. Many microorganisms have responded to the destructive potential of the Fc portion by evolving proteins that either bind it or cleave it, and so prevent the Fc region from working; examples are Protein A and Protein G of *Staphylococcus* and Protein D of *Haemophilus*. Researchers have exploited these proteins to help map the Fc region and also as immunological reagents. Not all immunoglobulin classes have the same capacity to engage each of the effector functions (see Fig. 4.7). For example, IgG1 and IgG3 have a higher affinity than IgG2 for the most common type of Fc receptor.

4-8 IgM and IgA can form polymers by interacting with the J chain.

Although all immunoglobulin molecules are constructed from a basic unit of two heavy and two light chains, both IgM and IgA can form multimers of these basic units (see Fig. 4.8). C regions of IgM and IgA can include a 'tailpiece' of 18 amino acids that contains a cysteine residue essential for polymerization. A separate 15-kDa polypeptide chain called the **J chain** promotes polymerization by linking to the cysteine of this tailpiece, which is found only in the secreted forms of the μ and α chains. (This J chain should not be confused with the immunoglobulin J region encoded by a J gene segment; see Section 5-1.) In the case of IgA, dimerization is required for transport through epithelia, as we will discuss in Chapter 10. IgM molecules are found as pentamers, and occasionally hexamers (without J chain), in plasma, whereas IgA is found mainly as a dimer in mucous secretions but as a monomer in plasma.

Immunoglobulin polymerization is also thought to be important in the binding of antibody to repetitive structures. An antibody molecule has at least two identical antigen-binding sites, each of which has a given affinity, or binding strength, for antigen. If the antibody attaches to multiple identical structures on a target antigen, it will dissociate only when all binding sites dissociate. The dissociation rate of the whole antibody will therefore be much slower than the dissociation rate for a single binding site; multiple binding sites thus give the antibody a greater total binding strength, or avidity. This consideration is particularly relevant for pentameric IgM, which has 10 antigen-binding sites.

IgM antibodies frequently recognize repetitive structures such as those on bacterial cell-wall polysaccharides, but individual binding sites are often of low affinity because IgM is made early in immune responses, before somatic hypermutation and affinity maturation. Multisite binding makes up for this, markedly improving the overall functional binding strength. This implies that binding of a single IgM pentamer to a target could be sufficient to mediate biological effector activity, whereas in the case of IgGs, two independent target molecules may need to be located in close proximity.

Summary.

The classes of immunoglobulins are defined by their heavy-chain C regions, with the different heavy-chain isotypes being encoded by different C-region genes. The heavy-chain C-region genes are present in a cluster 3′ to the V, D, and J gene segments. The constant region isotype of an antibody determines its effector functions, including binding to Fc receptors on effector cells such as phagocytes and mast cells, binding to the complement protein C1q, and binding to Fc receptors that mediate transport of antibodies between tissue compartments. Whereas all antibodies have two identical binding sites for antigen, some antibodies form multimeric complexes, thereby increasing their avidity for pathogen binding. Secreted IgM forms pentamers that include a small polypeptide called the J chain, creating a large antibody molecule with 10 antigen-binding sites. IgA that is transported into bodily secretions is a dimer of two IgA monomers plus the J chain. Differences in Fc-receptor binding, complement C1q binding, tissue localization, and antibody avidity are responsible for the specialized effector functions of each antibody isotype.

The interaction of the antibody molecule with specific antigen.

In this part of the chapter we look at the antigen-binding site of an immunoglobulin molecule in more detail. We discuss the different ways in which antigens can bind to antibody and address the question of how variation in the sequences of the antibody V domains determines the specificity for antigen.

4-9 Localized regions of hypervariable sequence form the antigen-binding site.

The V regions of any given antibody molecule differ from those of every other. Sequence variability is not, however, distributed evenly throughout the V region but is concentrated in certain segments, as is clearly seen in a **variability plot** (Fig. 4.9), in which the amino acid sequences of many different antibody V regions are compared. Three particularly variable segments can be

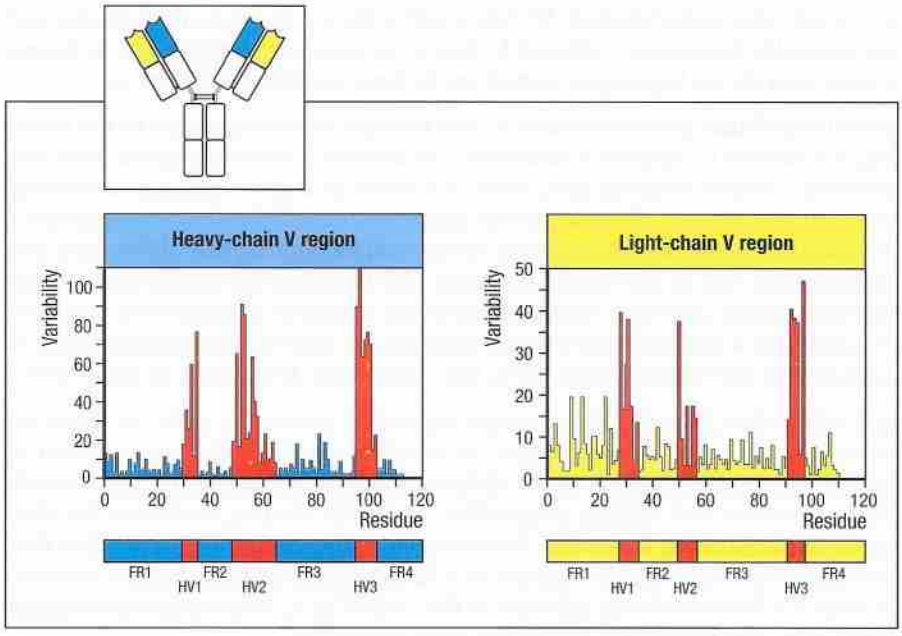

Fig. 4.9 There are discrete regions of hypervariability in V domains. The hypervariability regions of both the heavy chain and the light chain contribute to antigen binding of an antibody molecule. A variability plot derived from comparison of the amino acid sequences of several dozen heavy-chain and light-chain V domains is shown. At each amino acid position, the degree of variability is the ratio of the number of different amino acids seen in all of the sequences together to the frequency of the most common amino acid. Three hypervariable regions (HV1, HV2, and HV3) are indicated in red. They are flanked by less variable framework regions (FR1, FR2, FR3, and FR4, shown in blue or yellow).

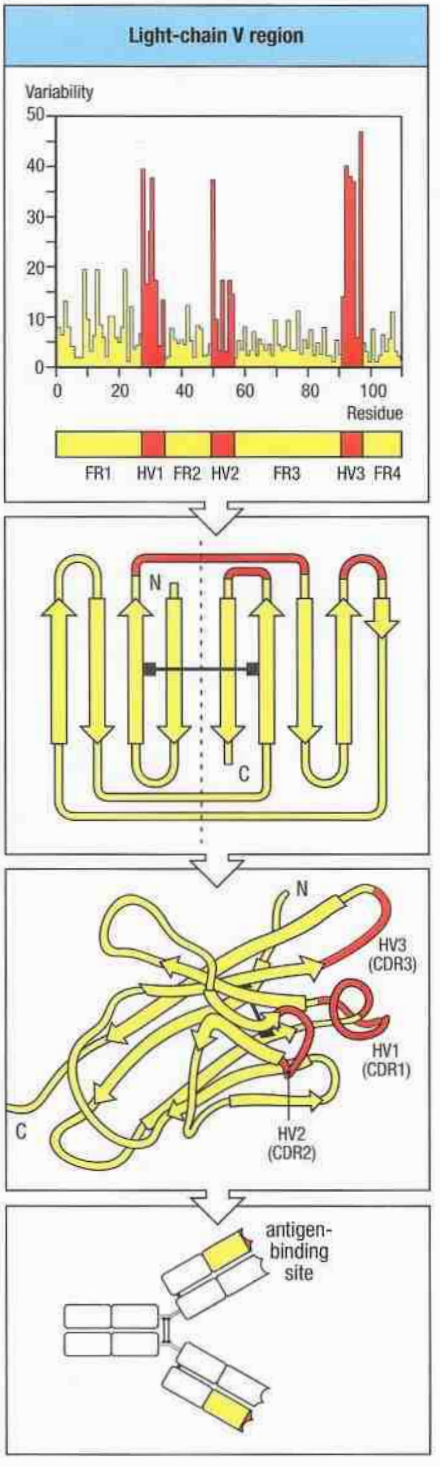

Fig. 4.10 The hypervariable regions lie in discrete loops of the folded structure. First panel: The hypervariable regions (red) are positioned on the structure of a map of the coding region of the V domain. Second panel: When shown as a flattened ribbon diagram, hypervariable regions are seen to occur in loops (red) that join particular β strands. Third panel: In the folded structure of the V domain, these loops (red) are brought together to form antigen-binding regions. Fourth panel: In a complete antibody molecule, the pairing of a heavy chain and a light chain brings together the hypervariable loops from each chain to create a single hypervariable surface, which forms the antigen-binding site at the tip of each arm. Because they are complementary to the antigen surface, the hypervariable regions are also commonly known as the complementarity-determining regions (CDRs). C, carboxyl terminus; N, amino terminus.

identified in both the V_H and V_L domains. They are designated **hypervariable regions** and are denoted HV1, HV2, and HV3. In the heavy chains they are located at residues 30 to 36, 49 to 65, and 95 to 103, respectively, while in the light chains they are located at residues 28 to 35, 50 to 56, and 91 to 98, respectively. The most variable part of the domain is in the HV3 region. The regions between the hypervariable regions comprise the rest of the V domain; they show less variability and are termed the **framework regions**. There are four such regions in each V domain, designated FR1, FR2, FR3, and FR4.

The framework regions form the β sheets that provide the structural framework of the immunoglobulin domain. The hypervariable sequences correspond to three loops and are positioned near one another in the folded domain at the outer edge of the β sandwich (Fig. 4.10). Thus, not only is diversity concentrated in particular parts of the V domain sequence, but it is also localized to a particular region on the surface of the molecule. When the V_H and V_L immunoglobulin domains are paired in the antibody molecule, the three hypervariable loops from each domain are brought together, creating a single hypervariable site at the tip of each arm of the molecule. This is the **antigen-binding site**, or **antibody-combining site**, which determines the antigen specificity of the antibody. These six hypervariable loops are more commonly termed the **complementarity-determining regions**, or **CDRs**, because the surface they form is complementary to that of the antigen they bind. There are three CDRs from each of the heavy and light chains, namely, CDR1, CDR2, and CDR3. In most cases, CDRs from both V_H and V_L domains contribute to the antigen-binding site; thus it is the combination of the heavy chain and the light chain that usually determines the final antigen specificity (see Fig. 4.9). However, there are some Fab crystal structures that show antigen interaction with just the heavy chain; for example, in one influenza Fab, antigen interaction involves binding mostly to the V_H CDR3 and only minor contacts with other CDRs. Thus, one way in which the immune system is able to generate antibodies of different specificities is by generating different combinations of heavy-chain and light-chain V regions. This is known as combinatorial diversity; we will encounter a second form of **combinatorial diversity** in Chapter 5 when we consider how the genes encoding the heavy-chain and light-chain V regions are created from smaller segments of DNA during the development of B cells in the bone marrow.

4-10 Antibodies bind antigens via contacts in CDRs that are complementary to the size and shape of the antigen.

In early investigations of antigen binding to antibodies, the only available sources of large quantities of a single type of antibody molecule were tumors of antibody-secreting cells. The antigen specificities of these antibodies were unknown, and therefore many compounds had to be screened to identify ligands that could be used to study antigen binding. In general, the substances found to bind to these antibodies were haptens (see Section 4-5) such as phosphocholine or vitamin K_1. Structural analysis of complexes of antibodies with their hapten ligands provided the first direct evidence that the hypervariable

regions form the antigen-binding site and demonstrated the structural basis of specificity for the hapten. Subsequently, with the discovery of methods of generating **monoclonal antibodies** (see Appendix I, Section A-8), it became possible to make large amounts of pure antibody specific for a given antigen. This has provided a more general picture of how antibodies interact with their antigens, confirming and extending the view of antibody–antigen interactions derived from the study of haptens.

The surface of the antibody molecule formed by the juxtaposition of the CDRs of the heavy and light chains is the site to which an antigen binds. The amino acid sequences of the CDRs are different in different antibodies, and so too are the shapes and properties of the surfaces created by these CDRs. As a general principle, antibodies bind ligands whose surfaces are complementary to that of the antigen-binding site. A small antigen, such as a hapten or a short peptide, generally binds in a pocket or groove lying between the heavy-chain and light-chain V domains (Fig. 4.11a and b). Some antigens, such as proteins, can be the same size as or larger than the antibody itself. In these cases, the interface between antigen and antibody is often an extended surface that involves all the CDRs and, in some cases, part of the framework region as well (Fig. 4.11c). This surface need not be concave but can be flat, undulating, or

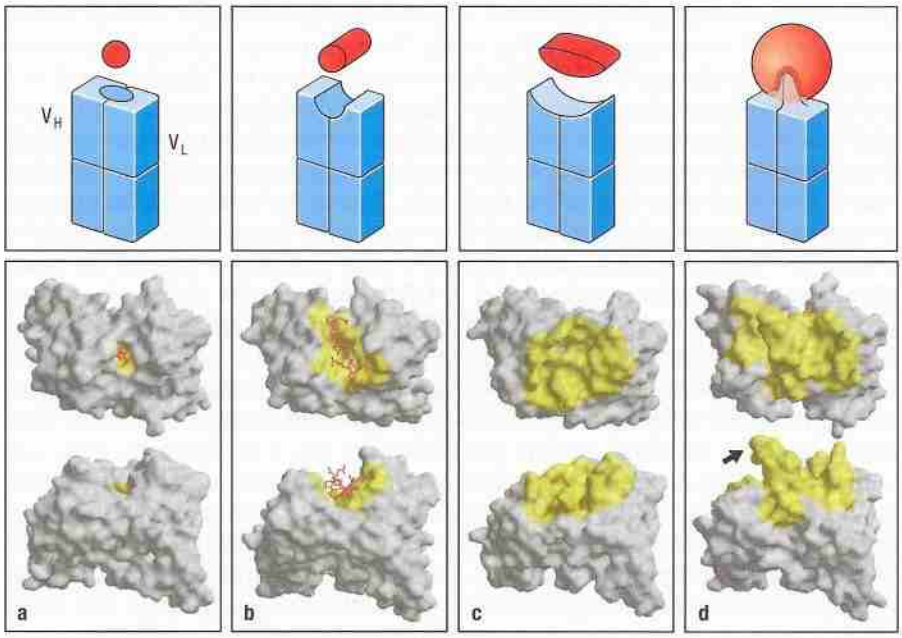

Fig. 4.11 Antigens can bind in pockets, or grooves, or on extended surfaces in the binding sites of antibodies. The panels in the top row show schematic representations of the different types of binding sites in a Fab fragment of an antibody: first panel, pocket; second panel, groove; third panel, extended surface; and fourth panel, protruding surface. Below are examples of each type. Panel a: The top image shows the molecular surface of the interaction of a small hapten with the complementarity-determining regions (CDRs) of a Fab fragment as viewed looking into the antigen-binding site. The ferrocene hapten, shown in red, is bound into the antigen-binding pocket (yellow). In the bottom image (and in those of panels b, c, and d), the molecule has been rotated by about 90° to give a side-on view of the binding site. Panel b: In a complex of an antibody with a peptide from the human immunodeficiency virus (HIV), the peptide (red) binds along a groove (yellow) formed between the heavy-chain and light-chain V domains. Panel c: Shown is a Fab fragment of an antibody specific for hen egg-white lysozyme (HyHel5). The surface on the antibody that comes into contact with the lysozyme is colored yellow. All six CDRs of the antigen-binding site are involved in the binding. Panel d: An antibody molecule against the HIV gp120 antigen has an elongated CDR3 loop (arrow) that protrudes into a recess on the side of the antigen. The structure of the complex between this antibody and gp120 has been solved, and in this case, only the heavy chain interacts with gp120.

even convex. In some cases, antibody molecules with elongated CDR3 loops can protrude a 'finger' into recesses in the surface of the antigen, as shown in Fig. 4.11d, where an antibody binding to the HIV gp120 antigen projects a long loop into its target.

4-11 Antibodies bind to conformational shapes on the surfaces of antigens using a variety of noncovalent forces.

The biological function of antibodies is to bind to pathogens and their products and to facilitate their removal from the body. An antibody generally recognizes only a small region on the surface of a large molecule such as a polysaccharide or protein. The structure recognized by an antibody is called an **antigenic determinant**, or **epitope**. Some of the most important pathogens have polysaccharide coats, and antibodies that recognize epitopes formed by the sugar subunits of these molecules are essential in providing immune protection against such pathogens. In many cases, however, the antigens that provoke an immune response are proteins. For example, many protective antibodies against viruses recognize viral coat proteins. In all such cases, the structures recognized by the antibody are located on the surface of the protein. Such sites are likely to be composed of amino acids from different parts of the polypeptide chain that have been brought together by protein folding. Antigenic determinants of this kind are known as **conformational** or **discontinuous epitopes** because the structure recognized is composed of segments of the protein that are discontinuous in the amino acid sequence of the antigen but are brought together in the three-dimensional structure (Fig. 4.12). In contrast, an epitope composed of a single segment of polypeptide chain is termed a **continuous** or **linear epitope**. Although most antibodies raised against intact, fully folded proteins recognize discontinuous epitopes, some will bind to peptide fragments of the protein. Conversely, antibodies raised against peptides of a protein or against synthetic peptides corresponding to part of its sequence are occasionally found to bind to the natural folded protein. This makes it possible, in some cases, to use synthetic peptides in vaccines that aim to raise antibodies against a pathogen's protein.

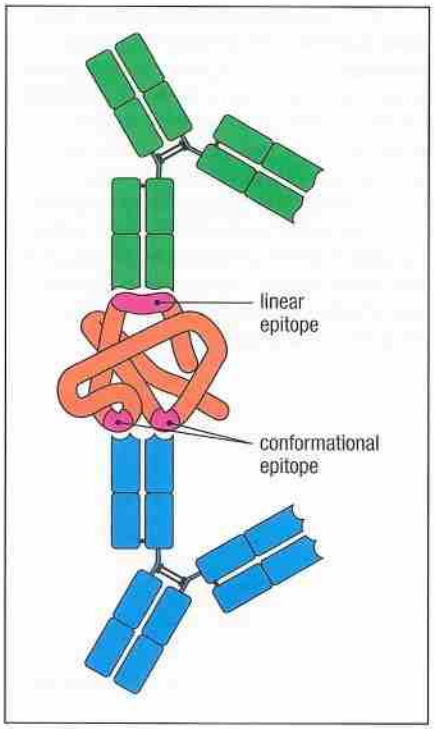

Fig. 4.12 Antibodies can recognize linear or conformational determinants in folded proteins. In a folded protein, antibodies can recognize amino acid sequences that are discontinuous in the linear amino acid sequence of the protein, but are brought into proximity in the three-dimensional structure. These are known as conformational or discontinuous epitopes. Antibodies can also bind to peptides that are continuous in the linear amino acid sequence of the protein and these are known as linear or continuous epitopes.

The interaction between an antibody and its antigen can be disrupted by high salt concentrations, by extremes of pH, by detergents, and sometimes by competition with high concentrations of the pure epitope itself. The binding is therefore a reversible noncovalent interaction. The forces, or bonds, involved in these noncovalent interactions are outlined in Fig. 4.13. **Electrostatic interactions** occur between charged amino acid side chains, as in salt bridges. Most antibody–antigen interactions involve at least one electrostatic interaction. Interactions also occur between electric dipoles, as in hydrogen bonds, or can involve short-range van der Waals forces. High salt concentrations and extremes of pH disrupt antigen–antibody binding by weakening electrostatic interactions and/or hydrogen bonds. This principle is employed in the purification of antigens by using affinity columns of immobilized antibodies (or in the purification of antibody by using antigens in a like manner) (see Appendix I, Section A-3). **Hydrophobic interactions** occur when two hydrophobic surfaces come together to exclude water. The strength of a hydrophobic interaction is proportional to the surface area that is hidden from water, and for some antigens, hydrophobic interactions probably account for most of the binding energy. In some cases, water molecules are trapped in pockets in the interface between antigen and antibody. These trapped water molecules, especially those between polar amino acid residues, may also contribute to binding and hence to the specificity of the antibody.

The contribution of each of these forces to the overall interaction depends on the particular antibody and antigen involved. A striking difference between antibody interactions with protein antigens and most other natural protein–protein interactions is that antibodies often have many aromatic amino acids

Noncovalent forces	Origin	
Electrostatic forces	Attraction between opposite charges	$-NH_3^{\oplus}$ $^{\ominus}OOC-$
Hydrogen bonds	Hydrogen shared between electronegative atoms (N, O)	$>N^{\delta-}-H^{\delta+}--O^{\delta-}=C<$
Van der Waals forces	Fluctuations in electron clouds around molecules polarize neighboring atoms oppositely	$\delta^+ \rightleftharpoons \delta^-$ $\delta^- \rightleftharpoons \delta^+$
Hydrophobic forces	Hydrophobic groups interact unfavorably with water and tend to pack together to exclude water molecules. The attraction also involves van der Waals forces	Cation-pi interaction	Noncovalent interaction between a cation and an electron cloud of a nearby aromatic group	
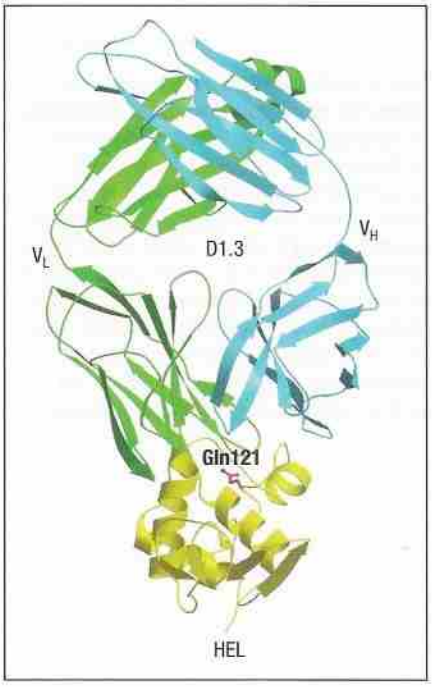
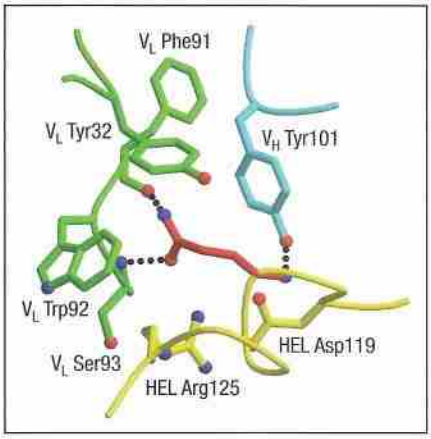
Fig. 4.13 The noncovalent forces that hold together the antigen:antibody complex. Partial charges found in electric dipoles are shown as δ^+ or δ^-. Electrostatic forces diminish as the inverse square of the distance separating the charges, whereas van der Waals forces, which are more numerous in most antigen–antibody contacts, fall off as the sixth power of the separation and therefore operate only over very short ranges. Covalent bonds never occur between antigens and naturally produced antibodies.





in their antigen-binding sites. These amino acids participate mainly in van der Waals and hydrophobic interactions, and sometimes in hydrogen bonds and **cation-pi interactions**. Tyrosine, for example, can take part in both hydrogen bonding and hydrophobic interactions; it is therefore particularly suitable for providing diversity in antigen recognition and is overrepresented in antigen-binding sites. In general, the hydrophobic and van der Waals forces operate over very short ranges and serve to pull together two surfaces that are complementary in shape: hills on one surface must fit into valleys on the other for good binding to occur. In contrast, electrostatic interactions between charged side chains as well as hydrogen bonds bridging oxygen and/or nitrogen atoms accommodate more specific chemical interactions while strengthening the interaction overall. The side chains of aromatic amino acids such as tyrosine can interact noncovalently through their pi-electron system with nearby cations, including nitrogen-containing side chains that may be in a protonated cationic state.

4-12 Antibody interaction with intact antigens is influenced by steric constraints.

An example of an antibody–antigen interaction involving a specific amino acid in the antigen can be seen in the complex of hen egg-white lysozyme with the antibody D1.3 (Fig. 4.14). In this structure, strong hydrogen bonds are formed

Fig. 4.14 The complex of lysozyme with the antibody D1.3. Top panel: The interaction of the Fab fragment of D1.3 with hen egg-white lysozyme (HEL) is shown. HEL is depicted in yellow, the heavy chain (V_H) in turquoise, and the light chain (V_L) in green. Bottom panel: A glutamine residue (Gln121) that protrudes from HEL (yellow) extends its side chain (shown in red) between the V_L (green) and V_H (turquoise) domains of the antigen-binding site and makes hydrogen bonds with the hydroxyl group (purple dots) of the indicated amino acids of both domains. These hydrogen bonds are important to the antigen–antibody binding.

Fig. 4.15 Steric hindrance occludes the binding of antibody to native antigen in the intact West Nile viral particle. Top panel: The monoclonal antibody E16 recognizes DIII, one of the three structural domains in the West Nile virus (WNV) glycoprotein E. Shown is a crystal structure of the E16 Fab bound to the DIII epitope. Bottom left panel: Cryo-electron microscopy (cryo-EM) reconstruction of saturating E16 Fab bound to West Nile virion confirmed the predicted steric hindrance. The vertices of the triangle shown in the figure indicate the icosahedral symmetry axes. Bottom right panel: A computer model was used to dock E16 Fab to the mature West Nile virion. E16 Fabs were able to bind 120 of the 180 DIII epitopes. Sixty of the fivefold clustered DIII epitopes are sterically hindered by the binding of Fab to four nearby DIII epitopes within that cluster. An example of an occluded epitope is the blue area indicated by the arrow.

between the antibody and a particular glutamine in the lysozyme molecule that protrudes between the V_H and V_L domains. Lysozymes from partridge and turkey have another amino acid in place of the glutamine and do not bind to this antibody. Overall surface complementarity must have an important role in antigen–antibody interactions, but in most antibodies that have been studied at this level of detail, only a few residues make a major contribution to the binding energy and hence to the final specificity of the antibody. Although many antibodies naturally bind their ligands with high affinity (in the nanomolar range), genetic engineering by site-directed mutagenesis can tailor an antibody to bind even more strongly to its epitope.

Even when antibodies have high affinity for antigens on a larger structure, such as an intact viral particle, antibody binding may be prevented by their particular arrangement. For example, the intact West Nile virion is built from an icosahedral scaffold that has 90 homodimers of a membrane-anchored envelope glycoprotein, E, which has three domains, DI, DII, and DIII. The DIII domain has four polypeptide loops that protrude outward from the viral particle. A neutralizing antibody against West Nile virus, E16, recognizes these loops of DIII, as shown in Fig. 4.15. In theory, there should be 180 possible antigen-binding sites for the E16 antibody on the West Nile viral particle. However, a combination of crystallographic and electron micrographic studies show that even with an excess of the E16 Fab fragment, only about 120 of the total 180 DIII domains of E are able to bind the E16 Fab fragment (see Fig. 4.14). This appears to result from steric hindrance, with the presence of one Fab blocking the ability of another Fab to bind to some nearby E protein sites. Presumably, such steric hindrance would become more severe with intact antibody than is evident with the smaller Fab fragment. This study also showed that the Fab binds to the DIII region with only one of its antigen-binding arms, indicating that antibodies may not always bind to antigens with both antigen-binding sites. Therefore, the orientation of the antigens being recognized on the pathogen places constraints that impact the ability of antibodies to neutralize their targets.

4-13 Some species generate antibodies with alternative structures.

Our focus in this chapter has been on the structure of antibodies produced by humans, which is generally similar in most mammalian species, including mice, an important model system for immunology research. However, some mammals have the ability to produce an alternative form of antibody that is based on the ability of a single V_H domain to interact with antigen in the absence of a V_L domain (Fig. 4.16). It has been known for some time that the serum of camels contains abundant immunoglobulin-like material composed of heavy-chain dimers that lack associated light chains but retain the capacity to bind antigens. These antibodies are called **heavy-chain-only IgGs (hcIgGs)**. This property is shared by other camelids, including llamas and alpacas. These species have retained the genes for the immunoglobulin light chains, and some IgG-like material in their sera remains associated with light

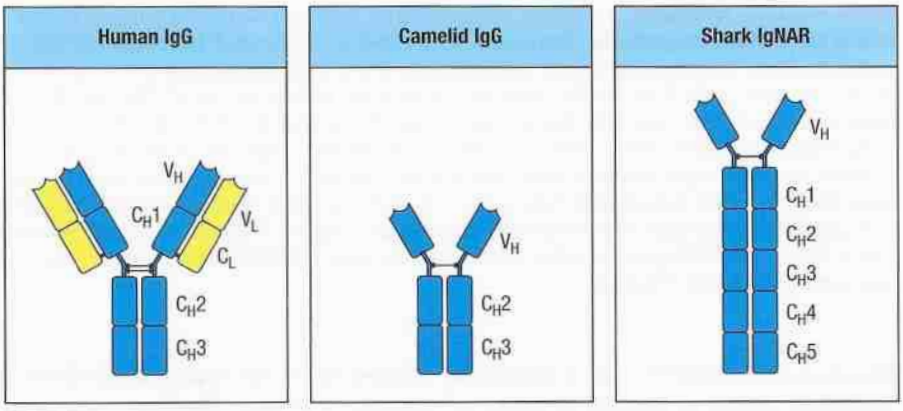

Fig. 4.16 Camelid and shark antibody can consist of heavy chain only. In the camelid heavy-chain-only antibody, a splicing event of the mature heavy chain can delete the exon encoding the C_H1 region and thereby create an in_frame hinge region linking the V_H to the C_H2 region. In the shark, the heavy-chain-only Ig molecule retains the C_H1 region, suggesting that this form of antibody may predate the evolution of light chains. For both, the repertoire of antigen-binding sites involves extensive variations in long CDR3 regions of the V_H domain relative to other types of antibody.

chains, and so it is unclear what led to this particular adaptation during their evolution. In camelids, the ability to produce hcIgGs arises from mutations that allow the alternative splicing of the heavy-chain mRNA, with loss of the C_H1 exon and thus the joining of the V_H directly to the C_H2 domain in the protein. Other mutations stabilize this structure in the absence of V_L domains.

Cartilaginous fish, in particular the shark, also have an antibody molecule that differs substantially from human or murine antibodies (see Fig. 4.16). Like camelids, the shark also has genes encoding both immunoglobulin heavy and light chains and does produce immunoglobulins containing both heavy and light chains. But sharks also produce an **immunoglobulin new antigen receptor (IgNAR)**, a heavy-chain-only antibody in which the V_H is spliced to the C_H1 exon, rather than the C_H1 exon being spliced out as in camelids. These differences suggest that hcIgG production by camelids and sharks represents an event of convergent evolution. The ability of camelid V_H domains to interact efficiently with antigens is the basis for producing so-called **single-chain antibody**. The simplification of using only a single domain for antigen recognition has prompted recent interest in single-chain monoclonal antibodies as an alternative to standard monoclonal antibodies, which we will discuss more in Chapter 16.

Summary.

X-ray crystallographic analyses of antigen:antibody complexes have shown that the hypervariable loops (complementarity-determining regions; CDRs) of immunoglobulin V regions determine the binding specificity of an antibody. Contact between an antibody molecule and a protein antigen usually occurs over a broad area of the antibody surface that is complementary to the surface recognized on the antigen. Electrostatic interactions, hydrogen bonds, van der Waals forces, and hydrophobic and cation-pi interactions can all contribute to binding. Depending on the size of the antigen, amino acid side chains in most or all of the CDRs make contact with antigen and determine both the specificity and the affinity of the interaction. Other parts of the V region normally play little part in the direct contact with the antigen, but they provide a stable structural framework for the CDRs and help to determine their position and conformation. Antibodies raised against intact proteins usually bind to the surface of the protein and make contact with residues that are discontinuous in the primary structure of the molecule; they may, however, occasionally bind peptide fragments of the protein, and antibodies raised against peptides derived from a protein can sometimes be used to detect the native protein molecule. Peptides binding to antibodies usually bind in a cleft or pocket between the V regions of the heavy and light chains, where they make specific contact with some, but not necessarily all, of the CDRs. This is also the usual mode of binding for carbohydrate antigens and small molecules such as haptens.

Antigen recognition by T cells.

In contrast to the immunoglobulins, which interact with pathogens and their toxic products in the extracellular spaces of the body, T cells recognize foreign antigens only when they are displayed on the surface of the body's own cells. These antigens can derive from pathogens such as viruses or intracellular bacteria, which replicate within cells, or from pathogens or their products that have been internalized by endocytosis from the extracellular fluid.

T cells detect the presence of an intracellular pathogen because the infected cells display peptide fragments of the pathogen's proteins on their surface. These foreign peptides are delivered to the cell surface by specialized host-cell glycoproteins—the MHC molecules. These are encoded in a large cluster of genes that were first identified by their powerful effects on the immune response to transplanted tissues. For that reason, the gene complex was called the major histocompatibility complex (MHC), and the peptide-binding glycoproteins are known as MHC molecules. The recognition of antigen as a small peptide fragment bound to an MHC molecule and displayed at the cell surface is one of the most distinctive features of T cells and will be the focus of this part of the chapter. How the peptide fragments of antigen are generated and become associated with MHC molecules will be described in Chapter 6.

We describe here the structure and properties of the T-cell receptor (TCR). As might be expected from the function of T-cell receptors as highly variable antigen-recognition structures, the genes for TCRs are closely related to those for immunoglobulins. There are, however, important differences between T-cell receptors and immunoglobulins, and these differences reflect the special features of antigen recognition by T cells.

4-14 The TCRαβ heterodimer is very similar to a Fab fragment of immunoglobulin.

T-cell receptors were first identified by using monoclonal antibodies that bound to a single cloned T-cell line: such antibodies either specifically inhibit antigen recognition by the clone or specifically activate it by mimicking the antigen (see Appendix I, Section A-21). These **clonotypic** antibodies were then used to show that each T cell bears about 30,000 identical antigen receptors on its surface, each receptor consisting of two different polypeptide chains, termed the **T-cell receptor α (TCRα)** and **β (TCRβ)** chains. Each chain of the **αβ heterodimer** is composed of two Ig domains, and the two chains are linked by a disulfide bond, similar to the structure of the Fab fragment of an immunoglobulin molecule (Fig. 4.17). Also similar to the antibody Fab fragment, the T-cell receptor αβ heterodimer is the antigen-binding portion of the T-cell receptor. On the surface of T cells, the αβ heterodimer is always found in a large multiprotein complex that contains six additional subunits: CD3γ, CD3δ, two copies of CD3ε, and two copies of the T-cell receptor ζ chain (Fig 4.17). These additional subunits function in signal transduction, rather than in antigen recognition, and unlike the αβ heterodimer, they do not vary between T cells. The functions of these receptor signaling subunits will be discussed in Chapter 7.

The TCRα and TCRβ chains of the αβ heterodimer account for antigen recognition by most T cells. A minority of T cells bear an alternative, but structurally similar, receptor made up of a different pair of polypeptide chains designated γ and δ. The **γδ T-cell receptors** have different antigen-recognition properties from the **αβ T-cell receptors**, and the functions of γδ T cells in immune responses are still being clarified as the various ligands they recognize are identified (see Section 6-20). In the rest of this chapter and elsewhere in the book, we use the term T-cell receptor to mean the αβ receptor, except

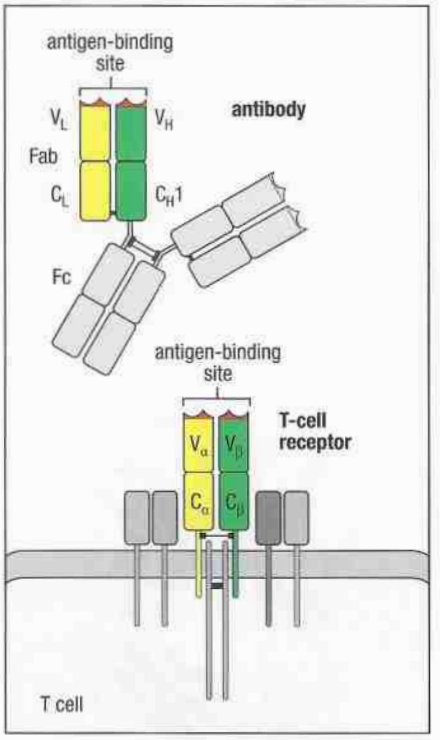

Fig. 4.17 The T-cell receptor resembles a membrane-bound Fab fragment. The Fab fragment of an antibody molecule is a disulfide-linked heterodimer, each chain of which contains one immunoglobulin C domain and one V domain; the juxtaposition of the V domains forms the antigen-binding site (see Section 4-6). The antigen-binding subunits of the T-cell receptor also form a disulfide-linked heterodimer, with each chain containing an immunoglobulin C-like domain and an immunoglobulin V-like domain. This heterodimer is always associated with six additional polypeptides (shown in gray) that form the complete membrane-bound T-cell receptor. As in the Fab fragment, the juxtaposition of the T-cell receptor V_α and V_β domains forms the site for antigen recognition.

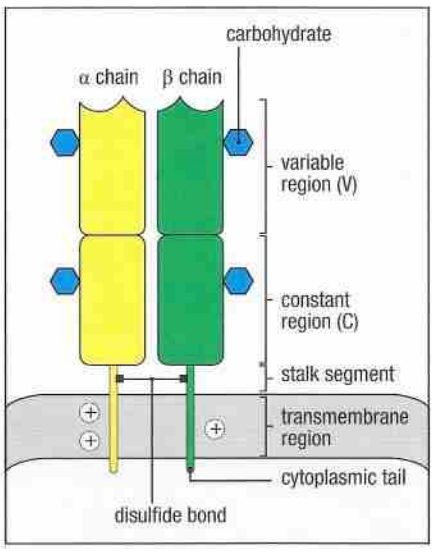

Fig. 4.18 Structure of the T-cell receptor. The T-cell receptor heterodimer is composed of two transmembrane glycoprotein chains, α and β. The extracellular portion of each chain consists of two domains, resembling immunoglobulin V and C domains, respectively. Both chains have carbohydrate side chains attached to each domain. A short stalk segment, analogous to an immunoglobulin hinge region, connects the Ig-like domains to the membrane and contains the cysteine residue that forms the interchain disulfide bond. The transmembrane helices of both chains are unusual in containing positively charged (basic) residues within the hydrophobic transmembrane segment. The α chain carries two such residues; the β chain has one. These basic residues are required for assembly of the T-cell receptor αβ heterodimer with the additional polypeptides that form the complete membrane-bound T-cell receptor complex.

where specified otherwise. Both types of T-cell receptors differ from the membrane-bound immunoglobulin that serves as the B-cell receptor in two main ways. A T-cell receptor has only one antigen-binding site, whereas a B-cell receptor has two, and T-cell receptors are never secreted, whereas immunoglobulins can be secreted as antibodies.

Further insights into the structure and function of the αβ T-cell receptor came from studies of cloned cDNA encoding the receptor chains. The amino acid sequences predicted from the cDNA showed that both chains of the T-cell receptor have an amino-terminal variable (V) region with sequence homology to an immunoglobulin V domain, a constant (C) region with homology to an immunoglobulin C domain, and a short stalk segment containing a cysteine residue that forms the interchain disulfide bond (Fig. 4.18). Each chain spans the lipid bilayer by a hydrophobic transmembrane domain and ends in a short cytoplasmic tail. These close similarities of T-cell receptor chains to the heavy and light immunoglobulin chains first enabled prediction of the structural resemblance of the T-cell receptor heterodimer to a Fab fragment of immunoglobulin.

The three-dimensional structure of the T-cell receptor αβ heterodimer determined by X-ray crystallography, illustrated in Fig. 4.19a, shows that T-cell

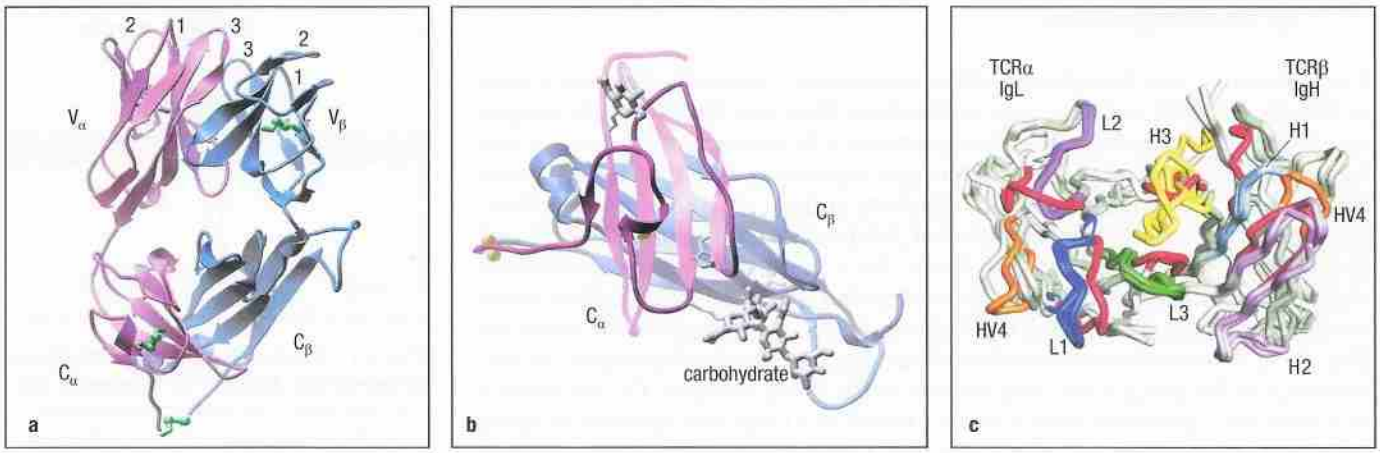

Fig. 4.19 The crystal structure of an αβ T-cell receptor resolved at 0.25 nm. In panels a and b, the α chain is shown in pink and the β chain in blue. Disulfide bonds are shown in green. In panel a, the T-cell receptor is viewed from the side as it would sit on a cell surface, with the CDR loops that form the antigen-binding site (labeled 1, 2, and 3) arrayed across its relatively flat top. In panel b, the C_α and C_β domains are shown. The C_α domain does not fold into a typical Ig-like domain; the face of the domain away from the C_β domain is mainly composed of irregular strands of polypeptide rather than β sheet. The intramolecular disulfide bond (far left) joins a β strand to this segment of α helix. The interaction between the C_α and C_β domains is assisted by carbohydrate (colored gray and labeled), with a sugar group from the C_α domain making hydrogen bonds to the C_β domain. In panel c, the T-cell receptor is shown aligned with the antigen-binding sites from three different antibodies. This view is looking down into the binding site. The V_α domain of the T-cell receptor is aligned with the V_L domains of the antigen-binding sites of the antibodies, and the V_β domain is aligned with the V_H domains. The CDRs of the T-cell receptor and immunoglobulin molecules are colored, with CDRs 1, 2, and 3 of the TCR shown in red and the HV4 loop in orange. For the immunoglobulin V domains, the CDR1 loops of the heavy chain (H1) and light chain (L1) are shown in light and dark blue, respectively, and the CDR2 loops (H2, L2) in light and dark purple, respectively. The heavy-chain CDR3 loops (H3) are in yellow; the light-chain CDR3 loops (L3) are in bright green. The HV4 loops of the TCR (orange) have no hypervariable counterparts in immunoglobulins.

receptor chains fold in much the same way as the regions comprising the Fab fragment shown in Fig. 4.1a. There are, however, some distinct structural differences between T-cell receptors and Fab fragments. The most striking is in the C_α domain, where the fold is unlike that of any other Ig-like domain. The half of the C_α domain that is juxtaposed with the C_β domain forms a β sheet similar to that found in other Ig-like domains, but the other half of the domain is formed of loosely packed strands and a short segment of α helix (Fig. 4.19b). In a C_α domain the intramolecular disulfide bond, which in Ig-like domains normally joins two β strands, joins a β strand to this segment of α helix.

There are also differences in the way in which the domains interact. The interface between the V and C domains of both T-cell receptor chains is more extensive than in most antibodies. The interaction between the C_α and C_β domains is distinctive, as it might be assisted by carbohydrates, with a sugar group from the C_α domain making a number of hydrogen bonds to the C_β domain (see Fig. 4.19b). Finally, a comparison of the variable binding sites shows that although the CDR loops align fairly closely with those of antibody molecules, there is some relative displacement (Fig. 4.19c). This is particularly marked in the V_α CDR2 loop, which is oriented at roughly right angles to the equivalent loop in antibody V domains, as a result of a shift in the β strand that anchors one end of the loop from one face of the domain to the other. A strand displacement also causes a change in the orientation of the V_β CDR2 loop in some V_β domains. These differences with antibodies influence the ability of the T-cell receptor to recognize their specific ligands, as we will discuss in the next section. In addition to the three hypervariable regions shared with immunoglobulins, the T-cell receptor has a fourth hypervariability region, HV4, in both of its chains (see Fig. 4.19c). These regions occur away from the antigen-binding face of the receptor and have been implicated in other functions of the TCR, such as superantigen binding, which we will describe in Section 6-14.

4-15 A T-cell receptor recognizes antigen in the form of a complex of a foreign peptide bound to an MHC molecule.

Antigen recognition by T-cell receptors clearly differs from recognition by B-cell receptors and antibodies. The immunoglobulin on B cells binds directly to the intact antigen, and, as discussed in Section 4-11, antibodies typically bind to the surface of protein antigens, contacting amino acids that are discontinuous in the primary structure but are brought together in the folded protein. In contrast, αβ T cells respond to short, continuous amino acid sequences. As we described in Section 1-10, these peptide sequences are often buried within the native structure of the protein. Thus, antigens cannot be recognized directly by T-cell receptors unless the protein is unfolded and processed into peptide fragments (Fig. 4.20) and then presented by an MHC molecule (see Fig. 1.15). We will discuss this process in Chapter 6.

The nature of the antigen recognized by T cells became clear with the realization that the peptides that stimulate T cells are recognized only when bound

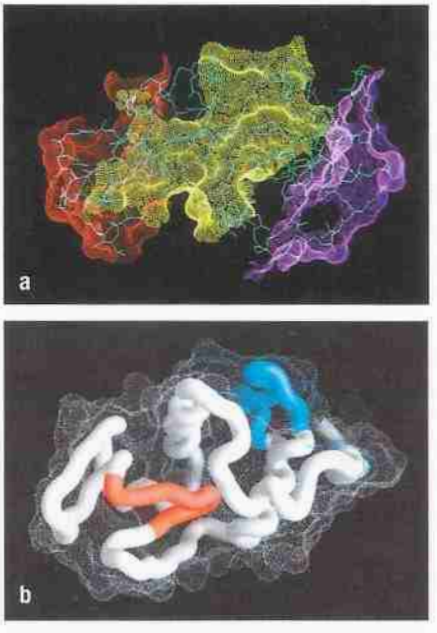

Fig. 4.20 Differences in the recognition of hen egg-white lysozyme by immunoglobulins and T-cell receptors. Antibodies can be shown by X-ray crystallography to bind epitopes on the surface of proteins, as shown in panel a, where the epitopes for three antibodies are shown in different colors (red, yellow, purple) on the surface of hen egg-white lysozyme (see also Fig. 4.11). In contrast, the epitopes recognized by T-cell receptors need not lie on the surface of the molecule, because the T-cell receptor recognizes not the antigenic protein itself but a peptide fragment of the protein. The peptides corresponding to two T-cell epitopes of lysozyme are shown in panel b. One epitope, shown in blue, lies on the surface of the protein, but a second, shown in red, lies mostly within the core and is inaccessible in the folded protein. This indicates that T-cell receptors do not recognize their epitopes in the native protein.

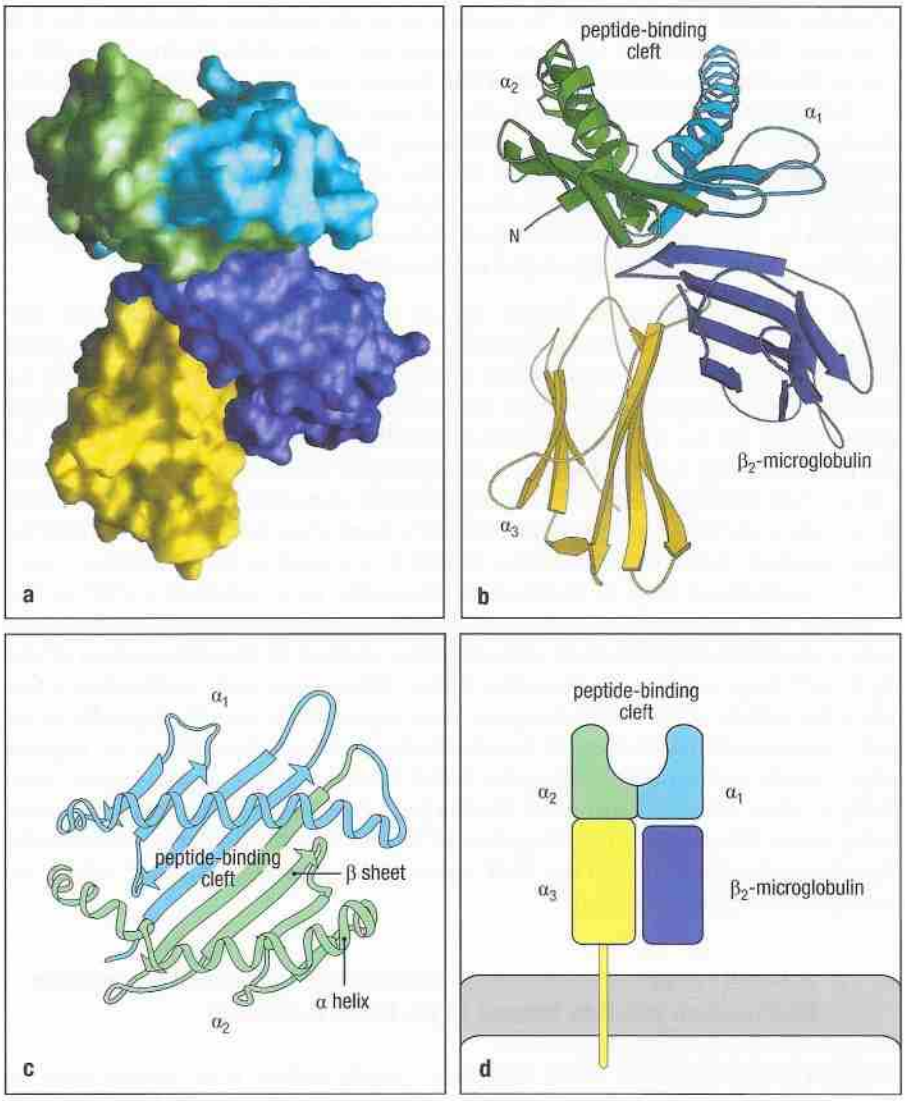

Fig. 4.21 The structure of an MHC class I molecule determined by X-ray crystallography. Panel a shows a computer-generated representation of a human MHC class I molecule, HLA-A2, which has been cleaved from the cell surface by the enzyme papain. The surface of the molecule is shown, colored according to the domains shown in panels b–d and described below. Panels b and c each show a ribbon diagram of the structure. Shown schematically in panel d, the MHC class I molecule is a heterodimer of a membrane-spanning α chain (molecular mass 43 kDa) bound noncovalently to β_2-microglobulin (12 kDa), which does not span the membrane. The α chain folds into three domains: α_1, α_2, and α_3. The α_3 domain and β_2-microglobulin show similarities in amino acid sequence to immunoglobulin C domains and have similar folded structures, whereas the α_1 and α_2 domains are part of the same polypeptide and fold together into a single structure consisting of two separated α helices lying on a sheet of eight antiparallel β strands. The folding of the α_1 and α_2 domains creates a long cleft or groove, which is the site at which peptide antigens bind to the MHC molecules. For class I molecules, this groove is open at only one end. The transmembrane region and the short stretch of peptide that connects the external domains to the cell surface are not seen in panels a and b because they have been removed by the digestion with papain. As can be seen in panel c, looking down on the molecule from above, the sides of the cleft are formed from the inner faces of the two α helices; the β pleated sheet formed by the pairing of the α_1 and α_2 domains creates the floor of the cleft.

to an MHC molecule. The ligand recognized by the T cell is thus a complex of peptide and MHC molecule. The evidence for involvement of the MHC in T-cell recognition of antigen was indirect at first, but it has been proven conclusively by stimulating T cells with purified peptide:MHC complexes. The T-cell receptor interacts with this ligand by making contacts with both the MHC molecule and the antigen peptide.

4-16 There are two classes of MHC molecules with distinct subunit compositions but similar three-dimensional structures.

There are two classes of MHC molecules—**MHC class I** and **MHC class II**—and they differ in both their structure and their expression pattern in the tissues of the body. As shown in Figs. 4.21 and 4.22, MHC class I and MHC class II molecules are closely related in overall structure but differ in their subunit composition. In both classes, the two paired protein domains nearest to the membrane resemble immunoglobulin domains, whereas the two domains furthest away from the membrane fold together to create a long cleft, or groove, which is the site at which a peptide binds. Purified peptide:MHC class I and peptide:MHC class II complexes have been characterized structurally, allowing us to describe in detail both the MHC molecules themselves and the way in which they bind peptides.

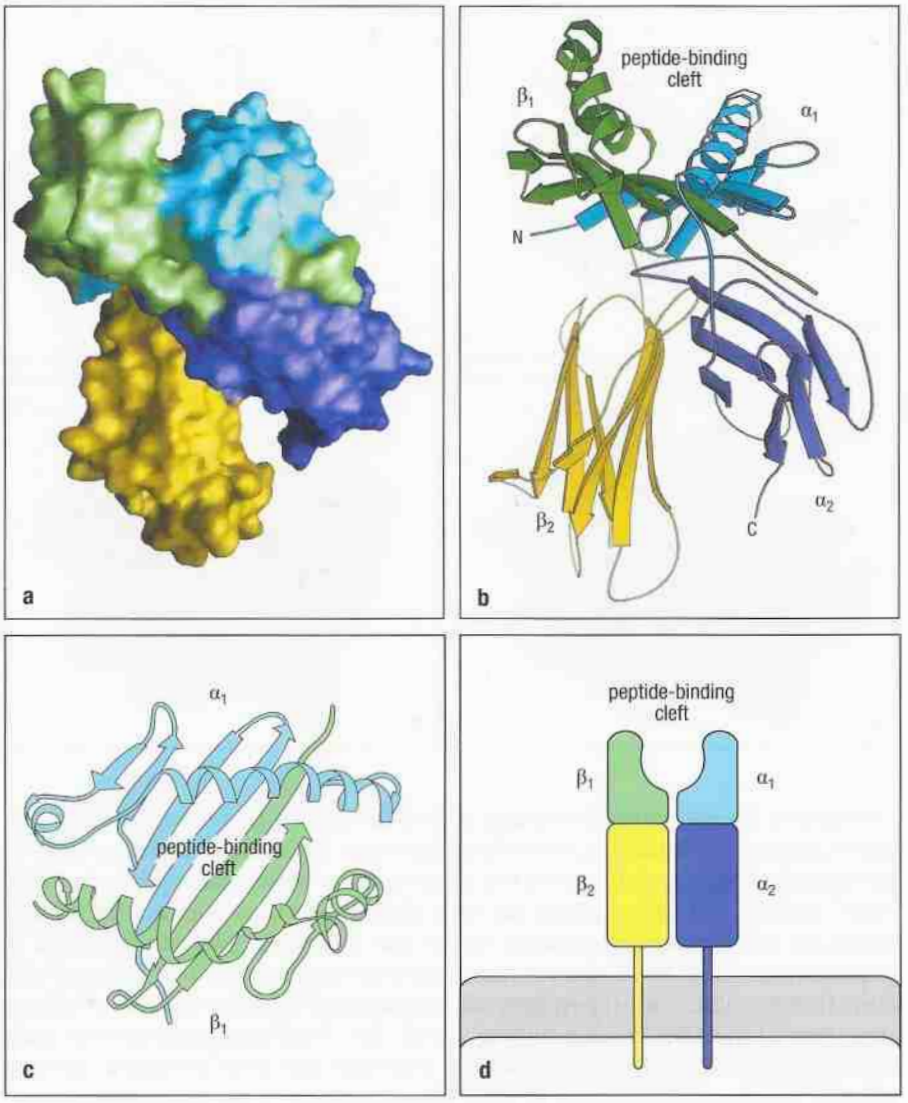

Fig. 4.22 MHC class II molecules resemble MHC class I molecules in overall structure. The MHC class II molecule is composed of two transmembrane glycoprotein chains, α (34 kDa) and β (29 kDa), as shown schematically in panel d. Each chain has two domains, and the two chains together form a compact four-domain structure similar to that of the MHC class I molecule (compare with panel d of Fig. 4.21). Panel a shows a computer-generated representation of the surface of the MHC class II molecule, in this case the human protein HLA-DR1, and panel b shows the equivalent ribbon diagram. N, amino terminus; C, carboxyl terminus. The α_2 and β_2 domains, like the α_3 and β_2-microglobulin domains of the MHC class I molecule, have amino acid sequence and structural similarities to immunoglobulin C domains; in the MHC class II molecule the two domains forming the peptide-binding cleft are contributed by different chains and are therefore not joined by a covalent bond (see panels c and d). Another important difference, not apparent in this diagram, is that the peptide-binding groove of the MHC class II molecule is open at both ends.

MHC class I molecules (see Fig. 4.21) consist of two polypeptide chains. One chain, the α chain, is encoded in the MHC (on chromosome 6 in humans) and is noncovalently associated with a smaller chain, **β_2-microglobulin**, which is encoded on a different chromosome—chromosome 15 in humans. Only the class I α chain spans the membrane. The complete MHC class I molecule has four domains, three formed from the MHC-encoded α chain, and one contributed by β_2-microglobulin. The α_3 domain and β_2-microglobulin closely resemble Ig-like domains in their folded structure. The folded α_1 and α_2 domains form the walls of a cleft on the surface of the molecule; because this is where the peptide binds, this part of the MHC molecule is known as the **peptide-binding cleft** or **peptide-binding groove**. The MHC molecules are highly polymorphic, and the major differences between the different allelic forms are located in the peptide-binding cleft, influencing which peptides will bind and thus the specificity of the peptide:MHC antigen presented to T cells. By contrast, β_2-microglobulin, which does not contribute directly to peptide binding, is not polymorphic.

An MHC class II molecule consists of a noncovalent complex of two chains, α and β, both of which span the membrane (see Fig. 4.22). The MHC class II α chain is a different protein from the class I α chain. The MHC class II α and β chains are both encoded within the MHC. The crystallographic structure of the MHC class II molecule shows that it is folded very much like the MHC class

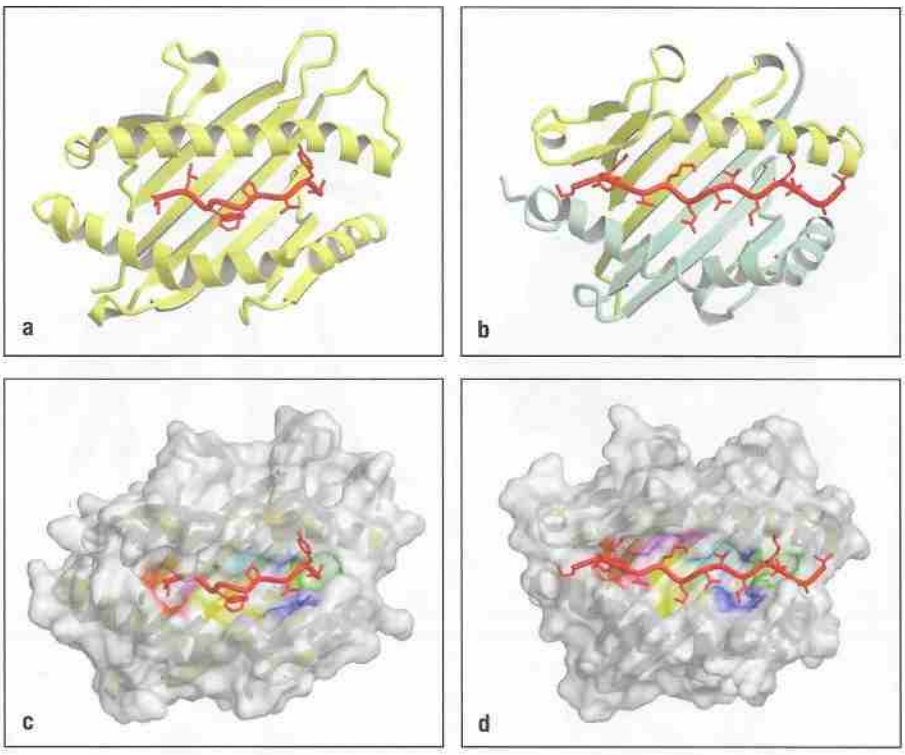

Fig. 4.23 MHC molecules bind peptides tightly within the cleft. When MHC molecules are crystallized with a single synthetic peptide antigen, the details of peptide binding are revealed. In MHC class I molecules (panels a and c), the peptide is bound in an elongated conformation with both ends tightly bound at either end of the cleft. In MHC class II molecules (panels b and d), the peptide is also bound in an elongated conformation, but the ends of the peptide are not tightly bound and the peptide extends beyond the cleft. The upper surface of the peptide:MHC complex is recognized by T cells and is composed of residues of the MHC molecule and the peptide. The amino acid side chains of the peptide insert into pockets in the peptide-binding groove of the MHC molecule; these pockets are lined with residues that are polymorphic within the MHC. In representations c and d, the surfaces of the different pockets for the different amino acids are depicted as areas of different colors.

I molecule, but the peptide-binding cleft is formed by two domains from different chains, the α_1 and β_1 domains. The major differences lie at the ends of the peptide-binding cleft, which are more open in MHC class II than in MHC class I molecules. Consequently, the ends of a peptide bound to an MHC class I molecule are substantially buried within the molecule, whereas the ends of peptides bound to MHC class II molecules are not. In both MHC class I and class II molecules, bound peptides are sandwiched between the two α-helical segments of the MHC molecule (Fig. 4.23). The T-cell receptor interacts with this compound ligand, making contacts with both the MHC molecule and the peptide antigen. As in the case of MHC class I molecules, the sites of major polymorphism in MHC class II molecules are located in the peptide-binding cleft.

4-17 Peptides are stably bound to MHC molecules and also serve to stabilize the MHC molecule on the cell surface.

An individual can be infected by a wide variety of pathogens, whose proteins will not generally have peptide sequences in common. For T cells to be able to detect the widest possible array of infections, the MHC molecules (both class I and class II) of an individual should be able to bind stably to many different peptides. This behavior is quite distinct from that of other peptide-binding receptors, such as those for peptide hormones, which usually bind only a single type of peptide. The crystal structures of peptide:MHC complexes have helped to show how a single binding site can bind a peptide with high affinity while retaining the ability to bind a wide variety of different peptides.

An important feature of the binding of peptides to MHC molecules is that the peptide is bound as an integral part of the MHC molecule's structure, and MHC molecules are unstable when peptides are not bound. This dependence on bound peptide applies to both MHC class I and MHC class II molecules. Stable peptide binding is important, because otherwise peptide exchanges occurring at the cell surface would prevent peptide:MHC complexes from being reliable indicators of infection or of uptake of a specific antigen. When MHC molecules are purified from cells, their stably bound peptides co-purify with them,

and this fact has allowed the peptides bound by particular MHC molecules to be analyzed. Peptides are released from the MHC molecules by denaturing the complex in acid, and they are then purified and sequenced. Pure synthetic peptides can also be incorporated into empty MHC molecules and the structure of the complex determined, revealing details of the contacts between the MHC molecule and the peptide. From such studies a detailed picture of the binding interactions has been built up. We discuss the peptide-binding properties of MHC class I molecules first.

4-18 MHC class I molecules bind short peptides of 8–10 amino acids by both ends.

Binding of a peptide to an MHC class I molecule is stabilized at both ends of the peptide-binding cleft by contacts between atoms in the free amino and carboxyl termini of the peptide and invariant sites that are found at each end of the cleft in all MHC class I molecules (Fig. 4.24). These are thought to be the main stabilizing contacts for peptide:MHC class I complexes, because synthetic peptide analogs lacking terminal amino and carboxyl groups fail to bind stably to MHC class I molecules. Other residues in the peptide serve as additional anchors. Peptides that bind to MHC class I molecules are usually 8–10 amino acids long. However, longer peptides are thought to bind, particularly if they can bind at their carboxyl terminus, but they are subsequently shortened to 8–10 amino acids through cleavage by exopeptidases present in the endoplasmic reticulum, which is where MHC class I molecules bind peptides. The peptide lies in an elongated conformation along the cleft; variations in peptide length seem to be accommodated, in most cases, by the peptide bulging out of the binding groove. However, in some cases, length variation can also be accommodated in MHC class I molecules by allowing the peptide to extend out of the cleft at the carboxyl terminus.

These interactions give MHC class I molecules a broad peptide-binding specificity. In addition, MHC molecules are highly polymorphic. As mentioned earlier, MHC genes are highly polymorphic, and there are hundreds of different

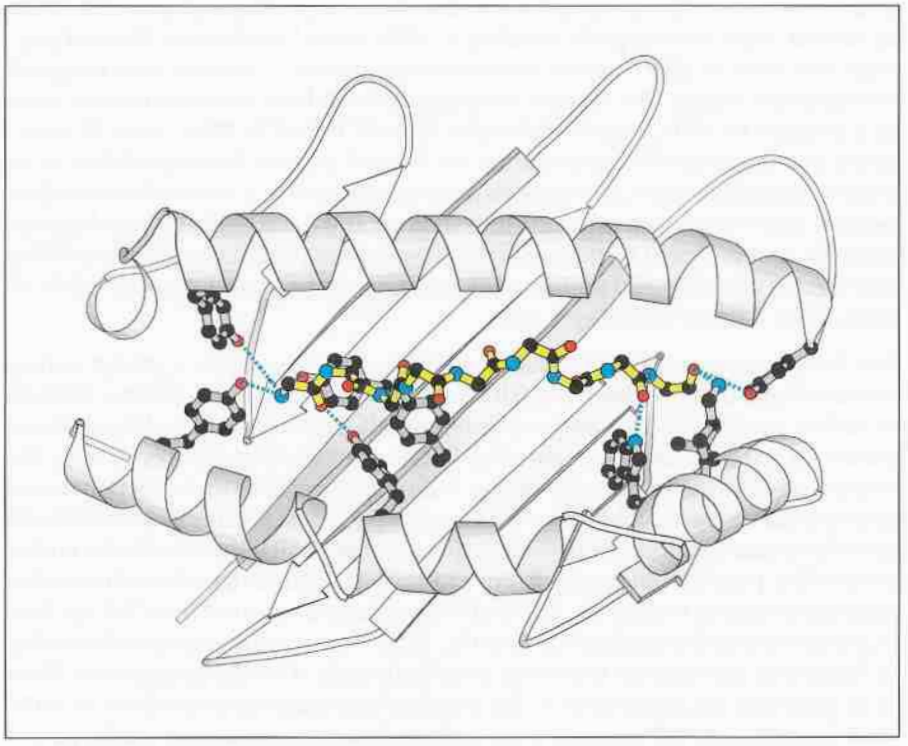

Fig. 4.24 Peptides are bound to MHC class I molecules by their ends. MHC class I molecules interact with the backbone of a bound peptide (shown in yellow) through a series of hydrogen bonds and ionic interactions (shown as dotted blue lines) at each end of the peptide. The amino terminus of the peptide is to the left, the carboxyl terminus to the right. Black circles are carbon atoms; red are oxygen; blue are nitrogen. The amino acid residues in the MHC molecule that form these bonds are common to all MHC class I molecules, and their side chains are shown in full (in gray) on a ribbon diagram of the MHC class I groove. A cluster of tyrosine residues common to all MHC class I molecules forms hydrogen bonds to the amino terminus of the bound peptide, while a second cluster of residues forms hydrogen bonds and ionic interactions with the peptide backbone at the carboxyl terminus and with the carboxyl terminus itself.

Fig. 4.25 Peptides bind to MHC molecules through structurally related anchor residues. The sequences of two sets of peptides eluted from two different MHC class I molecules are shown in the upper and lower panels. The anchor residues (green) differ for peptides that bind different allelic variants of MHC class I molecules but are similar for all peptides that bind to the same MHC molecule. The anchor residues that bind a particular MHC molecule need not be identical but are always related; for example, phenylalanine (F) and tyrosine (Y) are both aromatic amino acids, whereas valine (V), leucine (L), and isoleucine (I) are all large hydrophobic amino acids. Peptides also bind to MHC class I molecules through their amino (blue) and carboxyl (red) termini.

allelic variations of the MHC class I genes in the human population. Each individual carries only a small selection of these variants. The main differences between allelic MHC variants are found at certain sites in the peptide-binding cleft, resulting in different amino acids in key peptide-interaction sites. For this reason, different MHC variants preferentially bind different peptides. The peptides that can bind to a given MHC variant have the same or very similar amino acid residues at two or three particular positions along the peptide sequence. The amino acid side chains at these positions insert into pockets in the MHC molecule that are lined by the polymorphic amino acids. Because this binding anchors the peptide to the MHC molecule, the peptide residues involved are called the **anchor residues**, as illustrated in Fig. 4.25. Both the position and identity of these anchor residues can vary, depending on the particular MHC class I variant that is binding the peptide. However, most peptides that bind to MHC class I molecules have a hydrophobic (or sometimes basic) residue at the carboxyl terminus that also serves to anchor the peptide in the groove. Whereas changing an anchor residue will in most cases prevent the peptide from binding, not every synthetic peptide of suitable length that contains these anchor residues will bind the appropriate MHC class I molecule, and so the overall binding must also depend on the nature of the amino acids at other positions in the peptide. In some cases, particular amino acids are preferred in certain positions, whereas in others the presence of particular amino acids prevents binding. These additional amino acid positions are called 'secondary anchors.' These features of peptide binding enable an individual MHC class I molecule to bind a wide variety of different peptides, yet allow different MHC class I allelic variants to bind different sets of peptides. As we will see in Chapter 15, MHC polymorphisms also impact the binding of peptides derived from self proteins and can influence the susceptibility of an individual to various autoimmune diseases.

4-19 The length of the peptides bound by MHC class II molecules is not constrained.

Like MHC class I molecules, MHC class II molecules that lack bound peptide are unstable. Peptide binding to MHC class II molecules has also been analyzed by elution of bound peptides and by X-ray crystallography, and it differs in several ways from peptide binding to MHC class I molecules. Natural peptides that bind to MHC class II molecules are at least 13 amino acids long and can be much longer. The clusters of conserved residues that bind the two ends of a peptide in MHC class I molecules are not found in MHC class II molecules, and the ends of the peptide are not bound. Instead, the peptide lies in an extended conformation along the peptide-binding cleft. It is held there both by peptide side chains that protrude into shallow and deep pockets lined by polymorphic residues and by interactions between the peptide backbone and the side chains of conserved amino acids that line the peptide-binding cleft in all MHC class II molecules (Fig. 4.26).

The binding pockets of MHC class II molecules accommodate a greater variety of side chains than do those of MHC class I molecules, making it more difficult to define anchor residues and to predict which peptides will be able to bind a particular MHC class II variant (Fig. 4.27). Nevertheless, by comparing the sequences of known binding peptides, it is usually possible to detect patterns of amino acids that permit binding to different MHC class II variants and to model how the amino acids of this peptide sequence motif will interact with the amino acids of the peptide-binding cleft. For example, structural data show that amino acid side chains at residues 1, 4, 6, and 9 of peptides bound to HLA-DR3 are held in pockets lining the binding site (see Fig. 4.27). Because the peptide is bound by its backbone and allowed to emerge from both ends of the binding groove, there is, in principle, no upper limit to the length of peptides that could bind to MHC class II molecules. An example is the protein known as **invariant chain**, part of

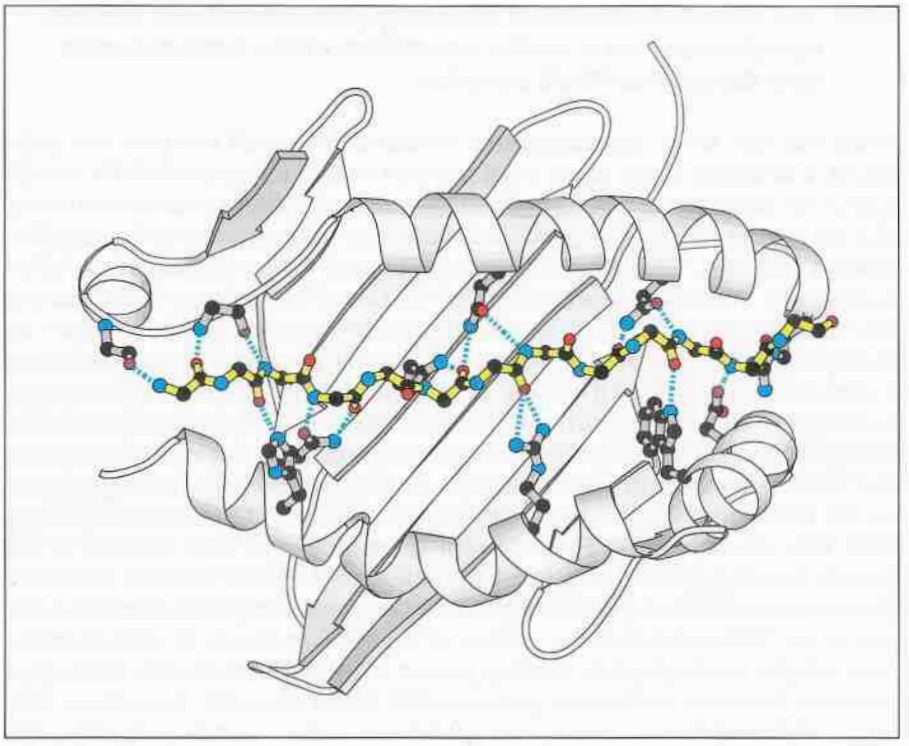

Fig. 4.26 Peptides bind to MHC class II molecules by interactions along the length of the binding groove. A peptide (yellow; shown as the peptide backbone only, with the amino terminus to the left and the carboxyl terminus to the right) is bound by an MHC class II molecule through a series of hydrogen bonds (dotted blue lines) that are distributed along the length of the peptide. The hydrogen bonds toward the amino terminus of the peptide are made with the backbone of the MHC class II polypeptide chain, whereas throughout the peptide's length, bonds are made with residues that are highly conserved in MHC class II molecules. The side chains of these residues are shown in gray on the ribbon diagram of the MHC class II groove.

which lies entirely across the peptide-binding groove of nascent MHC class II molecules during their synthesis in the endoplasmic reticulum. We will return in Chapter 6 to the role of the invariant chain in the loading of peptides onto MHC class II molecules. In most cases, long peptides bound to MHC class II molecules are trimmed by peptidases to a length of around 13–17 amino acids.

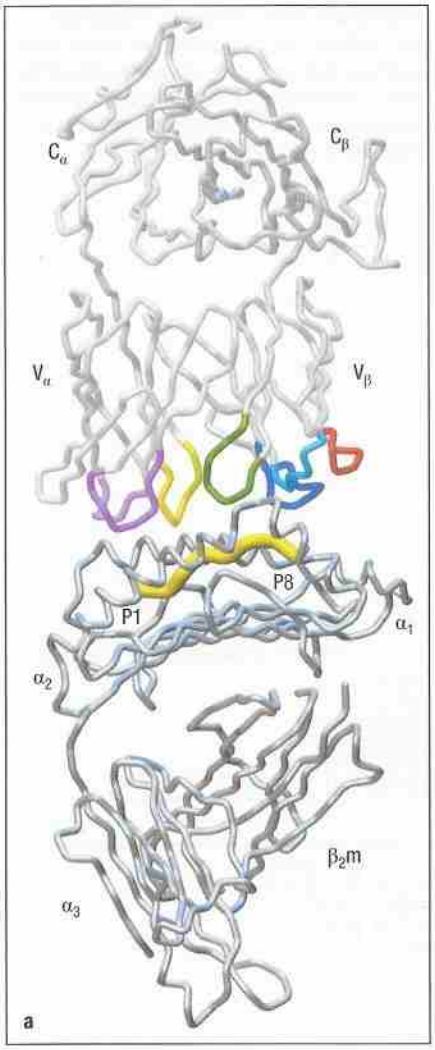
Fig. 4.27 Peptides that bind MHC class II molecules are variable in length, and their anchor residues lie at various distances from the ends of the peptide. The sequences of a set of peptides that bind to the mouse MHC class II A^k protein are shown in the upper panel. All contain the same core sequence (shaded) but differ in length. In the lower panel, different peptides binding to the human MHC class II protein HLA-DR3 are shown. Anchor residues are shown as green circles. The lengths of these peptides can vary, and so by convention the first anchor residue is denoted as residue 1. Note that all of the peptides share a hydrophobic residue in position 1, a negatively charged residue [aspartic acid (D) or glutamic acid (E)] in position 4, and a tendency to have a basic or polar residue [lysine (K), arginine (R), histidine (H), glutamine (Q), or asparagine (N)] in position 6 and a hydrophobic residue [for example, tyrosine (Y), leucine (L), or phenylalanine (F)] in position 9.

4-20 The crystal structures of several peptide:MHC:T-cell receptor complexes show a similar orientation of the T-cell receptor over the peptide:MHC complex.

When the first X-ray crystallographic structure of a T-cell receptor was published, a structure of the same T-cell receptor bound to a peptide:MHC class I ligand was also produced. The orientation revealed by these structures showed that the T-cell receptor is aligned diagonally over the peptide and the peptide-binding cleft (Fig. 4.28). The TCRα chain lies over the α_2 domain of the MHC molecule at the amino-terminal end of the bound peptide, as seen from the side view shown in Fig. 4.28a. The TCRβ chain lies over the MHC molecule's α_1 domain, closer to the carboxyl-terminal end of the peptide. Figure 4.27b shows a view of this structure as if looking down through a transparent T-cell receptor to indicate where it contacts the MHC molecule. The CDR3 loops of both TCRα and TCRβ chains come together and lie over central amino acids of the peptide. The T-cell receptor is threaded through a valley between the two high points on the two surrounding α helices that form the walls of the peptide-binding cleft. This can be seen in Fig. 4.29, which shows a view from the end of the peptide-binding groove of a peptide:MHC class II:T-cell receptor complex. Comparison of various peptide:MHC:T-cell receptor complexes shows that the axis of the TCR as it binds the surface of the MHC molecule is rotated somewhat relative to the peptide-binding groove of the MHC molecule, with some variation between individual peptide:MHC:T-cell receptor complexes (see Fig. 4.28b). In this orientation, the V_α domain makes contact primarily with the amino-terminal half of the bound peptide, whereas the V_β domain contacts primarily the carboxyl-terminal half. Both chains also interact with the α helices of the MHC class I molecule (see Fig. 4.28). The T-cell receptor contacts are not symmetrically distributed over the MHC molecule: whereas the V_α CDR1 and CDR2 loops are in close contact with the helices of the peptide:MHC complex around the amino terminus of the bound peptide, the β-chain CDR1 and CDR2 loops, which interact with the complex at the carboxyl terminus of the bound peptide, have variable contributions to the binding.

Comparison of the three-dimensional structure of an unliganded T-cell receptor and the same T-cell receptor complexed to its peptide:MHC ligand shows that the binding results in some degree of conformational change, or 'induced fit,' particularly within the V_α CDR3 loop. Subtle variations at amino acids that contact the T-cell receptor can have strikingly different effects on the recognition of an otherwise identical peptide:MHC ligand by the same T cell. The flexibility in the CDR3 loop demonstrated by these two structures helps to explain how the T-cell receptor can adopt conformations that recognize related, but different, peptide ligands.

The specificity of T-cell recognition involves both the peptide and its presenting MHC molecule. Simply changing a leucine to isoleucine in the peptide,



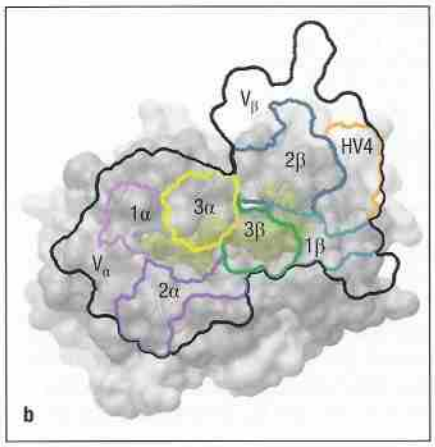


Fig. 4.28 The T-cell receptor binds to the peptide:MHC complex. Panel a: The T-cell receptor binds to the top of a peptide:MHC class I molecule, touching both the α_1 and α_2 domain helices. The CDRs of the T-cell receptor are shown in color: the CDR1 and CDR2 loops of the β chain are light and dark blue, respectively, and the CDR1 and CDR2 loops of the α chain are light and dark purple, respectively. The α-chain CDR3 loop is yellow, and the β-chain CDR3 loop is green. The β-chain HV4 loop is in red. The thick yellow line P1–P8 is the bound peptide. Panel b: The outline of the T-cell receptor's antigen-binding site (thick black line) is superimposed over the top surface of the peptide:MHC complex (the peptide is shaded dull yellow). The T-cell receptor lies at a somewhat diagonal angle across the peptide:MHC complex, with the α and β CDR3 loops of the T-cell receptor (3α, 3β, yellow and green, respectively) contacting the center of the peptide. The α-chain CDR1 and CDR2 loops (1α, 2α, light and dark purple, respectively) contact the MHC helices at the amino terminus of the bound peptide, whereas the β-chain CDR1 and CDR2 loops (1β, 2β, light and dark blue, respectively) make contact with the helices at the carboxyl terminus of the bound peptide.

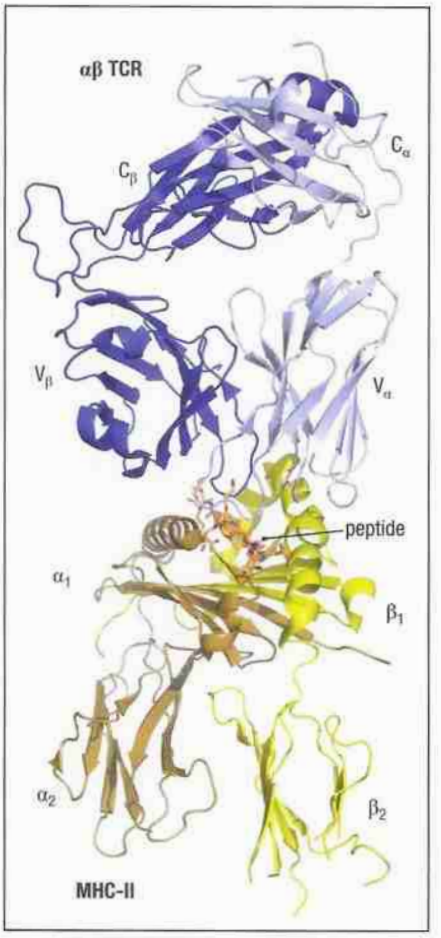

Fig. 4.29 The T-cell receptor interacts with MHC class I and MHC class II molecules in a similar fashion. Shown is the structure of a T-cell receptor, specific for a peptide derived from chicken cytochrome *c*, bound to an MHC class II molecule. This T-cell receptor's binding is at a site and orientation similar to that of the T-cell receptor bound to the MHC class I molecule shown in Fig. 4.28. The α and β chains of the T-cell receptor are colored in light and dark blue, respectively. The cytochrome *c* peptide is light orange. The T-cell receptor sits in a shallow saddle formed between the α-helical regions of the MHC class II α (brown) and β (yellow) chains at roughly 90° to the long axis of the MHC class II molecule and the bound peptide. Structure derived from PDB 3QIB.

for example, is sufficient to alter a T-cell response from strong killing to no response at all. Mutations of single residues in the presenting MHC molecules can have the same effect. This dual specificity for T-cell recognition of antigen underlies the MHC restriction of T-cell responses, a phenomenon that was observed long before the peptide-binding properties of MHC molecules were known. Another consequence of this dual specificity is a need for T-cell receptors to exhibit some inherent specificity for MHC molecules in order to be able to interact appropriately with the antigen-presenting surface of MHC molecules. We will return to these issues in Chapter 6, where we recount the discovery of MHC restriction in the context of T-cell recognition and MHC polymorphisms, and in Chapter 8, where we discuss the impact of these phenomena on T-cell development in the thymus.

4-21 The CD4 and CD8 cell-surface proteins of T cells directly contact MHC molecules and are required to make an effective response to antigen.

As we introduced in Section 1-21, T cells fall into two major classes distinguished by the expression of the cell-surface proteins **CD4** and **CD8**. CD8 is expressed by cytotoxic T cells, while CD4 is expressed by T cells whose function is to activate other cells. CD4 and CD8 were known as markers for these functional sets for some time before it became clear that the distinction was based on the ability of T cells to recognize different classes of MHC molecules. We now know that CD8 recognizes MHC class I molecules and CD4 recognizes MHC class II. During antigen recognition, CD4 or CD8 (depending on the type of T cell) associates with the T-cell receptor on the T-cell surface and binds to invariant sites on the MHC portion of the composite peptide:MHC ligand, away from the peptide-binding site. This binding contributes to the overall effectiveness of the T-cell response, and so CD4 and CD8 are called **co-receptors**.

CD4 is a single-chain protein composed of four Ig-like domains (Fig. 4.30). The first two domains (D1 and D2) are packed tightly together to form a rigid rod about 6 nm long, which is joined by a flexible hinge to a similar rod formed by the third and fourth domains (D3 and D4). The MHC-binding region on CD4 is located mainly on a lateral face of the D1 domain, and CD4 binds to a hydrophobic crevice formed at the junction of the α_2 and β_2 domains of the MHC class II molecule (Fig. 4.31a). This site is well away from the site where the T-cell receptor binds, as shown by the complete crystal structure of a T-cell receptor bound to peptide:MHC class II with bound CD4 (Fig. 4.32). This structure demonstrates that the CD4 molecule and the T-cell receptor can bind simultaneously to the same peptide:MHC class II complex. CD4 enhances sensitivity to antigen, as the T cell is about 100-fold more sensitive to the antigen when CD4 is present. The enhancement process results from the ability of the intracellular portion of CD4 to bind to a cytoplasmic tyrosine kinase called **Lck**. As we will discuss in detail Chapter 7, bringing Lck into proximity with the T-cell receptor complex helps activate the signaling cascade induced by antigen recognition.

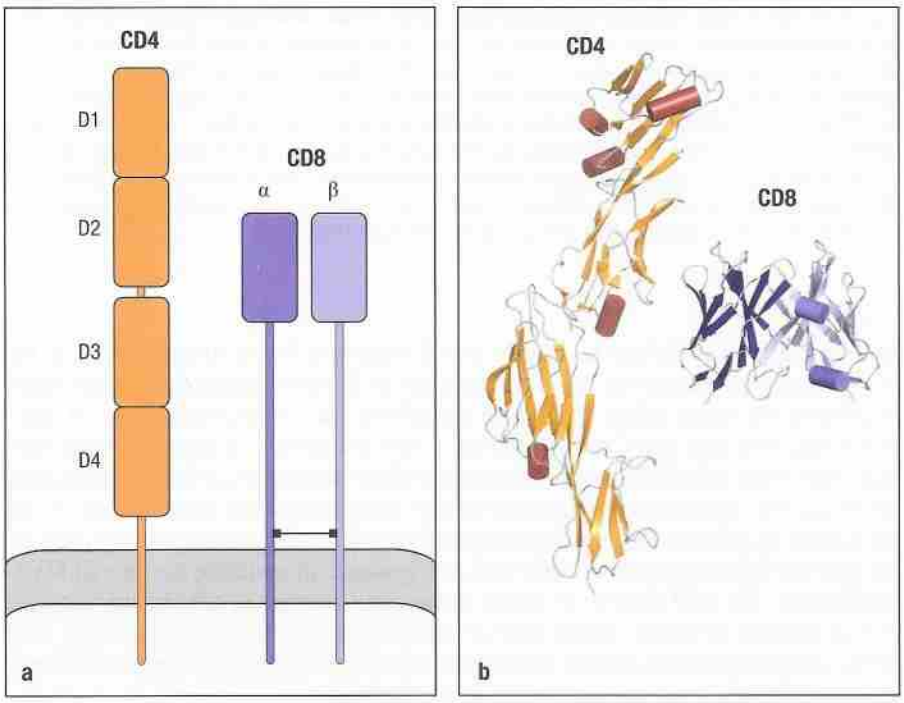

Fig. 4.30 The structures of the CD4 and CD8 co-receptor molecules. The CD4 molecule contains four Ig-like domains, shown in schematic form in panel a and as a ribbon diagram from the crystal structure in panel b. The amino-terminal domain, D1, is similar in structure to an immunoglobulin V domain. The second domain, D2, although related to an immunoglobulin domain, is different from both V and C domains and has been termed a C2 domain. The first two domains of CD4 form a rigid rodlike structure that is linked to the two carboxyl-terminal domains by a flexible link. The binding site for MHC class II molecules involves mainly the D1 domain. The CD8 molecule is a heterodimer of an α and a β chain covalently linked by a disulfide bond. An alternative form of CD8 exists as a homodimer of α chains. The heterodimer is depicted in panel a, whereas the ribbon diagram in panel b is of the homodimer. CD8α and CD8β chains have very similar structures, each having a single domain resembling an immunoglobulin V domain and a stretch of polypeptide chain, believed to be in a relatively extended conformation, that anchors the V-like domain to the cell membrane.

The structure of CD8 is quite different. It is a disulfide-linked dimer of two different chains, called α and β, each containing a single Ig-like domain linked to the membrane by a segment of extended polypeptide (see Fig. 4.30). This segment is extensively glycosylated, which is thought to maintain it in an extended conformation and protect it from cleavage by proteases. CD8α chains can form homodimers, although these are usually not found when CD8β is expressed. Naive T cells express CD8αβ, but the CD8αα homodimer can be expressed by highly activated effector and memory T cells. CD8αα is also expressed by a population of intraepithelial lymphocytes known as **mucosal associated invariant T cells (MAIT cells)**; these cells recognize metabolites of folic acid that are produced by bacteria in association with the nonclassical MHC class I molecule **MR1**, which we will describe in Chapter 6.

CD8αβ binds weakly to an invariant loop site in the α_3 domain of an MHC class I molecule (Fig. 4.31b). The CD8β chain interacts with residues in the base of the α_2 domain of the MHC class I molecule, while the α chain is in a lower position interacting with the α_3 domain of the MHC class I molecule. The strength of binding of CD8 to the MHC class I molecule is influenced by the glycosylation state of the CD8 molecule; increasing the number of sialic acid residues on CD8 carbohydrate structures decreases the strength of the interaction. The pattern of sialylation of CD8 changes during the maturation of T cells in the thymus and also on activation, and this likely has a role in modulating antigen recognition.

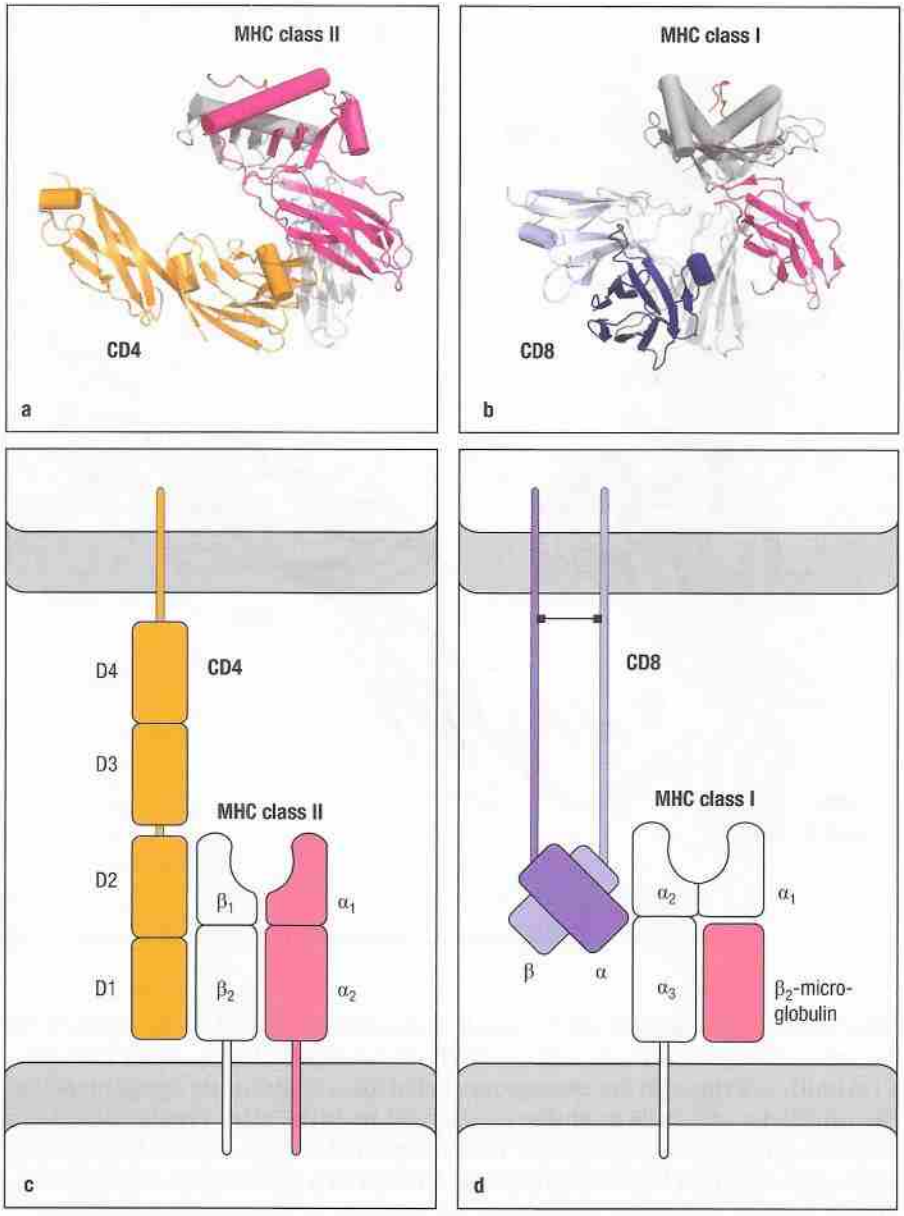

Fig. 4.31 The binding sites for CD4 and CD8 on MHC class II and class I molecules lie in the Ig-like domains. The binding sites for CD4 and CD8 on the MHC class II and class I molecules, respectively, lie in the Ig-like domains nearest to the membrane and distant from the peptide-binding cleft. The binding of CD4 to an MHC class II molecule is shown as a ribbon structure in panel a and schematically in panel c. The α chain of the MHC class II molecule is shown in pink, and the β chain in white, while CD4 is in gold. Only the D1 and D2 domains of the CD4 molecule are shown in panel a. The binding site for CD4 lies at the base of the β_2 domain of an MHC class II molecule, in the hydrophobic crevice between the β_2 and α_2 domains. The binding of CD8αβ to an MHC class I molecule is shown in panel b and schematically in panel d. The class I heavy chain and β_2-microglobulin are shown in white and pink, respectively, and the two chains of the CD8 dimer are shown in light (CD8β) and dark (CD8α) purple. The binding site for CD8 on the MHC class I molecule lies in a similar position to that of CD4 in the MHC class II molecule, but CD8 binding also involves the base of the α_1 and α_2 domains, and thus the binding of CD8 to MHC class I is not completely equivalent to the binding of CD4 to MHC class II. The cylindrical shapes in panels a and b represent the α helices lining the peptide-binding sites of MHC class II and MHC class I, respectively. Structures derived from PDB 3S4S (CD4/MHC class II) and PDB 3DMM (CD8αβ/MHC class I).

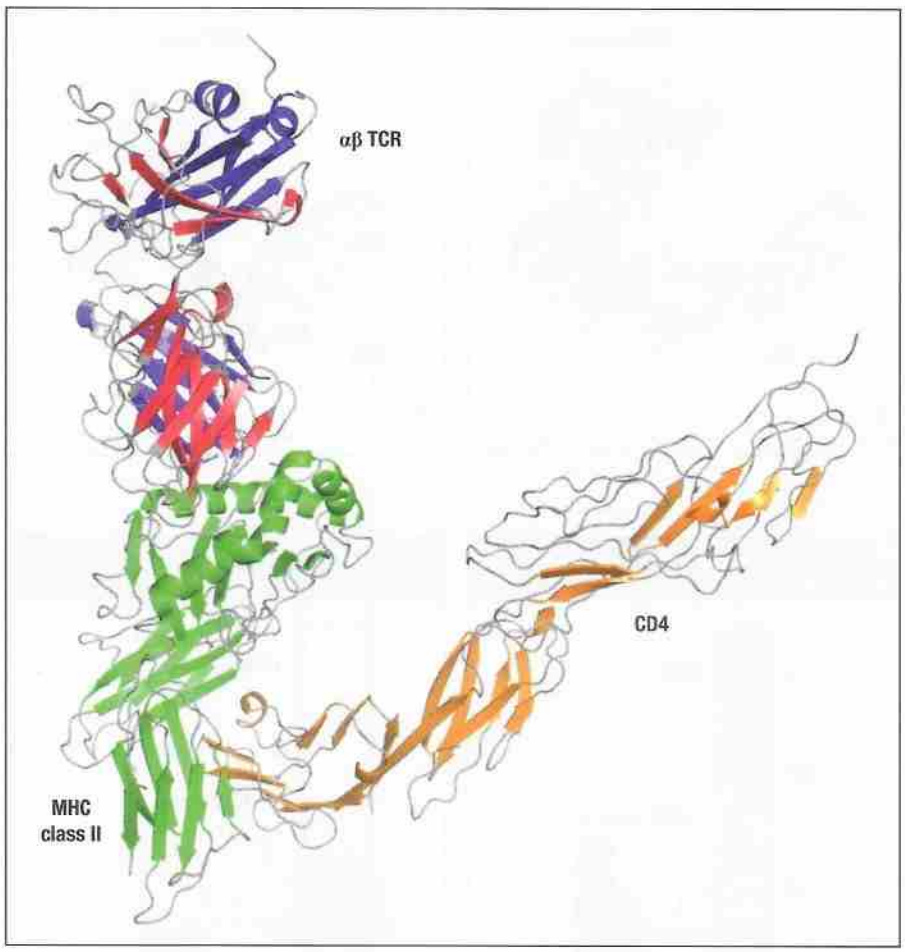

Fig. 4.32 CD4 and the T-cell receptor bind to distinct regions of the MHC class II molecule. A ribbon diagram is shown from a crystal structure of a complete αβ TCR:peptide-MHC:CD4 ternary complex. The α and β chains of the T-cell receptor (TCR) are blue and red, respectively. The peptide-MHC class II complex is green. CD4 is shown in orange. Structure derived from PDB 3T0E.

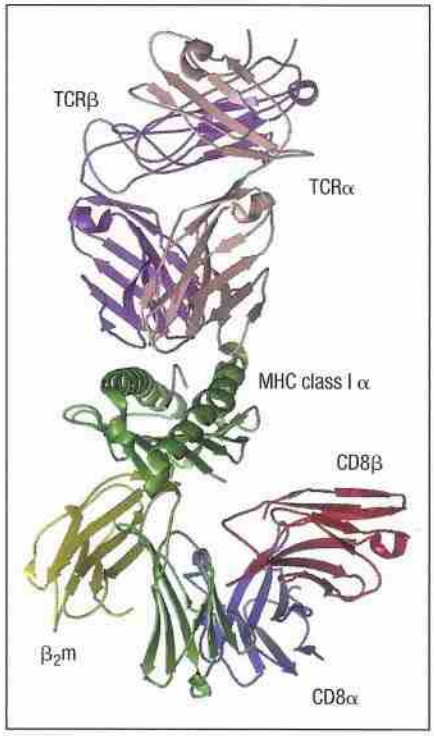

Fig. 4.33 CD8 binds to a site on MHC class I molecules that is distant from where the T-cell receptor binds. The relative binding positions of both the T-cell receptor and CD8 molecules can be seen in this hypothetical reconstruction of their interaction with MHC class I (α chain in dark green and β_2-microglobulin in light green). The α and β chains of the T-cell receptor are shown in brown and purple, respectively. The CD8αβ heterodimer is shown bound to the MHC class I α_3 domain. The CD8 α chain is in blue, and the CD8β chain is in red.

Like the interactions with MHC class II molecules, the T-cell receptor and CD8 can interact simultaneously with one MHC class I molecule (Fig. 4.33). Like CD4, CD8 binds Lck through the cytoplasmic tail of the α chain, and CD8αβ increases the sensitivity of T cells to antigen presented by MHC class I molecules about 100-fold. Although the molecular details are unclear, the CD8αα homodimer appears to function less efficiently than CD8αβ as a co-receptor and may negatively regulate activation. In contrast to CD8, CD4 is not thought to dimerize.

4-22 The two classes of MHC molecules are expressed differentially on cells.

MHC class I and MHC class II molecules have distinct distributions among cells, and these reflect the different effector functions of the T cells that recognize them (Fig. 4.34). MHC class I molecules present peptides from pathogens, commonly viruses, to CD8 cytotoxic T cells, which are specialized to kill any cell that they specifically recognize. Because viruses can infect any nucleated cell, almost all such cells express MHC class I molecules, although the level of constitutive expression varies from one cell type to the next. For example, cells of the immune system express abundant MHC class I on their surface, whereas liver cells (hepatocytes) express relatively low levels (see Fig. 4.34). Nonnucleated cells, such as mammalian red blood cells, express little or no MHC class I, and thus the interior of red blood cells is a site in which an infection can go undetected by cytotoxic T cells. Because red blood cells cannot support viral replication, this is of no great consequence for viral infection, but it might be the absence of MHC class I that allows the *Plasmodium* parasites that cause malaria to live in this privileged site.

In contrast, a major function of the CD4 T cells that recognize MHC class II molecules is to activate other effector cells of the immune system. Thus, MHC class II molecules are normally found on dendritic cells, B lymphocytes, and macrophages—antigen-presenting cells that participate in immune responses—but not on other tissue cells (see Fig. 4.34). The peptides presented by MHC class II molecules expressed by dendritic cells can function to activate naive CD4 T cells. When previously activated CD4 T cells recognize peptides bound to MHC class II molecules on B cells, the T cells secrete cytokines that can influence the isotype of antibody that those B cells will choose to produce. Upon recognizing peptides bound to MHC class II molecules on macrophages, CD4 T cells activate these cells, again in part through cytokines, to destroy the pathogens in their intracellular vesicles.

The expression of both MHC class I and MHC class II molecules is regulated by cytokines, in particular, interferons, released in the course of an immune response. Interferon-α (IFN-α) and IFN-β increase the expression of MHC class I molecules on all types of cells, whereas IFN-γ increases the expression of both MHC class I and MHC class II molecules and can induce the expression of MHC class II molecules on certain cell types that do not normally express them. Interferons also enhance the antigen-presenting function of MHC class I molecules by inducing the expression of key components of the intracellular machinery that enables peptides to be loaded onto the MHC molecules.

Tissue	MHC class I	MHC class II
Lymphoid tissues		
T cells	+++	+*
B cells	+++	+++
Macrophages	+++	++
Dendritic cells	+++	+++
Epithelial cells of thymus	+	+++
Other nucleated cells		
Neutrophils	+++	–
Hepatocytes	+	–
Kidney	+	–
Brain	+	–†
Nonnucleated cells		
Red blood cells	–	–

Fig. 4.34 The expression of MHC molecules varies among tissues. MHC class I molecules are expressed on all nucleated cells, although they are most highly expressed in hematopoietic cells. MHC class II molecules are normally expressed only by a subset of hematopoietic cells and by thymic stromal cells, although they may be expressed by other cell types on exposure to the inflammatory cytokine IFN-γ. *In humans, activated T cells express MHC class II molecules, whereas in mice all T cells are MHC class II–negative. †In the brain, most cell types are MHC class II–negative, but microglia, which are related to macrophages, are MHC class II–positive.

4-23 A distinct subset of T cells bears an alternative receptor made up of γ and δ chains.

During the search for the gene for the TCRα chain, another T-cell receptor–like gene was unexpectedly discovered. This gene was named TCRγ, and its discovery led to a search for further T-cell receptor genes. Another receptor chain was identified by using antibody against the predicted sequence of the γ chain and was called the δ chain. It was soon discovered that a minority population of T cells in lymphoid organs bore a distinct type of T-cell receptor made up of γδ heterodimers rather than αβ heterodimers. The development of these cells is described in Sections 8-17 and 8-18.

Like αβ T cells, γδ T cells can be found in the lymphoid tissues of all vertebrates, but they are more prominent as populations of intraepithelial lymphocytes, particularly in the skin and female reproductive tracts, where their receptors display very limited diversity. Unlike αβ T cells, γδ T cells do not generally recognize antigen as peptides presented by MHC molecules, and γδ T-cell receptors are not restricted by the 'classical' MHC class I and class II molecules that function in binding and presenting peptides to T cells. Instead, γδ T-cell receptors seem to recognize their target antigens directly and thus probably are able to recognize and respond rapidly to molecules expressed by many different cell types. Their ligands have been difficult to identify, but several have now been described and seem to indicate that γδ T cells play an intermediate, or transitional, role between wholly innate and fully adaptive immune responses.

Like NK-cell receptor ligands, such as the proteins MIC and RAET1 (see Section 3-27), many of the ligands seen by γδ T cells are induced by cellular stress or damage that is a consequence of infection or malignancy, rather than being pathogen- or tumor-specific antigens themselves. Some γδ T cells also bind antigens presented by 'nonclassical' **MHC class Ib molecules**, which we will discuss in Chapter 6. These proteins are related structurally to the MHC proteins we have already discussed, but have functions besides binding peptides for presentation to T cells. Additional ligands may include heat-shock proteins and nonpeptide ligands such as phosphorylated ligands or mycobacterial lipid antigens. One well-studied subset of human γδ T cells recognizes a class of pyrophosphate metabolites, called phosphoantigens, that are

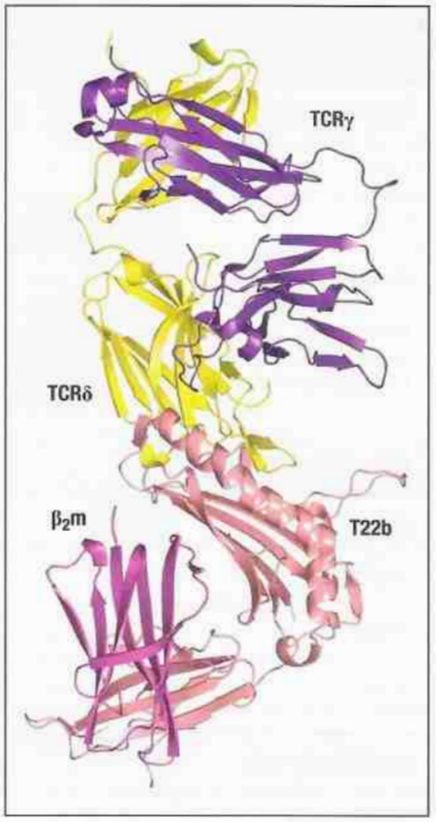

Fig. 4.35 Structures of γδ T-cell receptor bound to the nonclassical MHC class I molecule T22. The γδ T-cell receptor has a similar overall structure to the αβ T-cell receptor and the Fab fragment of an immunoglobulin. The C_δ domain is more like an immunoglobulin domain than is the corresponding C_α domain of the αβ T-cell receptor. In this structure, the overall orientation of the γδ T-cell receptor with respect to the nonclassical MHC molecule T22 is very different from the orientation of an αβ T-cell receptor with either MHC class I or class II molecules. Rather than lying directly over the peptide-binding groove, the γδ T-cell receptor is engaged with one end much more than the other; this is consistent with a lack of peptide contact and absence of MHC-restricted recognition.

produced by microbial pathogens or malignant cells. In this case, recognition of the phosphoantigen is not direct, but requires an interaction between the phosphoantigen and a protein of the butyrophilin family expressed on human cells. Currently the precise details of butyrophilin-mediated phosphoantigen recognition by these γδ T cells remains unclear.

The crystallographic structure of a γδ T-cell receptor reveals that, as expected, it is similar in shape to αβ T-cell receptors. Figure 4.35 shows a crystal structure of a γδ T-cell receptor complex bound to one of the nonclassical MHC class I molecules, called **T22**. This structure shows that the overall orientation of the γδ T-cell receptor with the MHC molecule is strikingly different from that of an αβ T-cell receptor, in that it interacts primarily with one end of the T22 molecule. However, the CDR3 regions of the γδ T-cell receptor still play a critical role in recognition, similar to that of antibodies and of αβ T-cell receptors. Further, the CDR3 of the γδ T-cell receptor is longer than either of these other two antigen receptors, and this could have implications for the type of ligand that the γδ T-cell receptor recognizes, as there is enormous combinatorial diversity from the CDR3 within the γδ T-cell receptor repertoire. We will return to discuss further the ligands and the development of γδ T cells in Chapters 6 and 8.

Summary.

The receptor for antigen on most T cells, the αβ T-cell receptor, is composed of two protein chains, TCRα and TCRβ, and resembles in many respects a single Fab fragment of immunoglobulin. αβ T-cell receptors are always membrane-bound and recognize a composite ligand of a peptide antigen bound to an MHC molecule. Each MHC molecule binds a wide variety of different peptides, but the different variants of MHC each preferentially recognize sets of peptides with particular sequences and physical features. The peptide antigen is generated intracellularly and is bound stably in a peptide-binding cleft on the surface of the MHC molecule. There are two classes of MHC molecules, and these are bound in their nonpolymorphic domains by CD8 and CD4 molecules that distinguish two different functional classes of αβ T cells. CD8 binds MHC class I molecules and can bind simultaneously to the same peptide:MHC class I complex being recognized by a T-cell receptor, thus acting as a co-receptor and enhancing the T-cell response; CD4 binds MHC class II molecules and acts as a co-receptor for T-cell receptors that recognize peptide:MHC class II ligands. A T-cell receptor interacts directly both with the antigenic peptide and with polymorphic features of the MHC molecule that displays it, and this dual specificity underlies the MHC restriction of T-cell responses. A second type of T-cell receptor, composed of a γ and a δ chain, is structurally similar to the αβ T-cell receptor, but it binds to different ligands, including nonpeptide ligands, nonpolymorphic nonclassical MHC molecules, and certain lipids. The receptor is thought not to be MHC-restricted and is found on a minority population of lymphoid and intraepithelial T cells, the γδ T cells.

Summary to Chapter 4.

B cells and T cells use different but structurally similar molecules to recognize antigen. The antigen-recognition molecules of B cells are immunoglobulins and are made both as a membrane-bound receptor for antigen, the B-cell receptor, and as secreted antibodies that bind antigens and elicit humoral effector functions. The antigen-recognition molecules of T cells, in contrast, are made only as cell-surface receptors and so elicit only cellular effector functions. Immunoglobulins and T-cell receptors are highly variable molecules, with the variability concentrated in that part of the molecule—the variable (V) region—that binds to antigen. Immunoglobulins bind a wide variety of chemically different antigens, whereas the major type of T-cell receptor, the αβ T-cell receptor, predominantly recognizes peptide fragments of foreign proteins bound to MHC molecules, which are ubiquitous on cell surfaces.

Binding of antigen by immunoglobulins has chiefly been studied with antibodies. The binding of antibody to its antigen is highly specific and is determined by the shape and physicochemical properties of the antigen-binding site. Located at the other end of the antibody from the antigen-binding site is the constant, or Fc, region, which influences the types of effector function the antibody can elicit. There are five main functional classes of antibodies, each encoded by a different type of constant region. As we will see in Chapter 10, these interact with different components of the immune system to incite an inflammatory response and eliminate the antigen.

T-cell receptors differ in several respects from the B-cell immunoglobulins. One is the absence of a secreted form of T-cell receptor, reflecting the functional differences between T cells and B cells. B cells deal with pathogens and their protein products circulating within the body; secretion of a soluble antigen-recognition molecule enables the B cell to act in the clearance of antigen effectively throughout the extracellular spaces of the body. T cells, in contrast, are specialized for active surveillance of pathogens, and T-cell recognition does not involve a soluble, secreted receptor. Some T cells, such as CD8 T cells, are able to detect intracellular infections and are able to kill infected cells that bear foreign antigenic peptides on their surface. Others, such as CD4 T cells, interact with cells of the immune system that have taken up foreign antigen and are displaying it on the cell surface.

T-cell receptors also recognize a composite ligand made up of the foreign peptide bound to a self MHC molecule and do not recognize intact antigen. This means T cells can interact only with a body cell displaying the antigen, not with the intact pathogen or protein. Each T-cell receptor is specific for a particular combination of peptide and a self MHC molecule. MHC molecules are encoded by a family of highly polymorphic genes. Expression of multiple variant MHC molecules, each with a different peptide-binding repertoire, helps to ensure that T cells from an individual will be able to recognize at least some peptides generated from nearly every pathogen.

Discussion Questions

4.1 When a mixture of IgG antibodies is treated with the proteolytic enzyme papain, each antibody is cleaved into three pieces. One of these pieces, the Fc fragment, was found to crystallize readily, indicating that the sequence of this fragment did not vary between individual antibody molecules, as did the Fab portion. Why is it important that the variability in amino acid sequence between different antibody molecules is restricted to the Fab portion of each antibody?

4.2 The initial antibody produced by an activated B cell is IgM. As an immune response progresses, B cells specific for the antigen can produce other antibody isotypes. What important functions are provided by antibodies of the IgG, IgA, or IgE class compared to IgM?

4.3 What advantage is conferred by antibodies that form multimers compared to those that are monomers?

4.4 Amino acid sequence variability (that is, the differences in sequence between many different antibodies) in antibody V_H and V_L domains is predominantly found in three short regions of sequence, known as CDR1, CDR2, and CDR3. Why is it important that the V_H and V_L domain sequences outside of these CDRs remain constant in all antibodies?

4.5 Unlike antibodies, T-cell antigen receptors only recognize foreign antigens that are displayed on the surface of the body's own cells. How does this mode of T-cell antigen recognition fit with the known functions of T lymphocytes? Why are T-cell receptor $\alpha\beta$ heterodimers never secreted by T cells?

4.6 MHC molecules are among the most polymorphic genes in the human population. For some human MHC genes, there are hundreds of different alleles. Where in the protein structure are most of the differences in amino acid sequence between the allelic forms? What are the consequences of these amino acid differences?

4.7 Many protein–protein interactions, such as an antibody binding to a protein antigen, are highly specific. Often, a single amino acid change in one of the proteins will abolish the binding to the second protein. In contrast, peptide binding to MHC proteins is much more promiscuous. Why is this lack of specificity an important aspect of peptide:MHC binding?

4.8 How do the CD4 and CD8 co-receptors contribute to peptide:MHC binding by T cells?

4.9 Why do MHC class I and MHC class II molecules have very different expression patterns among cells in the body? Which type of MHC molecule is more widely expressed and why?

The Generation of Lymphocyte Antigen Receptors

5

IN THIS CHAPTER

Primary immunoglobulin gene rearrangements and expression.

T-cell receptor gene rearrangement.

Evolution of the adaptive immune response.

A lymphocyte expresses many exact copies of a single antigen receptor that has a unique antigen-binding site (see Section 1-12). The clonal expression of antigen receptors means that each lymphocyte is unique among the billions of lymphocytes that each person possesses. Chapter 4 described the structural features of immunoglobulins and T-cell receptors, the antigen receptors on B cells and T cells, respectively. We saw that the vast repertoire of antigen receptors results from variations in the amino acid sequence at the antigen-binding site, which is composed of the two **variable regions** from the two chains of the receptor. In immunoglobulins these are the **heavy-chain variable region (V_H)** and the **light-chain variable region (V_L)**, and in T-cell receptors they are the V_α and V_β regions. The immunoglobulin domains of these regions contain three loops that comprise three **hypervariable regions**, or **complementarity-determining regions (CDRs)** (see Section 4-9), that determine the receptor's antigen binding site and allow for seemingly limitless diversity in specificity.

In the 1960s and 1970s, immunologists recognized that the limited size of the genome (at roughly 3 billion nucleotides) meant that the genome could not directly encode a sufficient number of genes to account for the observed diversity of antigen receptors. For example, encoding each distinct antibody by its own gene could easily fill the genome with nothing but antibody genes. As we will see, variable regions of the receptor chains are not directly encoded as a complete immunoglobulin domain by a single DNA segment. Instead, the variable regions are encoded by **gene segments** that each encode only a part of the immunoglobulin domain. During the development of each lymphocyte, these gene segments are rearranged by a process of **somatic DNA recombination** to form a complete and unique variable-region coding sequence. This process is known generally as **gene rearrangement**. A fully assembled variable region sequence is produced by combining two or three types of gene segments, each of which is present in multiple copies in the germline genome. The final diversity of the receptor repertoire is the result of assembling complete antigen receptors from the many different gene segments of each type during the development of each individual lymphocyte. This process gives each new lymphocyte only one of many possible combinations of antigen receptors, providing the repertoire of diverse antigen specificities of naive B cells and T cells.

The first part of this chapter describes the gene rearrangements that generate the primary repertoire of immunoglobulins. This part includes a brief explanation of the molecular mechanism that allows activated B cells to transition from production of transmembrane immunoglobulins to become plasma cells, which secrete their immunoglobulin proteins; the secreted form of an immunoglobulin is called an antibody. The second part of this chapter describes the gene rearrangements that generate the repertoire of T-cell receptors. Unlike immunoglobulins, T-cell receptors exist only as transmembrane receptors and are never secreted. The last part of this chapter briefly examines alternative evolutionary forms of gene rearrangements that give rise to different forms of adaptive immunity in other species.

Primary immunoglobulin gene rearrangements and expression.

Virtually any substance can be the target of an antibody response, and the response to even a single epitope comprises many different antibody molecules, each with a subtly different specificity for the epitope and a unique **affinity**, or binding strength. The total number of antibody specificities available to an individual is known as the **antibody repertoire** or **immunoglobulin repertoire**, and in humans the repertoire is at least 10^{11} and probably several orders of magnitude greater. However, the number of antibody specificities present at any one time is limited by the total number of B cells in an individual, as well as by each individual's previous encounters with antigens.

Before it was possible to examine the immunoglobulin genes directly, there were two main hypotheses for the origin of this diversity. The **germline theory** held that there is a separate gene for each different immunoglobulin chain and that the antibody repertoire is largely inherited. In contrast, **somatic diversification theories** proposed that the observed repertoire is generated from a limited number of inherited V-region sequences that undergo alteration within B cells during the individual's lifetime. Cloning of the immunoglobulin genes revealed that elements of both theories were correct and that the DNA sequence encoding each variable region is generated by rearrangements of a relatively small group of inherited gene segments. Diversity is further enhanced by the process of **somatic hypermutation** in mature activated B cells. Thus, somatic diversification theory was essentially correct, although the germline theory concept of the existence of multiple germline genes also proved true.

5-1 Complete immunoglobulin genes are generated by the somatic recombination of separate gene segments.

Figure 5.1 shows the relationships between a light-chain variable region's antigen-binding site, its domain structure, and the gene that encodes it. The variable regions of immunoglobulin heavy and light chains are based on the **immunoglobulin fold**, which is composed of nine β strands, forming two β sheets held together by a disulfide bond. The antibody-binding site is formed by three loops of amino acids known as hypervariable regions HV1, HV2, and HV3, or CDR1, CDR2, and CDR3 (see Fig. 5.1a). These loops are located between the pairs of β strands B and C, C′ and C″, and F and G (see Fig. 5.1b). In a mature B cell, the variable region for either a heavy or a light chain is encoded by a single exon; within a given heavy- or light-chain variable-region exon, the sequences encoding each of the three CDRs are not contiguous sequences, but are separated from one another within the exon (see Fig. 5.1c). This exon is the gene's second exon (exon 2). The first exon of the variable regions encodes the antibody's leader sequence, which directs the antibody into the endoplasmic reticulum for surface expression or secretion.

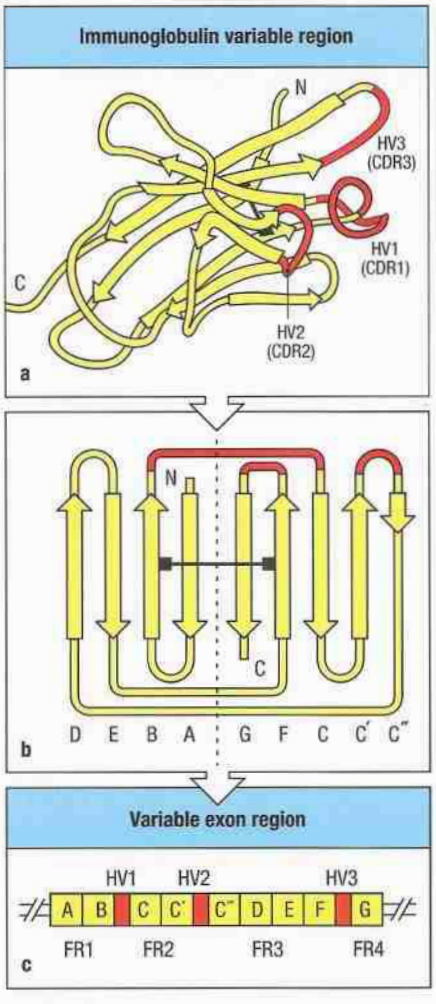

Fig. 5.1 Three hypervariable regions are encoded within a single V-region exon. Panel a: The variable region is based on the immunoglobulin (Ig) fold that is supported by framework regions (yellow) composed of nine β strands and contains three hypervariable (HV) regions (red) that determine its antigen specificity. Panel b: The three HV regions exist as loops of amino acids on the same face between the β strands of B and C, between C′ and C″, and between F and G. The dotted line separates the β strands forming each of the two β sheets composing the Ig fold. The black bar indicates the disulfide bond holding the two β sheets together. Panel c: A complete variable region in a lymphocyte is encoded within a single exon of the full antigen-receptor gene. The three HV regions are interspersed between four framework regions (FRs) made up of the β strands of the Ig domain and the loops on the face opposite of the CDRs.

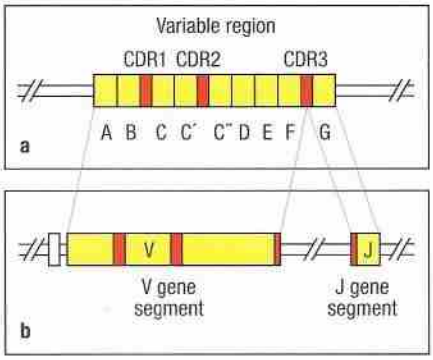

Fig. 5.2 The CDR3 region originates from two or more individual gene segments that are joined during lymphocyte development. Panel a: A complete light-chain variable region encoding the CDR1, CDR2, and CDR3 loops resides in a single exon. Panel b: The complete variable region is derived from distinct germline DNA sequences. A V gene segment encodes the CDR1 and CDR2 loops, and the CDR3 loop is formed by sequences from the end of the V gene segment and the beginning of the J gene segment, and by nucleotides added or lost when these gene segments are joined during lymphocyte development. The coding region of the CDR3 loop of the heavy chain is formed by the joining of sequences from V, D, and J gene segments and additional nucleotides added at random (not shown).

Unlike most genes, the complete DNA sequence of the variable-region exon is not present in the germline of the individual, but is originally encoded by separate DNA segments, as illustrated in Fig. 5.2. The rearrangements that produce the complete immunoglobulin light-chain and heavy-chain genes are shown in Fig. 5.3. For the light chain, the joining of a **variable or V gene**

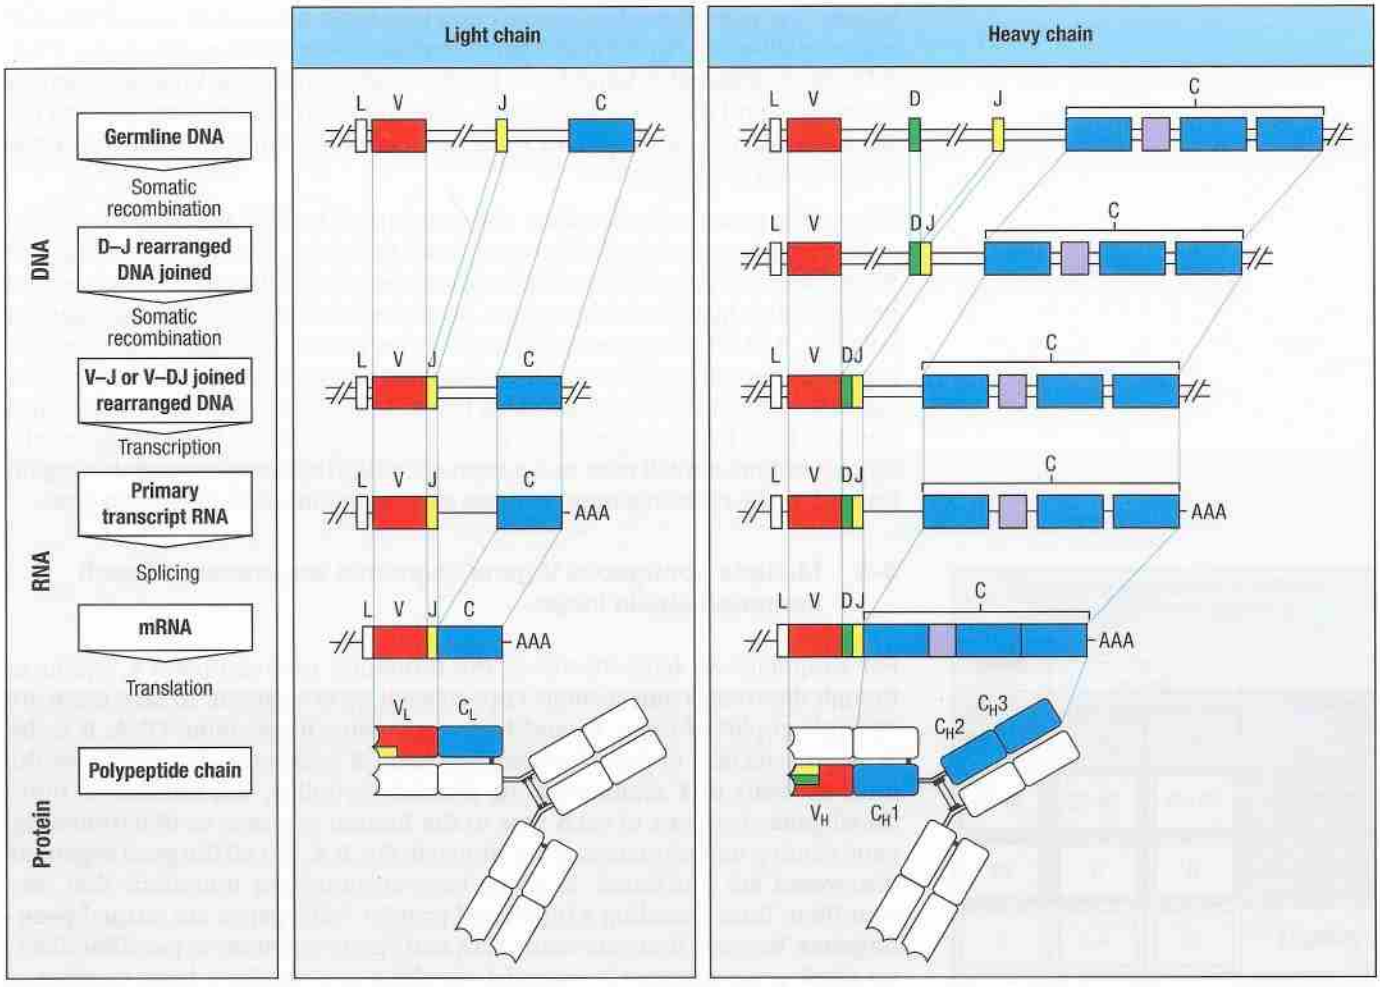

Fig. 5.3 V regions are constructed from gene segments. Light-chain V regions are constructed from two segments (center panel). A variable (V) and a joining (J) gene segment in the genomic DNA are joined to form a complete light-chain V-region exon. Immunoglobulin chains are extracellular proteins, and the V gene segment is preceded by an exon encoding a leader peptide (L), which directs the protein into the cell's secretory pathways and is then cleaved. The light-chain C region is encoded in a separate exon and is joined to the V-region exon by splicing of the light-chain RNA to remove the L-to-V and the J-to-C introns. Heavy-chain V regions are constructed from three gene segments (right panel). First, the diversity (D) and J gene segments join, and then the V gene segment joins to the combined DJ sequence, forming a complete V_H exon. A heavy-chain C region is encoded by several exons. The C-region exons, together with the leader sequence, are spliced to the V-domain sequence during processing of the heavy-chain RNA transcript. The leader sequence is removed after translation, and the disulfide bonds that link the polypeptide chains are formed. The hinge region is shown in purple. Only one V, one D, and one J segment is shown for each locus for simplicity; there are actually multiple gene segments of each type in the genome.

segment (denoted V_L for light-chain variable gene segment) and a **joining or J gene segment** (J_L in the case of the light chain) creates an exon that encodes the whole light-chain V_L region. In the unrearranged DNA, the V_L gene segments are located relatively far away from the exons encoding the constant region of the light chain (C_L region). The J_L gene segments are located close to the C_L region, however, and the joining of a V_L gene segment to a J_L gene segment also brings the V_L gene segment close to a C_L-region sequence. The J_L gene segment of the rearranged V_L region is separated from a C_L-region sequence only by a short intron. To make a complete immunoglobulin light-chain messenger RNA, the V-region exon is joined to the C-region sequence by RNA splicing after transcription.

For the heavy chain, there is one additional complication. The heavy-chain V region (V_H) is encoded in three gene segments, rather than two. In addition to the V and J gene segments (denoted V_H and J_H to distinguish them from the light-chain V_L and J_L), the heavy chain uses a third gene segment called the **diversity or D_H gene segment**, which lies between the V_H and J_H gene segments. The recombination process that generates a complete heavy-chain V region is shown in Fig. 5.3 (right panel) and occurs in two separate stages. First, a D_H gene segment is joined to a J_H gene segment; then a V_H gene segment rearranges and joins to DJ_H to make a complete V_H-region exon. As with the light-chain genes, RNA splicing joins the assembled V-region sequence to the neighboring C-region gene.

When this process is complete, the rearranged heavy- and light-chain loci each contain an exon (exon 2) that encodes the entire variable region. The first 95–101 amino acids of the variable region, encoding β strands A–F and the first two complete hypervariable regions, originate from the V_H or V_L gene segment (see Fig. 5.2). This segment also contributes part of the third hypervariable region. Other parts of the third hypervariable region, and the remainder of the variable region including β strand G (up to 13 amino acids), originate from D and J, or from J, gene segments in the heavy- or light-chain locus, respectively. By convention, we will refer to the exon encoding the complete variable region formed by the rearrangement of these gene segments as the **V-region gene**.

Number of functional gene segments in human immunoglobulin loci

Segment	Light chains		Heavy chain
	κ	λ	H
Variable (V)	31–35	29–32	38–46
Diversity (D)	0	0	23
Joining (J)	5	4–5	6
Constant (C)	1	4–5	9

Fig. 5.4 The number of functional gene segments for the human heavy- and light-chain genes. The numbers shown are derived from exhaustive cloning and sequencing of DNA from one individual and exclude all pseudogenes (mutated and nonfunctional versions of a gene sequence). As a result of genetic polymorphism, the numbers vary for different people.

5-2 Multiple contiguous V gene segments are present at each immunoglobulin locus.

For simplicity we have discussed the formation of a complete V region as though there were only a single copy of each gene segment. In fact, there are multiple copies of the V, D, and J gene segments in germline DNA. It is the random selection of just one gene segment of each type that produces the great diversity of V regions among immunoglobulins. The number of functional gene segments of each type in the human genome, as determined by gene cloning and sequencing, are shown in Fig. 5.4. Not all the gene segments discovered are functional, as some have accumulated mutations that prevent them from encoding a functional protein. Such genes are termed **pseudogenes**. Because there are many V, D, and J gene segments in germline DNA, no single gene segment is essential, resulting in a relatively large number of pseudogenes. Because some of these can undergo rearrangement just like a functional gene segment, a significant proportion of rearrangements incorporate a pseudogene and thus will be nonfunctional.

We saw in Section 4-1 that there are three sets of immunoglobulin chains—the heavy chain and two equivalent types of light chains, the **κ and λ chains**. The immunoglobulin gene segments that encode these chains are organized into three clusters or **genetic loci**—the κ, λ, and heavy-chain loci—each of which can assemble a complete V-region sequence. Each locus is on a different chromosome and is organized differently, as shown for the human loci in Fig. 5.5. At the λ light-chain locus, located on human chromosome 22, a cluster of Vλ

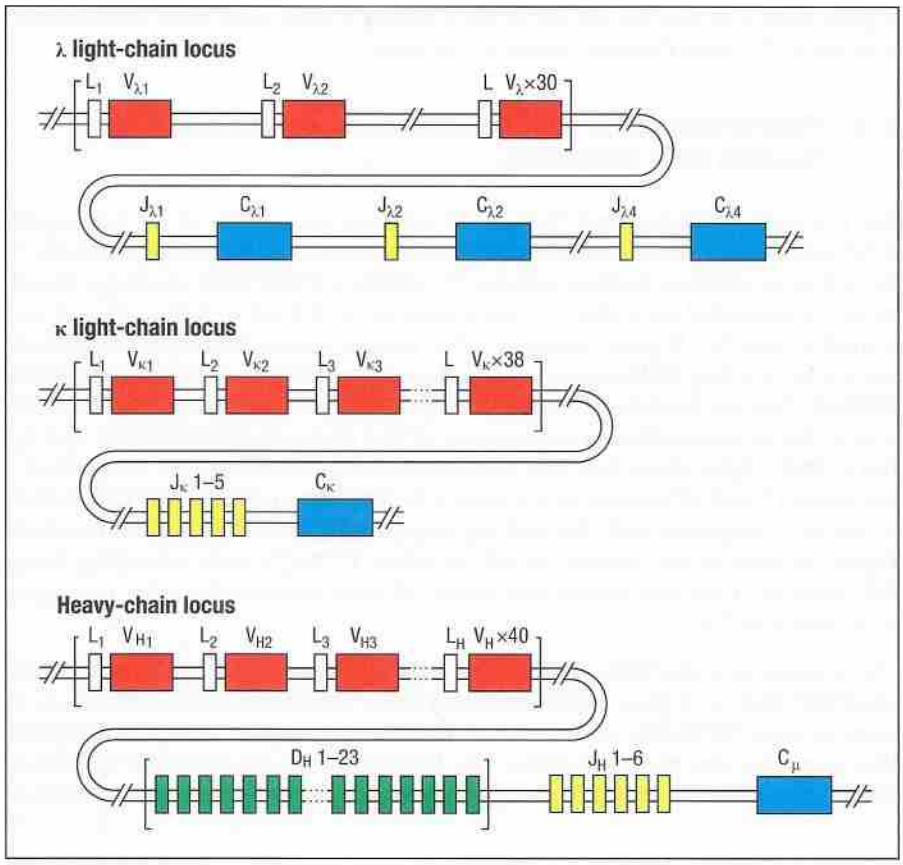

Fig. 5.5 The germline organization of the human immunoglobulin heavy- and light-chain loci. Depending on the individual, the genetic locus for the λ light chain (chromosome 22) has between 29 and 33 functional V_λ gene segments and four or five pairs of functional J_λ gene segments and C_λ genes. The κ locus (chromosome 2) is organized in a similar way, with about 49 functional Vκ gene segments accompanied by a cluster of 5 Jκ gene segments but with a single Cκ gene. In approximately 50% of individuals, the entire cluster of Vκ gene segments has undergone an increase by duplication (not shown, for simplicity). The heavy-chain locus (chromosome 14) has about 40 functional V_H gene segments and a cluster of around 23 D_H segments lying between these V_H gene segments and 6 J_H gene segments. The heavy-chain locus also contains a large cluster of C_H genes (see Fig. 4.6). For simplicity, all V gene segments have been shown in the same chromosomal orientation; only the first C_H gene (for C_μ) is shown, without illustrating its separate exons; and all pseudogenes have been omitted. This diagram is not to scale: the total length of the heavy-chain locus is more than 2 megabases (2 million bases), whereas some of the D gene segments are only 6 bases long.

gene segments is followed by four (or in some individuals five) sets of Jλ gene segments each linked to a single Cλ gene. In the κ light-chain locus, on chromosome 2, the cluster of Vκ gene segments is followed by a cluster of Jκ gene segments, and then by a single Cκ gene.

The organization of the heavy-chain locus, on chromosome 14, contains separate clusters of V_H, D_H, and J_H gene segments and of C_H genes. The heavy-chain locus differs in one important way: instead of a single C region, it contains a series of C regions arrayed one after the other, each of which corresponds to a different immunoglobulin isotype (see Fig. 4.6). While the Cλ locus contains several distinct C regions, these encode similar proteins, which function similarly, whereas the different heavy-chain isotypes are structurally quite distinct and have different functions, as outlined in Section 4-7.

B cells initially express the heavy-chain isotypes μ and δ, which is accomplished by alternative mRNA splicing and which leads to the expression of immunoglobulins IgM and IgD, as we shall see in Section 5-8. The expression of other isotypes, such as γ (giving IgG), occurs through DNA rearrangements referred to as **class switching** and takes place at a later stage, after a B cell has been activated by antigen in an immune response. We describe class switching in Chapter 10.

The human V gene segments can be grouped into families in which each member shares at least 80% DNA sequence identity with all others in the family. Both the heavy-chain and the κ-chain V gene segments can be subdivided into seven families, and there are eight families of V_λ gene segments. The families can be grouped into clans, made up of families that are more similar to each other than to families in other clans. Human V_H gene segments fall into three clans. All the V_H gene segments identified from amphibians, reptiles, and mammals also fall into the same three clans, suggesting that these clans existed in a common ancestor of these modern animal groups. Thus, the

V gene segments that we see today have arisen by a series of gene duplications and diversification through evolutionary time.

5-3 Rearrangement of V, D, and J gene segments is guided by flanking DNA sequences.

For a complete immunoglobulin or T-cell receptor chain to be expressed, DNA rearrangements must take place at the correct locations relative to the V, D, or J gene segment coding regions. In addition, these DNA rearrangements must be regulated such that a V gene segment is joined to a D or a J and not joined to another V gene segment. DNA rearrangements are guided by conserved noncoding DNA sequences, called **recombination signal sequences (RSSs)**, that are found adjacent to the points at which recombination takes place. The structure and arrangements of the RSSs are shown in Fig. 5.6 for the λ and κ light-chain loci and the heavy-chain locus. An RSS consists of a conserved block of seven nucleotides—the **heptamer** 5′CACAGTG3′, which is always contiguous with the coding sequence; followed by a nonconserved region known as the **spacer**, which is either 12 or 23 base pairs (bp) long; followed by a second conserved block of nine nucleotides, the **nonamer** 5′ACAAAAACC3′.

The sequences given here are the consensus sequences, but they can vary substantially from one gene segment to another, even in the same individual, as there is some flexibility in the recognition of these sequences by the enzymes that carry out the recombination. The heptamer-spacer-nonamer sequence motif—the RSS—is always found directly adjacent to the coding sequence of

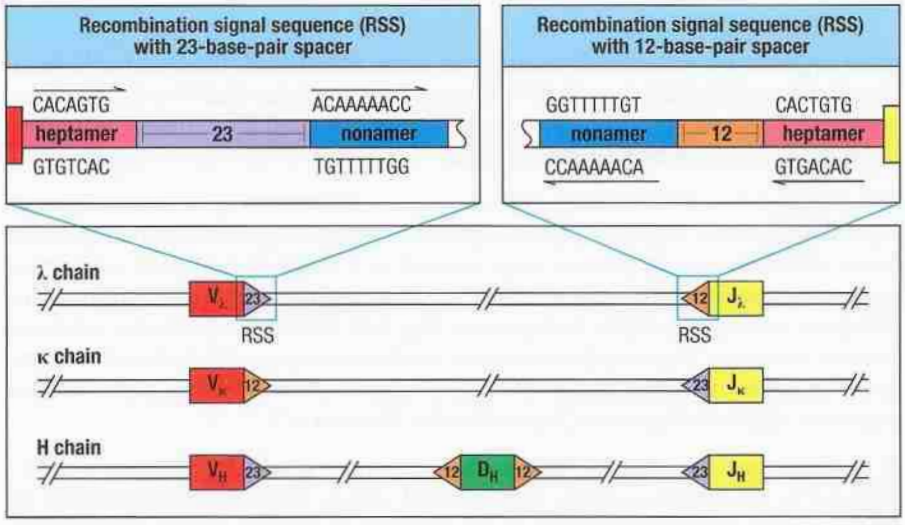

Fig. 5.6 Recombination signal sequences (RSSs) are conserved heptamer and nonamer sequences that flank the gene segments encoding the V, D, and J gene segments of immunoglobulins. Recombination signal sequences (RSSs) are composed of heptamer (CACAGTG) and nonamer (ACAAAAACC) sequences that are separated by either 12 bp or approximately 23 bp of nucleotides. The heptamer–12-bp spacer–nonamer motif is depicted here as an orange arrowhead; the motif that includes the 23-bp spacer is depicted as a purple arrowhead. Heptamers are found directly adjacent to the 3′ end of V segments, the 5′ end of J segments, and on both sides of D segments. Joining of gene segments almost always involves a 12-bp RSS and a 23-bp RSS—the 12/23 rule. The arrangement of RSSs in the V (red), D (green), and J (yellow) gene segments of heavy (H) and light (λ and κ) chains of immunoglobulin is shown here. The RAG-1 recombinase (see Section 5-4) cuts the DNA precisely between the last nucleotide of the V gene segment and the first C of the heptamer or between the last G of the heptamer and the first nucleotide of the D or J gene segment. Note that according to the 12/23 rule, the arrangement of RSSs in the immunoglobulin heavy-chain gene segments precludes direct V-to-J joining.

V, D, or J gene segments. Recombination normally occurs between gene segments located on the same chromosome. A gene segment flanked by an RSS with a 12-bp spacer typically can be joined only to one flanked by a 23-bp spacer RSS. This principle is known as the **12/23 rule**.

It is important to recognize that the pattern of 12- and 23-bp spacers used by the various gene segments is different between the λ, κ, and heavy-chain loci (see Fig. 5.6). Thus, for the heavy chain, a D_H gene segment can be joined to a J_H gene segment and a V_H gene segment to a D_H gene segment, but V_H gene segments cannot be joined to J_H gene segments directly, as both V_H and J_H gene segments are flanked by 23-bp spacers. However, they can be joined with a D_H gene segment between them, as D_H segments have 12-bp spacers on both sides (see Fig. 5.6).

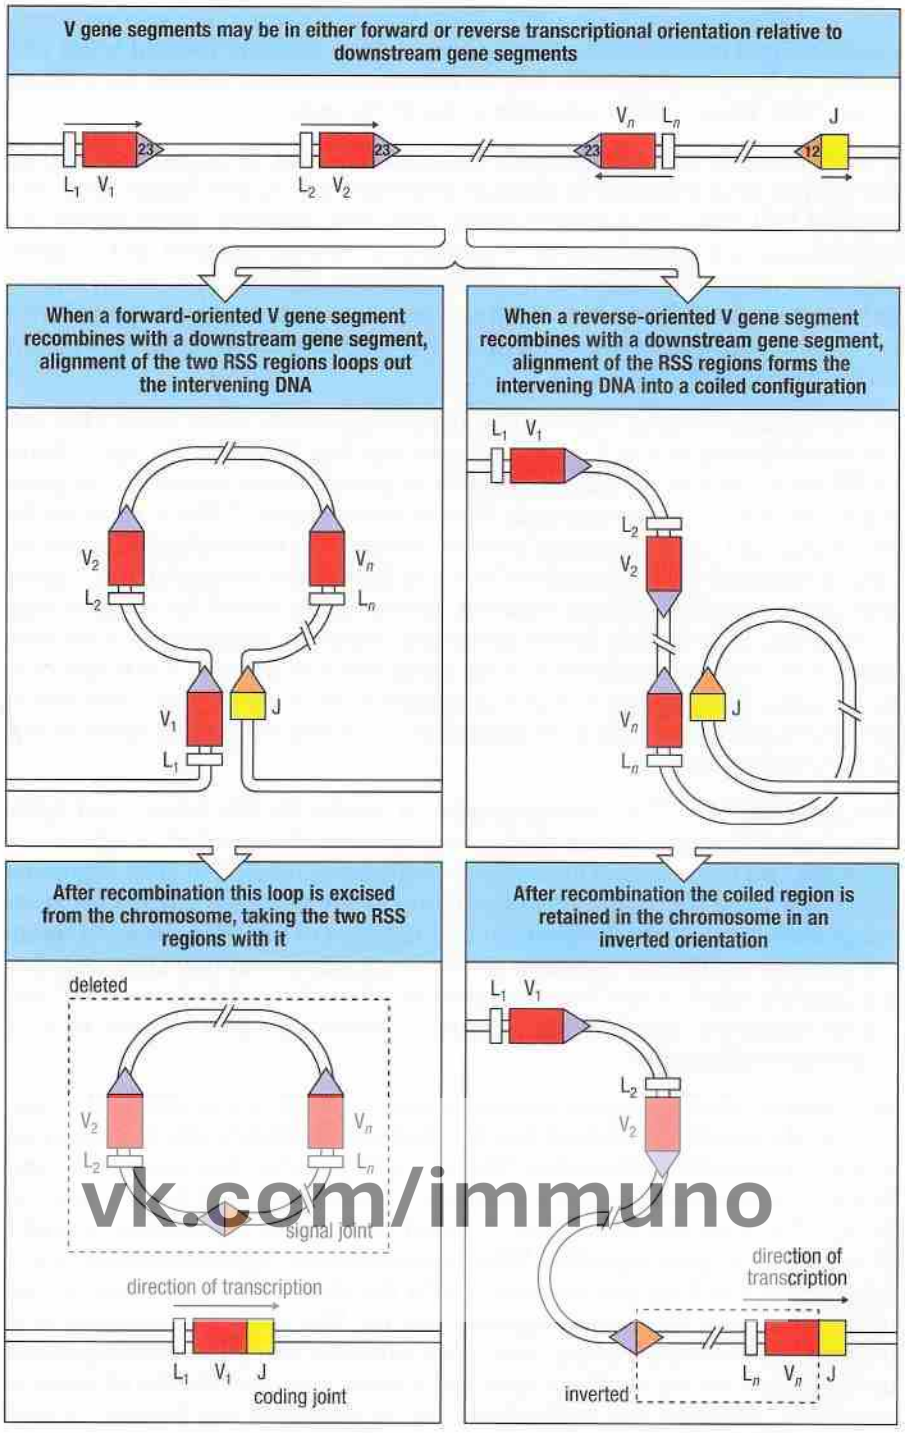
In the antigen-binding region of an immunoglobulin, CDR1 and CDR2 are encoded directly in the V gene segment (see Fig. 5.2). For the light chain, CDR3 is encoded by the additional DNA sequence that is created by the joining of the V and J gene segments; for the heavy chain, CDR3 is encoded by the V, D, and J gene segments. Further diversity in the antibody repertoire can be supplied by CDR3 regions that result from the joining of one D gene segment to another D gene segment, before being joined by a J gene segment. Such D–D joining is infrequent and seems to violate the 12/23 rule, suggesting that such violations of the 12/23 rule can occur at low frequency. In humans, D–D joining is found in approximately 5% of antibodies and is the major mechanism accounting for the unusually long CDR3 loops found in some heavy chains.

The mechanism of DNA rearrangement is similar for the heavy- and light-chain loci, although only one joining event is needed to generate a light-chain gene but two are required for a heavy-chain gene. When two gene segments are in the same transcriptional orientation in the germline DNA, their rearrangement involves the looping out and deletion of the DNA between them. This looped out DNA is a circular piece of **extrachromosomal DNA** (Fig. 5.7, left panels), which is lost from the genome when the cell divides. The V and J gene segments, which remain on the chromosome, join to form what is called the **coding joint**.

By contrast, when the gene segments have opposite transcriptional orientations, the rearrangement retains the intervening DNA in the chromosome but with an inverted orientation (Fig. 5.7, right panels). This mode of recombination is less common, but it accounts for about half of all Vκ to Jκ joins in humans because the orientation of half of the Vκ gene segments is opposite to that of the Jκ gene segments. After recombination of gene segments in this orientation, the RSSs are retained within the chromosome, and the region of DNA between the V gene segment and the RSS of the J gene segment is inverted to form the coding joint. This situation leads to **rearrangement by inversion**. As we shall see later, the coding joint junction in all cases is imprecise, meaning that nucleotides can be added or lost between joined segments during the rearrangement process. This imprecise nature of coding joint formation adds to the variability in the V-region sequence, called **junctional diversity**.

ANIMATION 5.1

The overall enzymatic mechanisms involved in V-region rearrangement, or **V(D)J recombination**, are illustrated in Fig. 5.8. Two RSSs are brought together by interactions between proteins that specifically recognize the length of the spacers and thus enforce the 12/23 rule for recombination. The DNA molecule is then precisely cleaved by endonuclease activity at two locations and is then rejoined in a different configuration. The ends of the heptamer sequences are joined in a head-to-head fashion to form a **signal joint**. In the majority of cases, no nucleotides are lost or added between the two heptamer sequences, creating a double-heptamer sequence 5′CACAGTGCACAGTG3′ within the DNA molecule.



V gene segments may be in either forward or reverse transcriptional orientation relative to downstream gene segments

Fig. 5.7 V gene segments are joined by recombination. Top panel: In every V-region recombination event, the recombination signal sequences (RSSs) flanking the gene segments are brought together to allow recombination to take place. The 12-bp-spaced RSSs are shown in orange, the 23-bp-spaced RSSs in purple. For simplicity, the recombination of a light-chain gene is illustrated; for a heavy-chain gene, two separate recombination events are required to generate a functional V region. Left panels: In most cases, the two segments undergoing rearrangement (the V and J gene segments in this example) are arranged in the same transcriptional orientation in the chromosome, and juxtaposition of the RSSs results in the looping out of the intervening DNA. Recombination occurs at the ends of the heptamer sequences in the RSSs, creating the so-called signal joint and releasing the intervening DNA in the form of a closed circle. Subsequently, the joining of the V and J gene segments creates the coding joint in the chromosomal DNA. Right panels: In other cases, the V and J gene segments are initially oriented in opposite transcriptional directions. In this case, alignment of the RSSs requires the coiled configuration shown, rather than a simple loop, so that joining the ends of the two heptamer sequences now results in the inversion and integration of the intervening DNA into a new position on the chromosome. Again, the joining of the V and J segments creates a functional V-region exon.

5-4 The reaction that recombines V, D, and J gene segments involves both lymphocyte-specific and ubiquitous DNA-modifying enzymes.

The complex of enzymes that act in concert to carry out somatic V(D)J recombination is termed the **V(D)J recombinase**. The lymphoid-specific components of the recombinase are called **RAG-1** and **RAG-2**, and they are encoded by two recombination-activating genes, *RAG1* and *RAG2*. This pair of genes is essential for V(D)J recombination, and they are expressed in developing lymphocytes only while the lymphocytes are engaged in assembling their antigen receptors, as described in more detail in Chapter 8. Indeed, the RAG genes

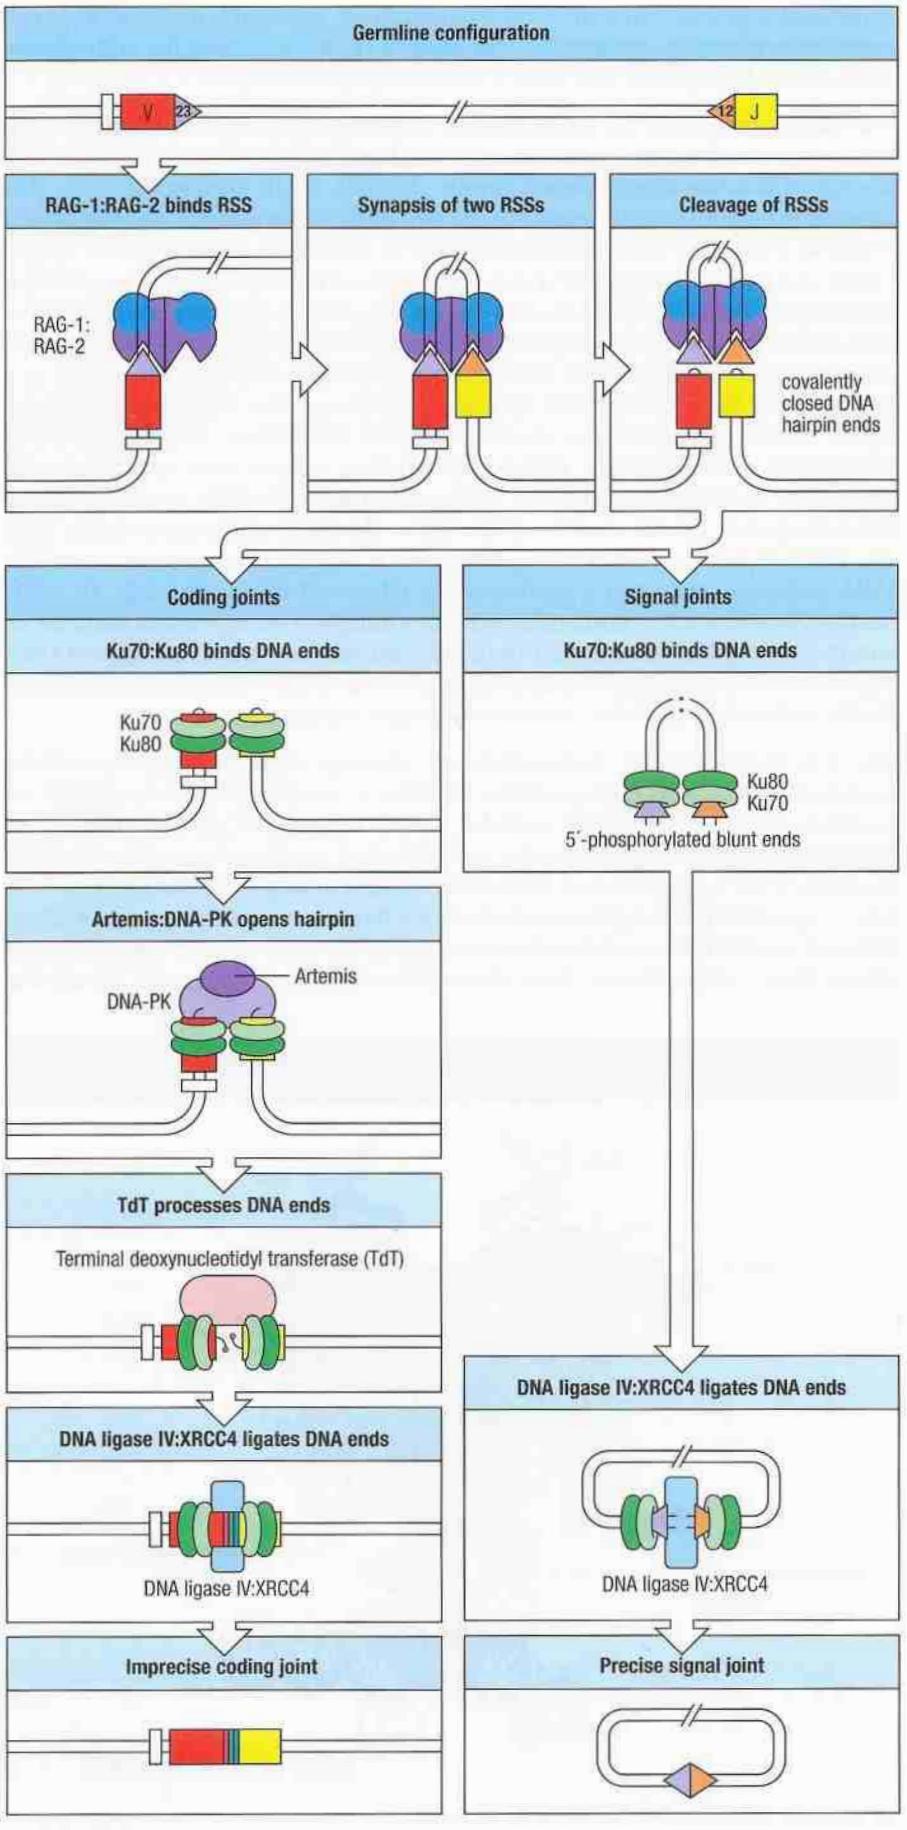

Fig. 5.8 Enzymatic steps in RAG-dependent V(D)J rearrangement. Recombination of gene segments containing recombination signal sequences (RSSs; triangles) begins with the binding of a complex of RAG-1 (purple), RAG-2 (blue), and high-mobility group (HMG) proteins (not shown) to one of the RSSs flanking the coding sequences to be joined (second row). The RAG complex then recruits the other RSS. In the cleavage step, the endonuclease activity of RAG makes single-strand cuts in the DNA backbone precisely between each coding segment and its RSS. At each cutting point this creates a 3′-OH group, which then reacts with a phosphodiester bond on the opposite DNA strand to generate a hairpin (see Fig. 5.11 for details), leaving a blunt double-strand break at the end of the RSS. These two types of DNA ends (hairpin and blunt) are resolved in different ways. At the coding ends (left panels), essential repair proteins such as Ku70:Ku80 (green) bind to the hairpin. Ku70:Ku80 forms a ring structure encircling the DNA. The Artemis:DNA-PK complex (purple) then joins the complex, and its endonuclease activity opens the DNA hairpin. The cut end is then modified by terminal deoxynucleotidyl transferase (TdT; pink) and the nuclease action of the Artemis:DNA-PK complex, which randomly add and remove nucleotides, respectively (this step is shown in more detail in Fig. 5.11). The two coding ends are finally ligated by DNA ligase IV in association with XRCC4 (turquoise). At the signal ends (right panels), Ku70:Ku80 binds to the RSS but the ends are not further modified. Instead, a complex of DNA ligase IV:XRCC4 joins the two ends to form the signal joint.

expressed together can confer on nonlymphoid cells such as fibroblasts the capacity to rearrange exogenous segments of DNA containing the appropriate RSSs; this is how RAG-1 and RAG-2 were initially discovered.

The other proteins in the recombinase complex are members of the ubiquitously expressed **nonhomologous end joining (NHEJ)** pathway of DNA repair known as **double-strand break repair (DSBR)**. In all noncycling cells, this process is responsible for rejoining the two ends at the site of a double-strand break in DNA. The DSBR joining process is imprecise, meaning that nucleotides are frequently gained or lost at the site of joining. In lymphocytes the imprecise nature of DSBR is critical for junctional diversity and adaptive immunity. Thus, this may be the driving pressure for NHEJ to mediate imprecise joining. One ubiquitous protein contributing to DSBR is **Ku**, which is a heterodimer (Ku70:Ku80); this forms a ring around the DNA and associates tightly with a protein kinase catalytic subunit, DNA-PKcs, to form the **DNA-dependent protein kinase (DNA-PK)**. Another protein that associates with DNA-PKcs is **Artemis**, which has nuclease activity. The DNA ends are finally joined together by the enzyme **DNA ligase IV**, which forms a complex with the DNA repair protein **XRCC4**, along with additional accessory proteins. DNA polymerases μ and λ participate in DNA-end fill-in synthesis. In addition, polymerase μ can add nucleotides in a template-independent manner. In summary, lymphocytes have co-opted several enzymes used in common DNA repair pathways to help complete the process of somatic V(D)J recombination that is initiated by the RAG-1 and RAG-2 V(D)J recombinases.

The first reaction is an endonucleolytic cleavage that requires the coordinated activity of both RAG proteins. Initially, a complex of RAG-1 and RAG-2 proteins, together with high-mobility group chromatin protein HMGB1 or HMGB2, recognizes and aligns the two RSSs that are the target of the cleavage reaction. RAG-1 operates as a dimer, with RAG-2 acting as a cofactor (Fig. 5.9). RAG-1 specifically recognizes and binds the heptamer and the nonamer of the RSS and contains the endonuclease activity of the RAG protein complex. As a dimer, RAG-1 aligns the two RSSs that will undergo rearrangement. Structural

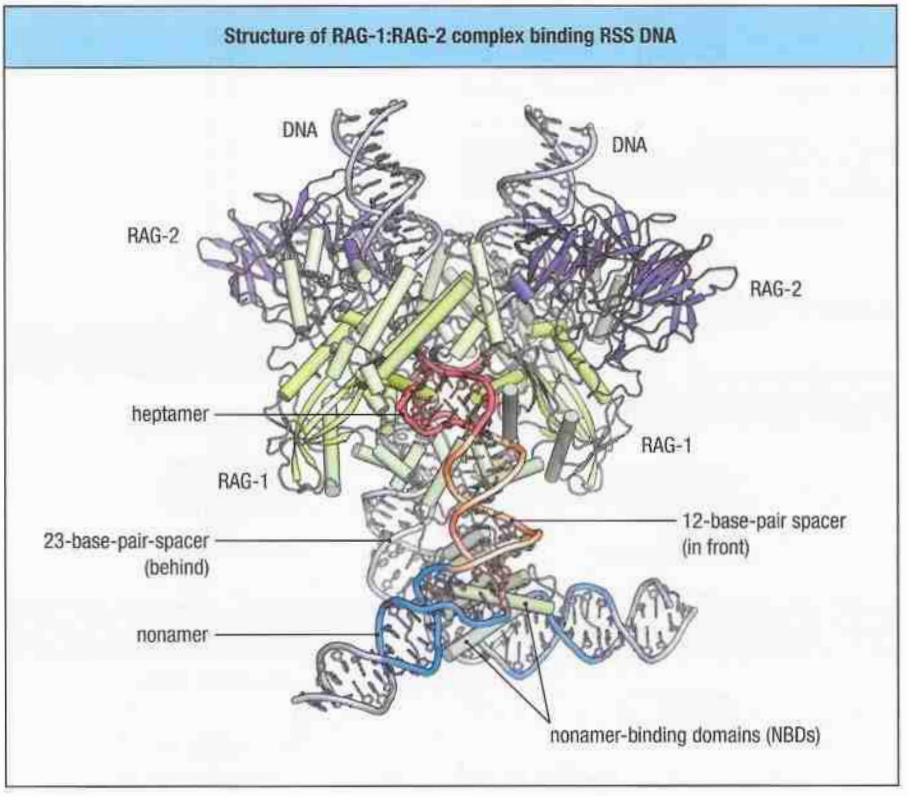

Fig. 5.9 RAG-1 and RAG-2 form a heterotetramer capable of binding to two RSSs. Shown as ribbon diagrams, the RAG-1:RAG-2 complex contains two RAG-1 (light green) and two RAG-2 (purple) proteins. The heterotetramer of RAG-1 and RAG-2 is synapsed with a pair of RSS elements. The heptamers of each RSS are shown in red, and the nonamers are in blue. The 12-bp spacer of one RSS (orange) is in front, and the 23-bp spacer of the second RSS (gray) is in back. This asymmetry in the spacer lengths creates a bend in the orientation of the nonamer-binding domains (NBDs) of each RAG-1 monomer relative to the rest of the structure.

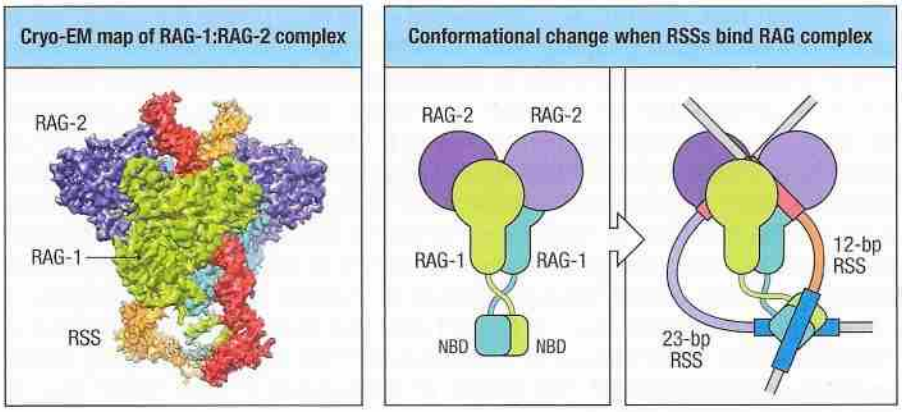

Fig. 5.10 The 12/23 base pair rule may result from asymmetric binding of RSSs to the RAG-1:RAG-2 dimer. Left panel: A space-filling model of the RAG-1:RAG-2 heterotetramer synapsed with a pair of 12-RSS and 23-RSS sequences that is based on the cryo-electron microscopy (cryo-EM) structure. One RAG-1 is shown in green, the second in blue. Both molecules of RAG-2 are in purple. The 12-RSS and 23-RSS are shown as red and orange, respectively. Middle panel: prior to RSS binding, the RAG-1:RAG-2 heterotetramer has a symmetrical structure. Right panel: Upon RSS engagement, the nonamer-binding domain (NBD) dimer tilts toward the 12-RSS and away from the 23-RSS because of induced asymmetry. In this image, the heptamers of each RSS are shown in red, and the nonamers in dark blue.

data show that the 12/23 rule is established because an essential asymmetric orientation of the RAG-1:RAG-2 complex induces a preference for binding to RSS elements of different types (Fig. 5.10). The bound RAG complex makes a single-strand DNA break at the nucleotide just 5′ of the heptamer of the RSS, thus creating a free 3′-OH group at the end of the coding segment. This nucleophilic 3′-OH group then attacks the phosphodiester bond on the opposite DNA strand, making a double-strand break and creating a DNA 'hairpin' at the coding region and a flush double-strand break at the end of the heptamer sequence. This cutting process occurs twice, once for each gene segment being joined, producing four ends: two hairpin ends at the coding regions and two flush ends at both heptamer sequences (see Fig. 5.8). These DNA ends do not float apart, however, but are held tightly in the complex until the joining step has been completed. The blunt ends of the heptamer sequence are precisely joined to form the signal joint.

Formation of the coding joint is more complex. The two coding hairpin ends are each bound by Ku, which recruits the DNA-PKcs subunit. Artemis is recruited into this complex and is phosphorylated by DNA-PK. Artemis then opens the DNA hairpins by making a single-strand nick in the DNA. This nicking can happen at various points along the hairpin, which leads to sequence variability in the final joint. The DNA repair enzymes in the complex modify the opened hairpins by removing nucleotides, while at the same time the lymphoid-specific enzyme **terminal deoxynucleotidyl transferase (TdT)**, which is also part of the recombinase complex, adds nucleotides randomly to the single-strand ends. Addition and deletion of nucleotides can occur in any order, and one does not necessarily precede the other. Finally, DNA ligase IV joins the processed ends together, thus reconstituting a chromosome that includes the rearranged gene. This repair process creates diversity in the joint between gene segments while ensuring that the RSS ends are ligated without modification and that unintended genetic damage such as a chromosome break is avoided. Despite the use of some ubiquitous mechanisms of DNA repair, adaptive immunity based on the RAG-mediated generation of antigen receptors by somatic recombination seems to be unique to the jawed vertebrates, and its evolution is discussed in the last part of this chapter.

The *in vivo* roles of the enzymes involved in V(D)J recombination have been established through both natural and artificially induced mutations. Mice lacking TdT have about 10% of the normal level of non-templated nucleotides added to the joints between gene segments. This small remainder may result from the template-independent activity of DNA polymerase μ.

Mice in which one of the RAG genes has been inactivated or which lack DNA-PKcs, Ku, or Artemis suffer a complete block in lymphocyte development at the gene-rearrangement stage or make only trivial numbers of B and T cells. They are said to suffer from **severe combined immune deficiency (SCID)**.

Omenn Syndrome

The original ***scid*** mutation was discovered some time before the components of the recombination pathway were identified and was subsequently identified as a mutation in DNA-PKcs. In humans, mutations in *RAG1* or *RAG2* that result in partial V(D)J recombinase activity are responsible for an inherited disorder called **Omenn syndrome**, which is characterized by an absence of circulating B cells and an infiltration of skin by activated oligoclonal T lymphocytes. Mice deficient in components of ubiquitous DNA repair pathways, such as DNA-PKcs, Ku, or Artemis, are defective in double-strand break repair in general and are therefore also hypersensitive to ionizing radiation (which produces double-strand breaks). Defects in Artemis in humans produce a combined immunodeficiency of B and T cells that is associated with increased radiosensitivity. SCID caused by mutations in DNA repair pathways is called **radiation-sensitive SCID (RS-SCID)** to distinguish it from SCID due to lymphocyte-specific defects.

Ataxia Telangiectasia

Another genetic condition in which radiosensitivity is associated with some degree of immunodeficiency is **ataxia telangiectasia**, which is due to mutations in the protein kinase **ATM** (ataxia telangiectasia mutated). Ataxia telangiectasia is associated with cerebellar degeneration, increased radiation sensitivity, and cancer risk. ATM is a serine/threonine kinase, like DNA-PKcs, and functions during V(D)J recombination to promote stabilization of the cleaved DNA ends in the RAG complex. This function of ATM greatly reduces the probability that the free DNA ends are prematurely released from the complex and available to participate in chromosomal translocations. Consequently, individuals with ATM deficiencies have a strong predisposition to develop B-cell and T-cell malignancies characterized by chromosomal translocations involving the antigen-receptor gene loci. However, ATM is not absolutely required for V(D)J recombination, as individuals with ataxia telangiectasia show substantial variability in the severity of their immune deficiencies, with some individuals having low numbers of B and T cells and/or a deficiency in antibody class switching that is less severe than that seen in patients with SCID. Evidence that ATM and DNA-PKcs are partially redundant in their functions comes from the observation that B cells lacking both kinases show much more severely abnormal signal joining sequences compared with B cells lacking either enzyme alone.

5-5 The diversity of the immunoglobulin repertoire is generated by four main processes.

The gene rearrangements that combine gene segments to form a complete V-region exon generate diversity in two ways. First, there are multiple different copies of each type of gene segment, and different combinations of gene segments can be used in different rearrangement events. This **combinatorial diversity** is responsible for a substantial part of the diversity of V regions. Second, junctional diversity is introduced at the joints between the different gene segments as a result of the addition and subtraction of nucleotides by the recombination process. A third source of diversity is also combinatorial, arising from the many possible different combinations of heavy- and light-chain V regions that pair to form the antigen-binding site in the immunoglobulin molecule. The two means of generating combinatorial diversity alone could give rise, in theory, to approximately 3×10^6 different antibody molecules, as we will see below. Coupled with junctional diversity, it is estimated that at least 10^{11} different receptors could make up the repertoire of receptors expressed by naive B cells, and diversity could even be several orders of magnitude greater, depending on how one calculates junctional diversity. Finally, somatic hypermutation, which we describe in Chapter 10, occurs only in B cells after the initiation of an immune response and introduces point mutations into the rearranged V-region genes. This process generates further diversity in the antibody repertoire that can be selected for enhanced binding to antigen.

5-6 The multiple inherited gene segments are used in different combinations.

There are multiple copies of the V, D, and J gene segments, each of which can contribute to an immunoglobulin V region. Many different V regions can therefore be made by selecting different combinations of these segments. For human κ light chains, there are approximately 30 functional Vκ gene segments and 5 Jκ gene segments, and thus potentially 150 different combinations of complete Vκ regions. For λ light chains, there are approximately 30 functional V_λ gene segments and 4–5 J_λ gene segments, yielding at least 120 possible V_λ regions (see Fig. 5.4). So, in all, 270 different light chains can be made as a result of combining different light-chain gene segments. For the heavy chains of humans, there are approximately 40 functional V_H gene segments, 23 D_H gene segments, and 6 J_H gene segments, and thus around 5500 different possible V_H regions ($40 \times 23 \times 6 = 5520$). During B-cell development, rearrangement at the heavy-chain gene locus to produce a heavy chain is followed by several rounds of cell division before light-chain gene rearrangement takes place, resulting in the same heavy chain being paired with different light chains in different cells. Because both the heavy- and the light-chain V regions contribute to antibody specificity, each of the 270 different light chains could be combined with each of the approximately 5500 heavy chains to give around 1.5×10^6 different antibody specificities.

This theoretical estimate of combinatorial diversity is based on the number of germline V gene segments contributing to functional antibodies (see Fig. 5.4); the total number of V gene segments is larger, but the additional gene segments are pseudogenes and do not appear in expressed immunoglobulin molecules. In practice, combinatorial diversity is likely to be less than one might expect from the calculations above. One reason is that not all V gene segments are used at the same frequency; some are common in antibodies, while others are found only rarely. Factors such as chromosomal architecture, DNA accessibility, and differences in RSS sequences contribute to biases in V gene segment usage. Also, not every heavy chain can pair with every light chain: certain combinations of V_H and V_L regions will not form a stable molecule. Cells in which heavy and light chains fail to pair may undergo further light-chain gene rearrangement until a suitable chain is produced or they will be eliminated. Nevertheless, it is thought that most heavy and light chains can pair with each other, and that this type of combinatorial diversity has a major role in forming an immunoglobulin repertoire with a wide range of specificities.

5-7 Variable addition and subtraction of nucleotides at the junctions between gene segments contributes to the diversity of the third hypervariable region.

As noted earlier, of the three hypervariable loops in an immunoglobulin chain, CDR1 and CDR2 are encoded within the V gene segment. CDR3, however, falls at the joint between the V gene segment and the J gene segment, and in the heavy chain it is partly encoded by the D gene segment. In both heavy and light chains, the diversity of CDR3 is significantly increased by the addition and deletion of nucleotides at two steps in the formation of the junctions between gene segments. The added nucleotides are known as P-nucleotides and N-nucleotides, and their addition is illustrated in Fig. 5.11.

P-nucleotides are so called because they make up palindromic sequences added to the ends of the gene segments. As described in Section 5-4, the RAG proteins generate DNA hairpins at the coding ends of the V, D, or J segments, after which Artemis catalyzes a single-strand cleavage at an asymmetric site in the hairpin bubble. This generates a single-strand tail including a few nucleotides of the coding sequence plus the complementary nucleotides

Fig. 5.11 The introduction of P- and N-nucleotides diversifies the joints between gene segments during immunoglobulin gene rearrangement. The process is illustrated for a D_H to J_H rearrangement (first panel); however, the same steps occur in V_H to D_H and in V_L to J_L rearrangements. After formation of the DNA hairpins (second panel), the two heptamer sequences are ligated to form the signal joint (not shown here), while the Artemis:DNA-PK complex cleaves the DNA hairpin at a random site (indicated by the arrows) to yield a single-strand DNA end (third panel). Depending on the site of cleavage, this single-stranded DNA may contain nucleotides that were originally complementary in the double-stranded DNA and which therefore form short DNA palindromes, such as TCGA and ATAT, as indicated by the light blue–shaded box. For example, the sequence GA at the end of the D segment shown is complementary to the preceding sequence TC. Such stretches of nucleotides that originate from the complementary strand are known as P-nucleotides. Where the enzyme terminal deoxynucleotidyl transferase (TdT) is present, nucleotides are added at random to the ends of the single-strand segments (fourth panel); these non-templated, or N, nucleotides are indicated by the shaded box. The two single-strand ends then pair (fifth panel). Exonuclease trimming of unpaired nucleotides (sixth panel) and repair of the coding joint by DNA synthesis and ligation (bottom panel) leaves both P- and N-nucleotides (indicated by light blue shading) in the final coding joint. The randomness of insertion of P- and N-nucleotides makes an individual P–N region virtually unique and a valuable marker for following an individual B-cell clone as it develops, for instance in studies of somatic hypermutation.

from the other DNA strand (see Fig. 5.11). In many light-chain gene rearrangements, DNA repair enzymes then fill in complementary nucleotides on the single-strand tails, which would leave short palindromic sequences (the P-nucleotides) at the joint if the ends were rejoined without any further exonuclease activity.

In heavy-chain gene rearrangements and in a proportion of human light-chain gene rearrangements, **N-nucleotides** are added by a quite different mechanism before the ends are rejoined. N-nucleotides are so called because they are non-template-encoded. They are added by the enzyme TdT to the ends of the coding DNA after hairpin cleavage. After the addition of up to 20 nucleotides, single-strand stretches may have some complementary base pairs. Repair enzymes then trim off nonmatching nucleotides, synthesize complementary DNA to fill in the remaining single-strand gaps, and ligate the new DNA to the palindromic region (see Fig. 5.11). TdT is maximally expressed during the period in B-cell development when the heavy-chain gene is being assembled, and so N-nucleotides are common in heavy-chain V–D and D–J junctions. N-nucleotides are less common in light-chain genes, which undergo rearrangement after heavy-chain genes, when TdT expression has been shut off, as we will explain further in Chapter 8 when discussing the specific developmental stages of B and T cells.

Nucleotides can also be deleted at gene segment junctions. This is accomplished by nucleases, and although these have not yet been identified, Artemis has dual endonuclease and exonuclease activity and so could well be involved in this step. Thus, a heavy-chain CDR3 can be shorter than even the smallest D segment. In some instances it is difficult, if not impossible, to recognize the D segment that contributed to CDR3 formation because of the excision of most of its nucleotides. Deletions may also erase the traces of P-nucleotide palindromes introduced at the time of hairpin opening. For this reason, many completed VDJ joins do not show obvious evidence of P-nucleotides. As the total number of nucleotides added by these processes is random, the added nucleotides often disrupt the reading frame of the coding sequence beyond the joint. Such frameshifts will lead to a nonfunctional protein, and DNA rearrangements leading to such disruptions are known as **nonproductive rearrangements**. As roughly two in every three rearrangements will be nonproductive, many B-cell progenitors never succeed in producing functional immunoglobulin and therefore never become mature B cells. Thus, junctional diversity is achieved only at the expense of considerable loss of cells during B-cell development. In Chapter 8, we return to this topic when we discuss

the cellular stages of B-cell development and how they relate to the temporal sequence of rearrangement of the V, D, and J gene segments of the antigen-receptor chains.

5-8 IgM and IgD are derived from the same pre-mRNA transcript and are both expressed on the surface of mature B cells.

Once a progenitor B completes its heavy- and light-chain gene rearrangements, it will express the transmembrane form of the immunoglobulin protein. Recall from Chapter 4 (Section 4-6) that the heavy-chain locus encodes different C regions (C_H) that are present as separate genes located downstream of the V-region segments. This C_H gene cluster spans about 200 kb to the 3′ side of the J_H gene segments (see Fig. 4.6). Each C_H gene is split into several exons (not shown in the figure), with each exon corresponding to an individual immunoglobulin domain in the folded C region. Initially, B cells express two of these C_H genes, the C_μ and C_δ genes, each of which is expressed along with the associated assembled V-region sequence on the surface of the same B cell, producing transmembrane IgM and IgD. The gene encoding the C_μ region lies closest to the J_H gene segments, and therefore closest to the assembled V_H-region exon (VDJ exon) after DNA rearrangement. Once rearrangement has been completed, transcription from a promoter just 5′ to the leader sequence exon adjacent to the rearranged VDJ exon produces a complete μ heavy-chain transcript. Any J_H gene segments remaining between the assembled V gene and the C_μ gene are removed during RNA processing to generate the mature mRNA. The μ heavy chains are therefore the first to be expressed, and IgM is the first immunoglobulin to be produced during B-cell development.

Immediately 3′ to the μ gene lies the δ gene, which encodes the C region of the IgD heavy chain (see Fig. 4.6). IgD is coexpressed with IgM on the surface of almost all mature B cells but is secreted in only small amounts by plasma cells. The unique function of IgD is still unclear and a matter of active research. Because IgD has hinge regions that are more flexible than those in IgM, IgD has been suggested to be an auxiliary receptor that may facilitate the binding of antigens by naive B cells. Mice lacking the C_δ exons show normal B-cell development and can generate largely normal antibody responses but show a delay in the process of affinity maturation of antibody for antigens. We return to this topic in Chapter 10, when we discuss somatic hypermutation.

B cells expressing IgM and IgD have not undergone class switching, which requires irreversible changes to the DNA. Instead, these B cells produce a long primary mRNA transcript that is differentially spliced to yield either of two distinct mRNA molecules (Fig. 5.12). In one transcript, the VDJ exon is spliced to the C_μ exons and undergoes polyadenylation from a nearby site (pA_2) to encode a complete membrane-bound IgM molecule. The second RNA transcript extends well beyond this site and includes the downstream C_δ exons. In this transcript, the VDJ exon is spliced to these C_δ exons, and polyadenylation occurs at a separate site downstream (pA_4). This transcript encodes a membrane-bound IgD molecule.

It has been known since the 1980s that the processing of the long mRNA transcript is developmentally regulated, with immature B cells making mostly the μ transcript and mature B cells making mostly the δ along with some μ, although there was little to no molecular explanation until recently. A forward genetic screen of *N*-ethyl-*N*-nitrosourea (ENU)-induced mutagenesis in mice identified a gene involved in IgD expression that regulates the alternative splicing process. The gene encodes **ZFP318**, a protein structurally related to the U1 small nuclear ribonucleoprotein of the spliceosome, the RNA:protein complex that is required for mRNA splicing. ZFP318 is not expressed in immature B cells, where the IgD transcript is not produced, but becomes expressed in mature and activated B cells that coexpress IgD with

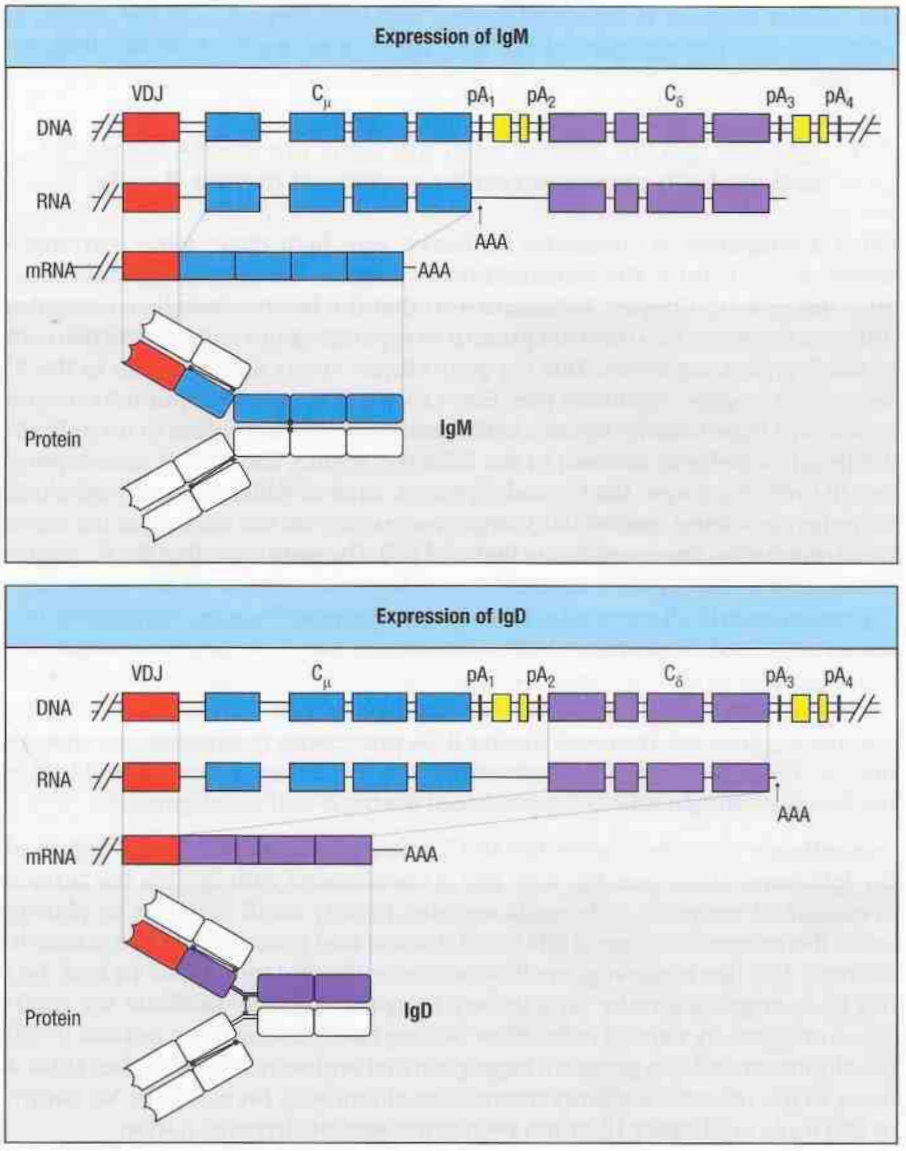

Fig. 5.12 Coexpression of IgD and IgM is regulated by RNA processing. In mature B cells, transcription initiated at the V_H promoter extends through both C_μ and C_δ exons. This long primary transcript is then processed by cleavage and polyadenylation (AAA) and by splicing. Cleavage and polyadenylation at the μ site (pA_2) and splicing between C_μ exons yields an mRNA encoding the μ heavy chain (top panel). Cleavage and polyadenylation at the δ site (pA_4) and a different pattern of splicing that joins the V region exon to the C_δ exons and removes the C_μ exons yields mRNA encoding the complete δ heavy chain (bottom panel).

IgM. ZFP318 functions by suppressing transcription termination and polyadenylation at the pA_2 site (see Fig.5.12) and by this mechanism promotes transcript elongation and polyadenylation at the pA_4 site. The longer pre-mRNA is preferentially spliced to eliminate the C_μ exons and include the C_δ exons instead. As a consequence, cells expressing ZFP318 express high levels of IgD and lower levels of IgM.

5-9 Transmembrane and secreted forms of immunoglobulin are generated from different heavy-chain mRNA transcripts.

Each of the immunoglobulin isotypes can be produced either as a membrane-bound receptor or as secreted antibodies. B cells initially express the transmembrane form of IgM; after stimulation by antigen, some of their progeny differentiate into plasma cells producing IgM antibodies, whereas others undergo class switching to express transmembrane immunoglobulins of a different class, followed by the production of secreted antibody of the new class. The membrane-bound forms of all immunoglobulin classes are monomers comprising two heavy and two light chains. IgM and IgA polymerize only when they have been secreted. The membrane-bound form of the immunoglobulin heavy chain has at the carboxyl terminus a hydrophobic transmembrane

domain of about 25 amino acid residues that anchors it to the surface of the B lymphocyte. The secreted form replaces this transmembrane domain with a carboxyl terminus composed of a hydrophilic secretory tail. These two forms of carboxyl termini are encoded by different exons found at the end of each C_H gene as these exons undergo alternative RNA processing.

For example, the IgM heavy-chain gene contains four exons—$C_{\mu 1}$ to $C_{\mu 4}$—that encode its four heavy-chain Ig domains (Fig. 5.13). The end of the $C_{\mu 4}$ exon also encodes the carboxyl terminus for the secreted form. Two additional downstream exons, M_1 and M_2, encode the transmembrane region and cytoplasmic tail. If the primary transcript is cleaved at the polyadenylation site (pA_1) located just downstream of the $C_{\mu 4}$ exon but before the last two exons, then only the secreted molecule can be produced. If the polymerase transcribes through this first polyadenylation site, then splicing can occur from a non-consensus splice-donor site within the $C_{\mu 4}$ exon to the M_1 exon. In this case, polyadenylation occurs at a downstream site (pA_2), and the cell-surface form of immunoglobulin can be produced. This alternative splicing is incompletely understood but may involve the regulation of RNA polymerase activity as the polymerase transcribes through the IgM locus. One factor that regulates the polyadenylation of RNA transcripts is a **cleavage stimulation factor** subunit, **CstF-64**, which favors production of the transcript for secreted IgM. The transcription elongation factor **ELL2**, which is induced in plasma cells, also promotes polyadenylation at the pA_1 site and favors the secreted form. CstF-64 and ELL2 co-associate with RNA polymerase within the immunoglobulin locus. This differential RNA

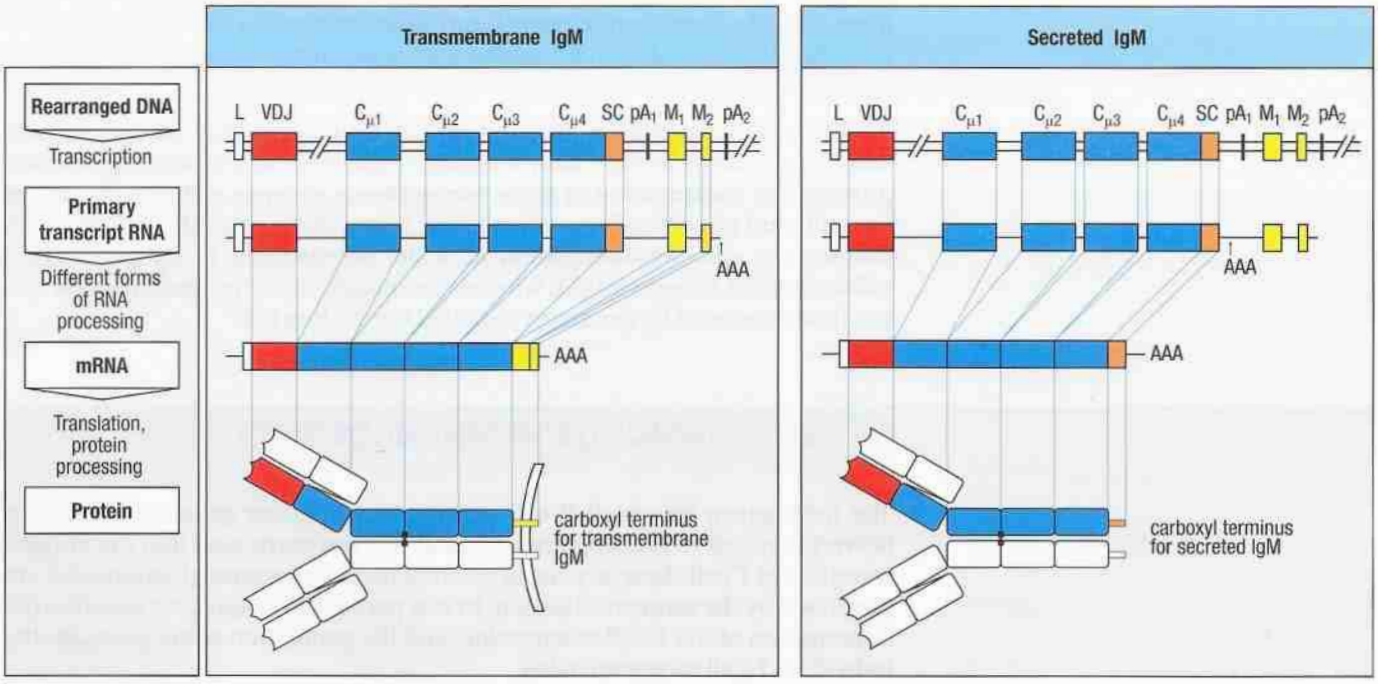

Fig. 5.13 Transmembrane and secreted forms of immunoglobulins are derived from the same heavy-chain sequence by alternative RNA processing. At the end of a heavy-chain C gene, there are two exons (M_1 and M_2; yellow) that together encode the transmembrane region and cytoplasmic tail of the transmembrane form. Within the last C-domain exon, a secretion-coding (SC) sequence (orange) encodes the carboxyl terminus of the secreted form. In the case of IgD, the SC sequence is in a separate exon (not shown), but for all other isotypes, including IgM as shown here, the SC sequence is contiguous with the last C-domain exon. The events that dictate whether a heavy-chain RNA will result in a secreted or a transmembrane immunoglobulin occur during processing of the pre-mRNA transcript. Each heavy-chain C gene has two potential polyadenylation sites (shown as pA_1 and pA_2 for C_μ). Left panel: The transcript is cleaved and polyadenylated (AAA) at the second site (pA_2). Splicing occurs from a site located within the last $C_{\mu 4}$ exon just upstream of the SC sequence (orange) to a second site at the 5′ end of the M_1 exons (yellow). This results in removal of the SC sequence and joining of the $C_{\mu 4}$ exon to the exons M_1 and M_2 and generates the transmembrane form of the heavy chain. Right panel: Polyadenylation occurs at the first poly(A) addition site (pA_1), and transcription terminates before the exons M_1 and M_2, preventing the generation of the transmembrane form of the heavy chain and producing the secreted form.

processing is illustrated for C_μ in Fig. 5.13, but it occurs in the same way for all isotypes. In activated B cells that differentiate to become antibody-secreting plasma cells, most of the transcripts are spliced to yield the secreted rather than the transmembrane form of whichever heavy-chain isotype the B cell is expressing.

Summary.

The extraordinary diversity of the immunoglobulin repertoire is achieved in several ways. Perhaps the most important factor enabling this diversity is that V regions are encoded by separate gene segments (V, D, and J gene segments), which are brought together by a somatic recombination process—V(D)J recombination—to produce a complete V-region exon. Many different gene segments are present in the genome of an individual, thus providing a heritable source of diversity that this combinatorial mechanism can use. Unique lymphocyte-specific recombinases, the RAG proteins, are absolutely required to catalyze this rearrangement, and the evolution of RAG proteins coincided with the appearance of the modern vertebrate adaptive immune system. Another substantial fraction of the functional diversity of immunoglobulins comes from the imprecise nature of the joining process itself. Variability at the coding joints between gene segments is generated by the insertion of random numbers of P- and N-nucleotides and by the variable deletion of nucleotides at the ends of some segments. These are brought about by the opening of the hairpin by Artemis and by the actions of TdT. The association of different light- and heavy-chain V regions to form the antigen-binding site of an immunoglobulin molecule contributes further diversity. The combination of all of these sources of diversity generates a vast primary repertoire of antibody specificities.

B cells initially coexpress IgM and IgD as transmembrane receptors, each carrying the same heavy-chain V-region sequence and the same light-chain protein. The coexpression of these two antibody isotypes is due to the use of two different polyadenylation sites in the heavy-chain pre-mRNA. Transcript termination and polyadenylation at a site downstream of C_μ generates a spliced mRNA encoding IgM, whereas termination and polyadenylation at a site downstream of C_δ generates the mRNA encoding IgD.

T-cell receptor gene rearrangement.

The mechanism by which B-cell antigen receptors are generated is such a powerful means of creating diversity that it is not surprising that the antigen receptors of T cells bear structural resemblances to immunoglobulins and are generated by the same mechanism. In this part of the chapter, we describe the organization of the T-cell receptor loci and the generation of the genes for the individual T-cell receptor chains.

5-10 The T-cell receptor gene segments are arranged in a pattern similar to that of immunoglobulin gene segments and are rearranged by the same enzymes.

Like immunoglobulin light and heavy chains, T-cell receptor (TCR) α and β chains each consist of a variable (V) amino-terminal region and a constant (C) region (see Section 4-14). The organization of the TCRα and TCRβ loci is shown in Fig. 5.14. The organization of the gene segments is broadly homologous to that of the immunoglobulin gene segments (see Sections 5-2 and 5-3).

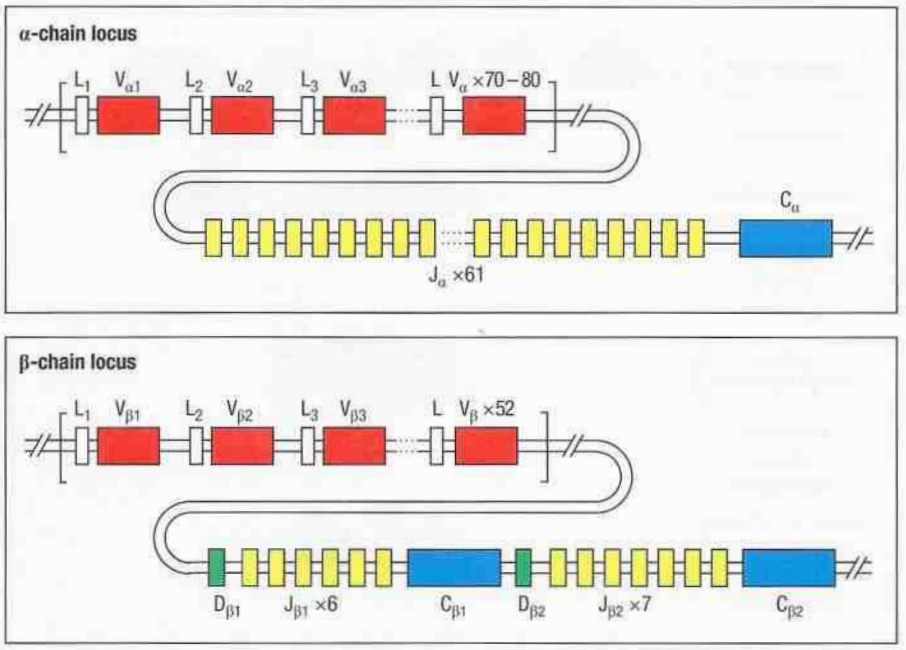

Fig. 5.14 The germline organization of the human T-cell receptor α and β loci. The arrangement of the gene segments for the T-cell receptor resembles that at the immunoglobulin loci, with separate variable (V), diversity (D), and joining (J) gene segments and constant (C) genes. The TCRα locus (chromosome 14) consists of 70–80 V_α gene segments, each preceded by an exon encoding the leader sequence (L). How many of these V_α gene segments are functional is not known exactly. A cluster of 61 J_α gene segments is located a considerable distance from the V_α gene segments. The J_α gene segments are followed by a single C gene, which contains separate exons for the constant and hinge domains and a single exon encoding the transmembrane and cytoplasmic regions (not shown). The TCRβ locus (chromosome 7) has a different organization, with a cluster of 52 functional V_β gene segments located distant from two separate clusters that each contain a single D gene segment together with six or seven J gene segments and a single C gene. Each TCRβ C gene has separate exons encoding the constant domain, the hinge, the transmembrane region, and the cytoplasmic region (not shown). The TCRα locus is interrupted between the J and V gene segments by another T-cell receptor locus—the TCRδ locus (not shown here; see Fig. 5.19).

The TCRα locus, like the loci of the immunoglobulin light chains, contains V and J gene segments (V_α and J_α). The TCRβ locus, like the locus of the immunoglobulin heavy chain, contains D gene segments in addition to V_β and J_β gene segments. The T-cell receptor gene segments rearrange during T-cell development to form complete V-domain exons (Fig. 5.15). T-cell receptor gene rearrangement takes place in the thymus; the order and regulation of the rearrangements are dealt with in detail in Chapter 8. Essentially, however, the mechanics of gene rearrangement are similar for B and T cells. The T-cell receptor gene segments are flanked by 12-bp and 23-bp spacer recombination signal sequences (RSSs) that are homologous to those flanking immunoglobulin gene segments (Fig. 5.16; see Section 5-3) and are recognized by the same enzymes. The DNA circles resulting from gene rearrangement (see Fig. 5.7) are known as **T-cell receptor excision circles (TRECs)** and are used as markers for T cells that have recently emigrated from the thymus. All known defects in genes that control V(D)J recombination affect T cells and B cells equally, and animals with these genetic defects lack functional B and T lymphocytes altogether (see Section 5-4). A further shared feature of immunoglobulin and T-cell receptor gene rearrangement is the presence of P- and N-nucleotides in the junctions between the V, D, and J gene segments of the rearranged TCRβ gene. In T cells, P- and N-nucleotides are also added between the V and J gene segments of all rearranged TCRα genes, whereas only about half of the

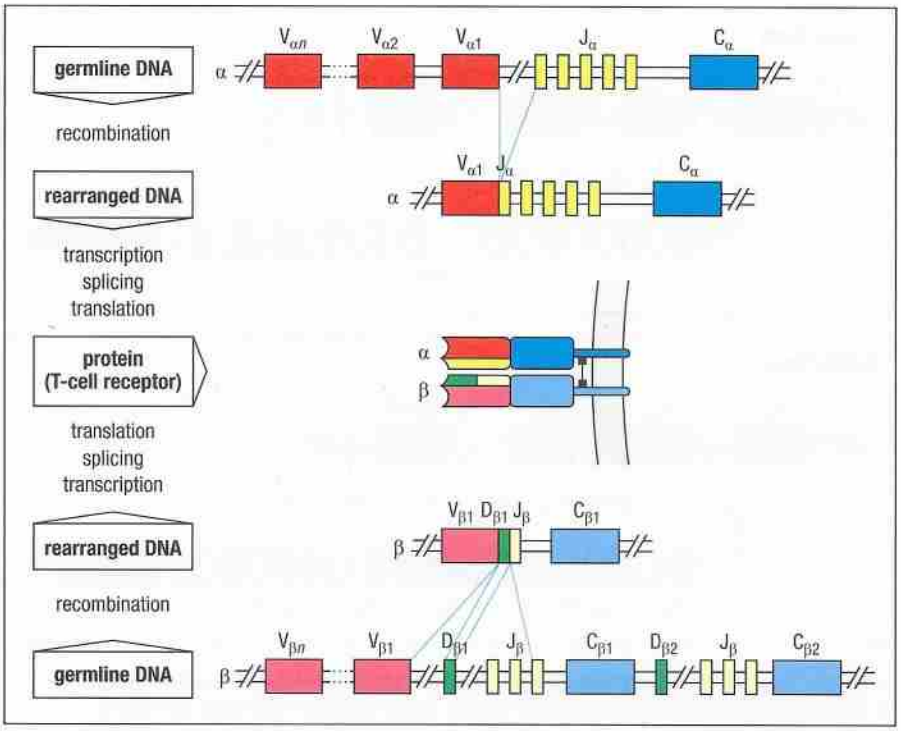

Fig. 5.15 T-cell receptor α- and β-chain gene rearrangement and expression. The TCRα-chain and TCRβ-chain genes are composed of discrete segments that are joined by somatic recombination during development of the T cell. Functional α- and β-chain genes are generated in the same way that complete immunoglobulin genes are created. For the α chain (upper part of figure), a V_α gene segment rearranges to a J_α gene segment to create a functional V-region exon. Transcription and splicing of the VJ_α exon to C_α generates the mRNA that is translated to yield the T-cell receptor α-chain protein. For the β chain (lower part of figure), like the immunoglobulin heavy chain, the variable domain is encoded in three gene segments, V_β, D_β, and J_β. Rearrangement of these gene segments generates a functional VDJ_β V-region exon that is transcribed and spliced to join to C_β; the resulting mRNA is translated to yield the T-cell receptor β chain. The α and β chains pair soon after their synthesis to yield the αβ T-cell receptor heterodimer. Not all J gene segments are shown, and the leader sequences preceding each V gene segment are omitted for simplicity.

V–J joints in immunoglobulin light-chain genes are modified by N-nucleotide addition, and these are often left without any P-nucleotides as well (Fig. 5.17; see Section 5-7).

The main differences between the immunoglobulin genes and those encoding T-cell receptors reflect the differences in how B cells and T cells function. All the effector functions of B cells depend on secreted antibodies whose different heavy-chain C-region isotypes trigger distinct effector mechanisms. The effector functions of T cells, in contrast, depend on cell–cell contact and are not mediated directly by the T-cell receptor, which serves only for antigen recognition. Thus, the C regions of the TCRα and TCRβ loci are much simpler than

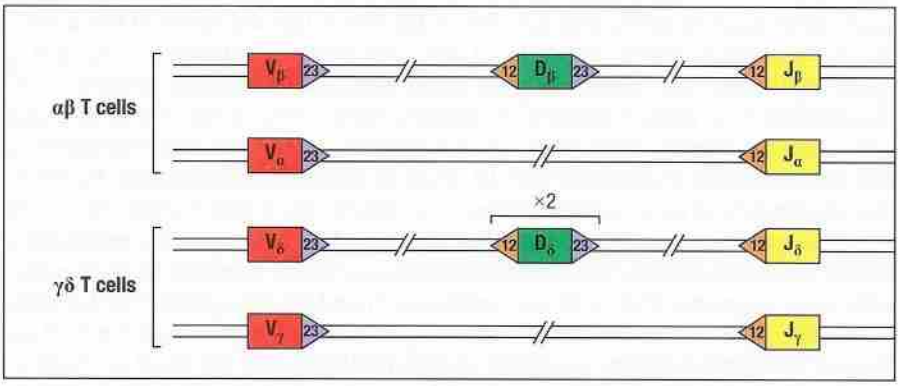

Fig. 5.16 Recombination signal sequences flank T-cell receptor gene segments. As in the immunoglobulin gene loci (see Fig. 5.6), the individual gene segments at the TCRα and TCRβ loci are flanked by heptamer–spacer–nonamer recombination signal sequences (RSSs). RSS motifs containing 12-bp spacers are depicted here as orange arrowheads, and those containing 23-bp spacers are shown in purple. Joining of gene segments almost always follows the 12/23 rule. Because of the disposition of heptamer and nonamer RSSs in the TCRβ and TCRδ loci, direct V_β to J_β joining is in principle allowed by the 12/23 rule (unlike in the immunoglobulin heavy-chain gene), although this occurs very rarely owing to other types of regulation.

Element	Immunoglobulin		αβ T-cell receptors	
	H	κ+λ	β	α
Number of variable segments (V)	~40	~60	~30	~100
Number of diversity segments (D)	23	0	2	0
Number of D segments read in three frames	rarely	–	often	–
Number of joining segments (J)	6	5(κ) 4(λ)	12	~50
Number of joints with N- and P-nucleotides	2 (VD and DJ)	50% of joints	2 (VD and DJ)	1 (VJ)
Number of V gene pairs	1.5×10^6		2.7×10^6	
Total diversity with nucleotide addition and deletion	$\sim 5 \times 10^{13}$		$\sim 10^{18}$	

Fig. 5.17 The number of human T-cell receptor gene segments and the sources of T-cell receptor diversity compared with those of immunoglobulins. Note that only about half of human κ chains contain N-nucleotides. Somatic hypermutation as a source of diversity is not included in this figure because it does not occur in T cells.

those of the immunoglobulin heavy-chain locus. There is only one C_α gene, and although there are two C_β genes, they are very closely homologous and there is no known functional distinction between their products. The T-cell receptor C-region genes encode only transmembrane polypeptides.

Another difference between the rearrangement of immunoglobulin genes and T-cell receptor genes is in the nature of the RSSs surrounding the D gene segments. For the immunoglobulin heavy chain, the D segment is surrounded by two RSSs, both with a 12-bp spacing (see Fig. 5.6), whereas the D segments in the TCRβ and TCRδ loci have a 5′ 12-bp RSS and a 3′ 23-bp RSS (see Fig. 5.16). The arrangement in the immunoglobulin locus naturally enforces the inclusion of D segments in the heavy-chain V region, because direct V to J joining would violate the 12/23 rule. However, in the T-cell receptor loci, direct V to J joining would not violate this rule, because the 23-bp RSS of the V_β or V_δ segment is compatible with the 12-bp RSS of the J gene segment, and yet normally, little direct joining is observed. Instead, regulation of gene rearrangements appears to be controlled by mechanisms beyond the 12/23 rule, and these mechanisms are still being investigated.

5-11 T-cell receptors concentrate diversity in the third hypervariable region.

The three-dimensional structure of the antigen-recognition site of a T-cell receptor looks much like that of the antigen-recognition site of an antibody molecule (see Sections 4-10 and 4-20, respectively). In an antibody, the center of the antigen-binding site is formed by the CDR3 loops of the heavy and light chains. The structurally equivalent third hypervariable loops of the T-cell receptor α and β chains, to which the D and J gene segments contribute, also form the center of the antigen-binding site of a T-cell receptor; the periphery of the site consists of the CDR1 and CDR2 loops, which are encoded within the germline V gene segments for the α and β chains. The extent and pattern of variability in T-cell receptors and immunoglobulins reflect the distinct nature of their ligands. Whereas the antigen-binding sites of immunoglobulins must conform to the surfaces of an almost infinite variety of different antigens, and thus come in a wide variety of shapes and chemical properties, the ligand for the major class of human T-cell receptors (αβ) is always a peptide bound to an MHC molecule. As a group, the antigen-recognition sites of T-cell receptors would therefore be predicted to have a less variable shape, with most of the

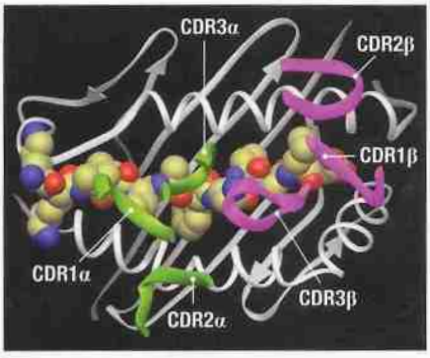

Fig. 5.18 The most variable parts of the T-cell receptor interact with the peptide of a peptide:MHC complex. The CDR loops of a T-cell receptor are shown as colored tubes, which in this figure are superimposed on the peptide:MHC complex (MHC, gray; peptide, yellow-green with O atoms in red and N atoms in blue). The CDR loops of the α chain are in green, while those of the β chain are in purple. The CDR3 loops lie in the center of the interface between the T-cell receptor and the peptide:MHC complex and make direct contact with the antigenic peptide.

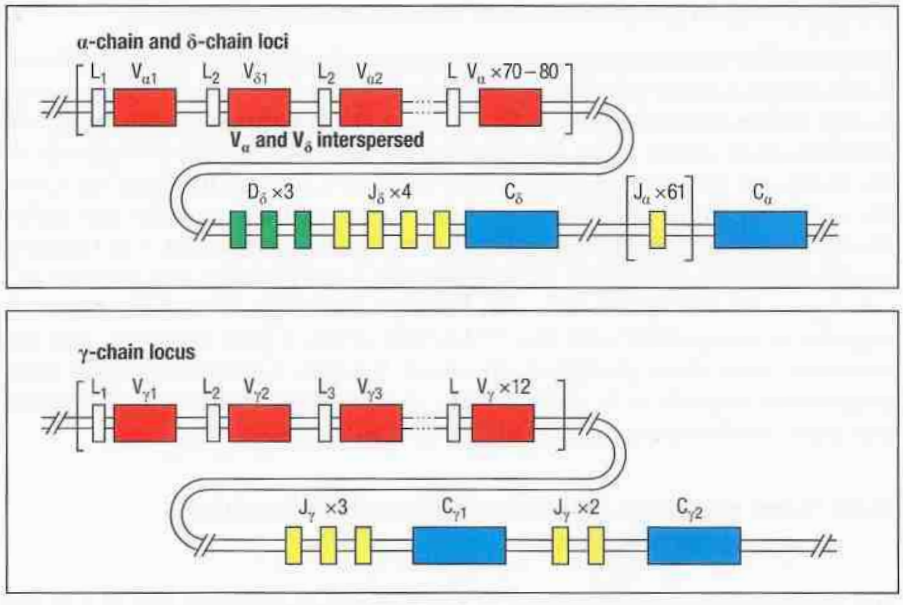
variability focused on the bound antigenic peptide occupying the center of the surface in contact with the receptor. Indeed, the less variable CDR1 and CDR2 loops of a T-cell receptor mainly contact the relatively less variable MHC component of the ligand, whereas the highly variable CDR3 regions mainly contact the unique peptide component (Fig. 5.18).

5-12 γδ T-cell receptors are also generated by gene rearrangement.

A minority of T cells bear T-cell receptors composed of γ and δ chains (see Section 4-23). The organization of the TCRγ and TCRδ loci (Fig. 5.19) resembles that of the TCRα and TCRβ loci, although there are important differences. The cluster of gene segments encoding the δ chain is found entirely within the TCRα locus, between the V_α and the J_α gene segments. V_δ genes are interspersed with the V_α genes but are located primarily in the 3′ region of the locus.



α-chain and δ-chain loci
L1 Vα1 L2 Vδ1 L2 Vα2 L Vα ×70–80
Vα and Vδ interspersed
Dδ ×3 Jδ ×4 Cδ Jα ×61 Cα
γ-chain locus
L1 Vγ1 L2 Vγ2 L3 Vγ3 L Vγ ×12
Jγ ×3 Cγ1 Jγ ×2 Cγ2

Fig. 5.19 The organization of the T-cell receptor γ- and δ-chain loci in humans. The TCRγ and TCRδ loci, like the TCRα and TCRβ loci, have discrete V, D, and J gene segments as well as C genes. Uniquely, the locus encoding the δ chain is located entirely within the α-chain locus. The three D_δ gene segments, four J_δ gene segments, and the single δ C gene lie between the cluster of V_α gene segments and the cluster of J_α gene segments. There are two V_δ gene segments (not shown) located near the δ C gene, one just upstream of the D regions and one in inverted orientation just downstream of the C gene. In addition, there are six V_δ gene segments interspersed among the V_α gene segments. Five are shared with V_α and can be used by either locus, and one is unique to the δ locus. The human TCRγ locus resembles the TCRβ locus in having two C genes, each with its own set of J gene segments. The mouse γ locus (not shown) has a more complex organization and there are three functional clusters of γ gene segments, each containing V and J gene segments and a C gene. Rearrangement at the γ and δ loci proceeds as for the other T-cell receptor loci, with the exception that during TCRδ rearrangement, two D segments can be used in the same complete V gene. The use of two D segments greatly increases the variability of the δ chain, mainly because N-region nucleotides can be added at the junction between the two D gene segments as well as at the V–D and D–J junctions.

Because all V_α gene segments are oriented such that rearrangement will delete the intervening DNA, any rearrangement at the α locus results in the loss of the δ locus (Fig. 5.20). There are substantially fewer V gene segments at the TCRγ and TCRδ loci than at either the TCRα or TCRβ loci or any of the immunoglobulin loci. Increased junctional variability in the δ chains may compensate for the small number of V gene segments and has the effect of focusing almost all the variability in the γδ receptor in the junctional region. As we have seen for the αβ T-cell receptors, the amino acids encoded by the junctional regions lie at the center of the T-cell receptor binding site. T cells bearing γδ receptors are a distinct lineage of T cells, and as discussed in Chapter 4, some γδ T cells recognize nonclassical MHC class I molecules and other molecules whose expression may be an indication of cellular damage or infection. As we saw in Section 4-23, the CDR3 of a γδ T cell is frequently longer than the CDR3 in an αβ T-cell receptor; this permits the CDR3 of γδ T cell receptors to interact directly with ligand and also contributes to the great diversity of these receptors.

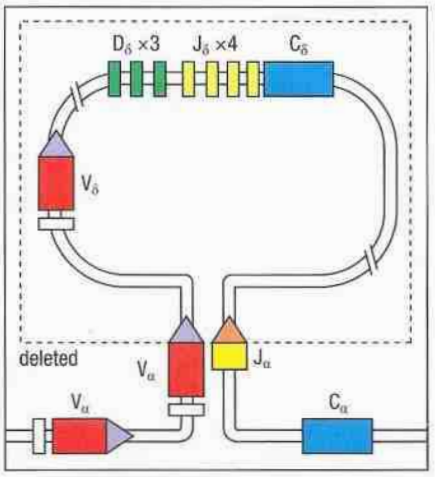


Fig. 5.20 Deletion of the TCRδ locus is induced by rearrangement of a V_α to J_α gene segment. The TCRδ locus is entirely contained within the chromosomal region containing the TCRα locus. When any V region in the V_α/V_δ region rearranges to any one of the J_α segments, the intervening region, and the entire V_δ locus, is deleted. Thus, V_α rearrangement prevents any continued expression of a V_δ gene and precludes lineage development down the γδ pathway.

Summary.

T-cell receptors are structurally similar to immunoglobulins and are encoded by homologous genes. T-cell receptor genes are assembled by somatic recombination from sets of gene segments in the same way that the immunoglobulin genes are. Diversity is distributed differently, however, in immunoglobulins and T-cell receptors: the T-cell receptor loci have roughly the same number of V gene segments as the immunoglobulin loci but more J gene segments, and there is greater diversification of the junctions between gene segments during the process of gene rearrangement. Thus, the greatest diversity of the T-cell receptor is in the central part of the receptor, within the CDR3, which, in the case of αβ T-cell receptors, contacts the bound peptide fragment of the ligand. Most of the diversity among γδ T-cell receptors is also within the CDR3, which is frequently longer than the CDR3 of αβ T-cell receptors and can also directly interact with ligands recognized by the γδ T cells.

Evolution of the adaptive immune response.

The form of adaptive immunity that we have discussed so far in this book depends on the action of the RAG-1:RAG-2 recombinase to generate an enormously diverse clonally distributed repertoire of immunoglobulins and T-cell receptors. This system is found only in the jawed vertebrates, the **gnathostomes**, which split off from the other vertebrates around 500 million years ago. Adaptive immunity seems to have arisen abruptly in evolution. Even the cartilaginous fishes, the earliest group of jawed fishes to survive to the present day, have organized lymphoid tissue, T-cell receptors, and immunoglobulins, as well as the ability to mount adaptive immune responses. The diversity generated within the vertebrate adaptive immune system was once viewed as unique among animal immune systems. But we now know that organisms as different as insects, echinoderms, and mollusks use a variety of genetic mechanisms to increase their repertoires of pathogen-detecting molecules, although they do not achieve true adaptive immunity. Nearer to home, it has been found that the surviving species of jawless vertebrates, the **agnathans**—the lampreys and hagfish—have a form of adaptive or 'anticipatory' immunity that is based on non-immunoglobulin antibody-like proteins and involves a system of somatic gene rearrangement that is quite distinct from RAG-dependent V(D)J rearrangement. So we should now view our adaptive immune system as only one solution to the problem of generating highly diverse systems for pathogen recognition.

5-13 Some invertebrates generate extensive diversity in a repertoire of immunoglobulin-like genes.

Until recently, it was thought that invertebrate immunity was limited to an innate system that had limited diversity in recognizing pathogens. This idea was based on the knowledge that innate immunity in vertebrates relies on around 10 distinct Toll-like receptors and a similar number of other receptors that also recognize PAMPs, and also on the assumption that the number of receptors in invertebrates was no greater. Recent studies have, however, uncovered at least two invertebrate examples of extensive diversification of an immunoglobulin superfamily member, which could potentially provide an extended range of recognition of pathogens.

In *Drosophila*, fat-body cells and hemocytes act as part of the immune system. Fat-body cells secrete proteins, such as the antimicrobial defensins (see Chapter 2), into the hemolymph. Another protein found in hemolymph is the **Down syndrome cell adhesion molecule (Dscam)**, a member of the immunoglobulin superfamily. Dscam was originally discovered in the fly as a protein involved in specifying neuronal wiring. It is also made in fat-body cells and hemocytes, which can secrete it into the hemolymph, where it is thought to recognize invading bacteria and aid in their engulfment by phagocytes.

The Dscam protein contains multiple, usually 10, immunoglobulin-like domains. However, the gene that encodes Dscam has evolved to contain a large number of alternative exons for several of these domains (Fig. 5.21). Exon 4 of the gene encoding the Dscam protein can be any 1 of 12 different exons, each specifying an immunoglobulin domain of differing sequence. Exon cluster 6 has 48 alternative exons, cluster 9 another 33, and cluster 17 a further 2; it is estimated that the Dscam gene could encode around 38,000 protein isoforms. A role for Dscam in immunity was proposed when it was found that *in vitro* phagocytosis of *Escherichia coli* by isolated hemocytes lacking Dscam was less efficient than by normal hemocytes. These observations suggest that at least some of this extensive repertoire of alternative exons may have evolved to diversify insects' ability to recognize pathogens. This role for Dscam has been confirmed in the mosquito *Anopheles gambiae*, in which silencing of the *Dscam* homolog *AgDscam* has been shown to weaken the mosquito's normal

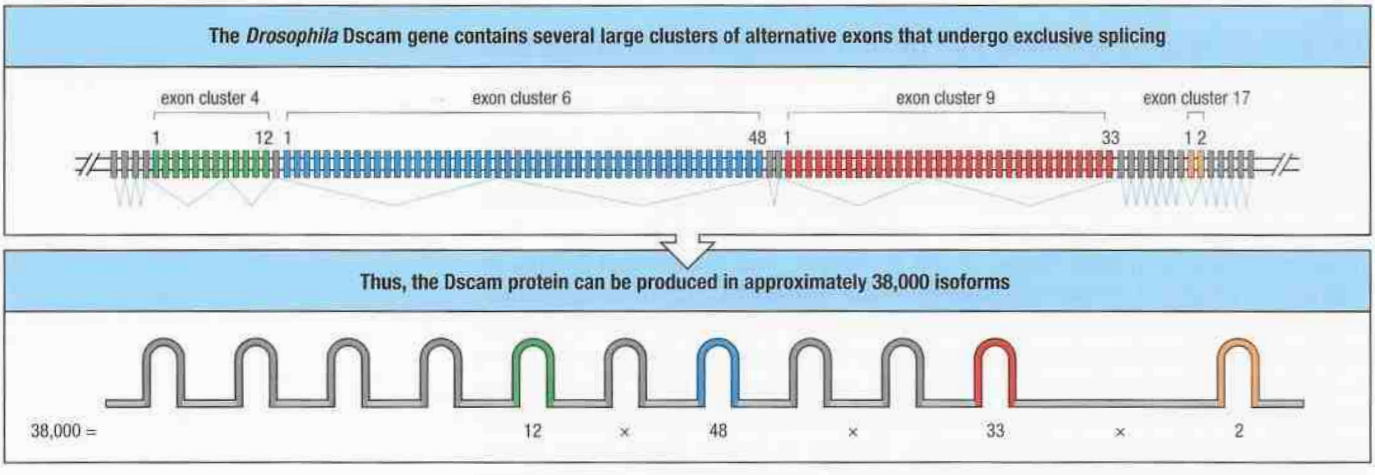

Fig. 5.21 The Dscam protein of *Drosophila* innate immunity contains multiple immunoglobulin domains and is highly diversified through alternative splicing. The gene encoding Dscam in *Drosophila* contains several large clusters of alternative exons. The clusters encoding exon 4 (green), exon 6 (light blue), exon 9 (red), and exon 17 (orange) contain 12, 48, 33, and 2 alternative exons, respectively. For each of these clusters, only one alternative exon is used in the complete *Dscam* mRNA. There is some differential usage of exons in neurons, fat-body cells, and hemocytes. All three cell types use the entire range of alternative exons for exons 4 and 6. For exon 9, there is restricted use of alternative exons in hemocytes and fat-body cells. The combinatorial use of alternative exons in the Dscam gene makes it possible to generate more than 38,000 protein isoforms.

resistance to bacteria and to the malaria parasite *Plasmodium*. There is also evidence from the mosquito that some Dscam exons have specificity for particular pathogens. It is not clear whether Dscam isoforms are expressed in a clonal manner.

Another invertebrate, this time a mollusk, uses a different strategy to diversify an immunoglobulin superfamily protein for use in immunity. The freshwater snail *Biomphalaria glabrata* expresses a small family of **fibrinogen-related proteins (FREPs)** thought to have a role in innate immunity. FREPs have one or two immunoglobulin domains at their amino-terminal end and a fibrinogen domain at their carboxyl terminus. The immunoglobulin domains may interact with pathogens, while the fibrinogen domain may confer on the FREP lectin-like properties that help precipitate the complex. FREPs are produced by hemocytes and secreted into the hemolymph. Their concentration increases when the snail is infected by parasites—it is, for example, the intermediate host for the parasitic schistosomes that cause human schistosomiasis.

The *B. glabrata* genome contains many copies of FREP genes that can be divided into approximately 13 subfamilies. A study of the sequences of expressed FREP3 subfamily members has revealed that the FREPs expressed in an individual organism are extensively diversified compared with the germline genes. There are fewer than five genes in the FREP3 subfamily, but an individual snail was found to generate more than 45 distinct FREP3 proteins, all with slightly different sequences. An analysis of the protein sequences suggested that this diversification was due to the accumulation of point mutations in one of the germline FREP3 genes. Although the precise mechanism of this diversification, and the cell type in which it occurs, are not yet known, it does suggest some similarity to somatic hypermutation that occurs in the immunoglobulins. Both the insect and *Biomphalaria* examples seem to represent a way of diversifying molecules involved in immune defense, but although they resemble in some ways the strategy of an adaptive immune response, there is no evidence of clonal selection—the cornerstone of true adaptive immunity.

5-14 Agnathans possess an adaptive immune system that uses somatic gene rearrangement to diversify receptors built from LRR domains.

Since the early 1960s it has been known that certain jawless fishes, the hagfish and the lamprey, could mount a form of accelerated rejection of transplanted skin grafts and exhibit a kind of immunological delayed-type hypersensitivity. Their serum also seemed to contain an activity that behaved as a specific agglutinin, meaning that after immunization with an antigen, the serum would cause aggregation of the antigen when the two were mixed together *in vitro*, a process known as **agglutination**. Importantly, this agglutination activity increased in titer after secondary immunization, similar to antibody responses in higher vertebrates. Although these phenomena seemed reminiscent of adaptive immunity, there was no evidence of a thymus or of immunoglobulins, but these animals did have cells that could be considered to be genuine lymphocytes on the basis of morphological and molecular analysis. Analysis of the genes expressed by lymphocytes of the sea lamprey *Petromyzon marinus* revealed none related to T-cell receptor or immunoglobulin genes. However, these cells expressed large amounts of mRNAs from genes encoding proteins with multiple leucine-rich repeat (LRR) domains, the same protein domain from which the pathogen-recognizing Toll-like receptors (TLRs) are built (see Section 3-5).

This might simply have meant that these cells are specialized for recognizing and reacting to pathogens, but the LRR proteins expressed had some surprises in store. Instead of being present in a relatively few forms (like the invariant TLRs), they were found to have highly variable amino acid sequences, with a

large number of variable LRR units placed between less variable amino-terminal and carboxyl-terminal LRR units. These LRR-containing proteins, called **variable lymphocyte receptors (VLRs)**, have an invariant stalk region connecting them to the plasma membrane by a glycosylphosphatidylinositol linkage, and they can either be tethered to the cell or be secreted into the blood, like antibodies.

Analysis of the expressed lamprey VLR genes indicates that they are assembled by a process of somatic gene rearrangement (Fig. 5.22). In the germline configuration, there are three incomplete VLR genes, *VLRA*, *VLRB*, and *VLRC*, each encoding a signal peptide, a partial amino-terminal LRR unit, and a partial carboxyl-terminal LRR unit, but these three blocks of coding sequence are

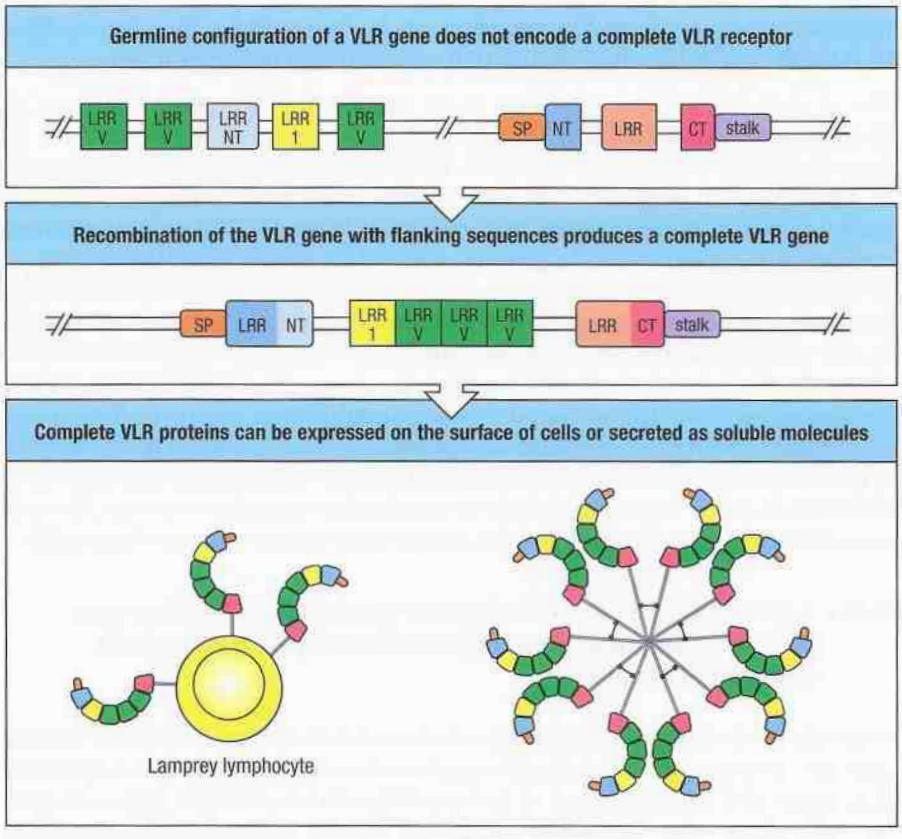

Fig. 5.22 Somatic recombination of an incomplete germline variable lymphocyte receptor (VLR) gene generates a diverse repertoire of complete VLR genes in the lamprey. Top panel: An incomplete germline copy of a lamprey VLR gene contains a framework (right) for the complete gene: the portion encoding the signal peptide (SP), part of an amino-terminal LRR unit (NT, dark blue), and a carboxyl-terminal LRR unit that is split into two parts (LRR, light red; and CT, red) by intervening noncoding DNA sequences. Nearby flanking regions (left) contain multiple copies of VLR gene 'cassettes' with single or double copies of variable LRR domains (green) and cassettes that encode part of the amino-terminal LRR domains (light blue, yellow). Middle panel: Somatic recombination causes various LRR units to be copied into the original VLR gene. This creates a complete VLR gene that contains the assembled amino-terminal LRR cassette (LRR NT) and first LRR (yellow), followed by several variable LRR units (green) and the completed carboxyl-terminal LRR unit, and ends with the portion that encodes the stalk region of the VLR receptor. The cytidine deaminases PmCDA1 and PmCDA2 from the lamprey *P. marinus* are candidates for enzymes that may initiate this gene rearrangement. Expression of the rearranged gene results in a complete receptor that can be attached to the cell membrane by glycosylphosphatidylinositol (GPI) linkage of its stalk. Bottom panel: An individual lymphocyte undergoes somatic gene rearrangement to produce a unique VLR receptor. These receptors can be tethered to the surface of the lymphocyte via the GPI linkage or can be secreted into the blood as decamers. Unique somatic rearrangement events in each developing lymphocyte generate a repertoire of VLR receptors of differing specificities.

separated by noncoding DNA that contains neither typical signals for RNA splicing nor the RSSs present in immunoglobulin genes (see Section 5-3). Instead, the regions flanking the incomplete VLR genes include a large number of DNA 'cassettes' that contain LRR units—one, two, or three LRR domains at a time. Each mature lamprey lymphocyte expresses a complete and unique VLR gene, either *VLRA, VLRB,* or *VLRC,* which has undergone recombination of these flanking regions with the germline VLR gene.

The creation of a complete VLR gene is currently thought to occur during replication of lamprey lymphocyte DNA by a 'copy-choice' mechanism that is similar, but not identical, to gene conversion (described in Section 5-16). During DNA replication, LRR units flanking the VLR gene are copied into the VLR gene—presumably when a DNA strand being synthesized switches templates and copies sequences from one of these LRR units. Although final proof is still lacking, this template-switching mechanism may be triggered by enzymes of the AID-APOBEC family that are expressed by lamprey lymphocytes, and whose **cytidine deaminase activity (CDA)** could cause the single-strand DNA breaks that can start the copy-choice process. Lampreys possess a family of such enzymes. The first discovered members, CDA1 and CDA2, are expressed in *VLRA/VLRC*-lineage and *VLRB*-lineage lymphocytes, respectively. The final VLR gene contains a complete amino-terminal capping LRR subunit, followed by the addition of up to seven internal LRR domains, each 24 amino acids long, and the removal of the internal noncoding regions to complete the formation of the carboxyl-terminal LRR domain (see Fig. 5.22).

It is estimated that this somatic rearrangement mechanism can generate as much diversity in the VLR proteins as is possible for immunoglobulins. Indeed, the crystal structure of a VLR protein shows that the concave surface formed by the series of LRR repeats interacts with a variable insert in the carboxyl-terminal LRR to form a surface capable of interacting with a great diversity of antigens. Thus, the diversity of the anticipatory repertoire of agnathans may be limited not by the numbers of possible receptors they can generate but by the number of lymphocytes present in any individual, as in the adaptive immune system of their evolutionary cousins, the gnathostomes. As noted above, each lamprey lymphocyte rearranges only one of the three germline VLR genes, expressing a complete VLRA, VLRB, or VLRC protein. Whereas VLRB-expressing cells share characteristics with mammalian B lymphocytes, VLRA- and VLRC-expressing cells resemble αβ T-cell receptor–expressing and γδ T-cell receptor–expressing lymphocytes, respectively. These parallels between lamprey VLR-expressing cell subsets and the subsets of mammalian lymphocytes is reinforced by findings that identify key lineage-associated transcription factors expressed by each cell subset. For example, VLRA-expressing lymphocytes transcribe the lamprey orthologs of TCF1, NOTCH1, and BCL11B; VLRB-expressing lymphocytes, the orthologs of E2A, PAX5, and BLIMP1; whereas VLRC-expressing lymphocytes produce the ortholog of SOX13, a key factor in γδ T-cell lineage determination. In addition, VLR-expressing cell subsets also transcribe genes related to mammalian cytokine and antigen-receptor signaling genes in a pattern that correlates with their mammalian lymphocyte counterparts. Overall, these observations support the conclusion of identical functions in lamprey and our own adaptive immune cells.

5-15 RAG-dependent adaptive immunity based on a diversified repertoire of immunoglobulin-like genes appeared abruptly in the cartilaginous fishes.

Within the vertebrates, we can trace the development of immune functions from the agnathans through the cartilaginous fishes (sharks, skates, and rays) to the bony fishes, then to the amphibians, to reptiles and birds, and finally to mammals. RAG-dependent V(D)J recombination has not been

found in agnathans, other chordates, or any invertebrate. The origins of RAG-dependent adaptive immunity are now becoming clearer as the genome sequences of many more animals become available. The first clue was that RAG-dependent recombination shares many features with the transposition mechanism of **DNA transposons**—mobile genetic elements that encode their own **transposase**, an enzymatic activity that allows them to excise from one site in the genome and reinsert themselves elsewhere. The mammalian RAG complex can act as a transposase *in vitro*, and even the structure of the RAG genes, which lie close together in the chromosome and lack the usual introns of mammalian genes, is reminiscent of a transposon. In addition, a transposable element was recently discovered in lancelets, a fish-like vertebrate lineage that diverged from the other two chordate lineages more than half a billion years ago. This transposable element, named ProtoRAG, is flanked by terminal repeat sequences that resemble RSS elements; between these inverted repeats lie *RAG1*- and *RAG2*-like genes, suggesting that ProtoRAG may be an ancestor of the RAG recombination system active in vertebrate immune cells. These findings provoked speculation that the origin of RAG-dependent adaptive immunity was the invasion of a DNA transposon into a gene similar to an immunoglobulin or a T-cell receptor V-region gene, an event that would have occurred in some ancestor of the jawed vertebrates (Fig. 5.23). Subsequent duplication, reduplication, and recombination of the immune-receptor gene and its inserted RSSs eventually led to the separation of the RAG genes from the rest of the relic transposon and to the multi-segmented immunoglobulin and T-cell receptor loci of present-day vertebrates.

The earliest origins of the RSSs, the RAG-1 catalytic core, and possibly RAG-2 are now thought to lie in the **Transib** superfamily of DNA transposons, and genome sequencing has led to the discovery of sequences related to *RAG1* in animals as distantly related to vertebrates as the sea anemone *Nematostella*. Additionally, a *RAG1–RAG2*-related gene cluster was recently discovered in sea urchins, invertebrate relatives of the chordates. Sea urchins themselves show no evidence of immunoglobulins, T-cell receptors, or adaptive immunity, but the proteins expressed by the sea-urchin RAG genes form a complex with each other and with RAG proteins from the bull shark (*Carcharhinus leucas*), a primitive jawed vertebrate, but not with those from mammals. This suggests that these proteins could indeed be related to the vertebrate RAGs, and that RAG-1 and RAG-2 were already present in a common ancestor of chordates and echinoderms (the group to which sea urchins belong), presumably

Fig. 5.23 Integration of a transposon into a V-type immunoglobulin receptor gene is thought to have given rise to the T-cell receptor and immunoglobulin genes. First panel: A DNA transposon in an ancestor of the deuterostomes (the large group of phyla to which the chordates belong) is thought to have had genes related to *RAG1* and *RAG2*—prototype *RAG1* (purple) and *RAG2* (blue), which acted as its transposase. DNA transposons are bounded by terminal repeat (TR) sequences that are inverted relative to one another as indicated by the directionality of the arrowheads. Second panel: To excise a transposon from DNA, the transposase proteins (purple and blue) bind the TRs, bringing them together, and the transposase enzymatic activity cuts the transposon out of the DNA, leaving a footprint in the host DNA that resembles the TRs. After excision from one site, the transposon reinserts elsewhere in the genome, in this case into a V-type immunoglobulin receptor (green). The enzymatic activity of the transposase enables the transposon to insert into DNA in a reaction that is the reverse of the excision reaction. Third panel: The integration of the *RAG1/2*-like transposon into the middle of the gene for a V-type immunoglobulin receptor splits the V exon into two parts. Fourth and fifth panels: In the evolution of the immunoglobulin and T-cell receptor genes, the initial integration event has been followed by DNA rearrangements that separate the transposase genes (now known as *RAG1* and *RAG2*) from the transposon TRs, which we now term the recombination signal sequences (RSSs). The purple sea urchin (an invertebrate deuterostome) has a *RAG1/2*-like gene cluster (not shown) and expresses proteins similar to RAG-1 and RAG-2 proteins, but does not have immunoglobulins, T-cell receptors, or adaptive immunity. The RAG-like proteins presumably retain some other cellular function (so far unknown) in this animal.

fulfilling some other cellular function. Current models propose that a Transib family transposon was present in this ancestral species and that ProtoRAG, the *RAG1–RAG2*-related genes in sea urchins, and the vertebrate *RAG1–RAG2* all descended from this primitive transposable element.

The evidence indicating the transposon origin of the RAG recombination system raises questions concerning the identities of the genes this transposon inserted into. Proteins containing Ig-like domains are ubiquitous throughout the plant, animal, and bacterial kingdoms, making this one of the most abundant protein superfamilies; in species whose genomes have been fully sequenced, the immunoglobulin superfamily is one of the largest families of protein domains in the genome. The functions of the members of this superfamily are very disparate, and they are a striking example of natural selection taking a useful structure—the basic Ig-domain fold—and adapting it to different purposes. The immunoglobulin superfamily domains can be divided into four families on the basis of differences in the structure and sequence of the immunoglobulin domain. These are V (resembling an immunoglobulin variable domain), C1 and C2 (resembling constant-region domains), and a type of immunoglobulin domain called an I domain (for intermediate). The target of the RSS-containing element is likely to have been a gene encoding a cell-surface receptor containing an Ig-like V domain, most probably a type similar to present-day VJ domains. These domains are found in some invariant receptor proteins and are so called because of the resemblance of one of the strands to a J segment. It is possible to imagine how transposon movement into such a gene could produce separate V and J gene segments (see Fig. 5.23). On the basis of phylogenetic analysis, **agnathan paired receptors resembling Ag receptors,** or **APARs**, which are encoded by a multigene family found in hagfish and lamprey, are currently the best candidates for being relatives of the ancestor of the antigen receptor. Their DNA sequences predict single-pass transmembrane proteins with a single extracellular VJ domain and a cytoplasmic region containing signaling modules. APARs are expressed in leukocytes.

5-16 Different species generate immunoglobulin diversity in different ways.

Most of the vertebrates we are familiar with generate a large part of their antigen-receptor diversity in the same way as mice and humans, by putting together gene segments in different combinations. There are exceptions, however, even within the mammals. Some animals use gene rearrangement to always join together the same V and J gene segment initially, and then diversify this recombined V region. In birds, rabbits, cows, pigs, sheep, and horses, there is little or no germline diversity in the V, D, and J gene segments that are rearranged to form the genes for the initial B-cell receptors, and the rearranged V-region sequences are identical or similar in most immature B cells. These immature B cells migrate to specialized microenvironments—the **bursa of Fabricius** in the gut of chickens, and another intestinal lymphoid organ in rabbits. Here, B cells proliferate rapidly, and their rearranged immunoglobulin genes undergo further diversification.

In birds and rabbits this diversification occurs mainly by gene conversion, a process by which short sequences in the expressed rearranged V-region gene are replaced with sequences from an upstream V gene segment pseudogene. The germline arrangement of the chicken heavy-chain locus is a single set of rearranging V, J, D, and C gene segments and multiple copies of V-segment pseudogenes. Diversity in this system is created by gene conversion in which sequences from the V_H pseudogenes are copied into the single rearranged V_H gene (Fig. 5.24). It seems that gene conversion is related to somatic hypermutation in its mechanism, because gene conversion in a chicken B-cell line has been shown to require the enzyme **activation-induced cytidine deaminase (AID)**.

Activation-Induced Cytidine Deaminase Deficiency

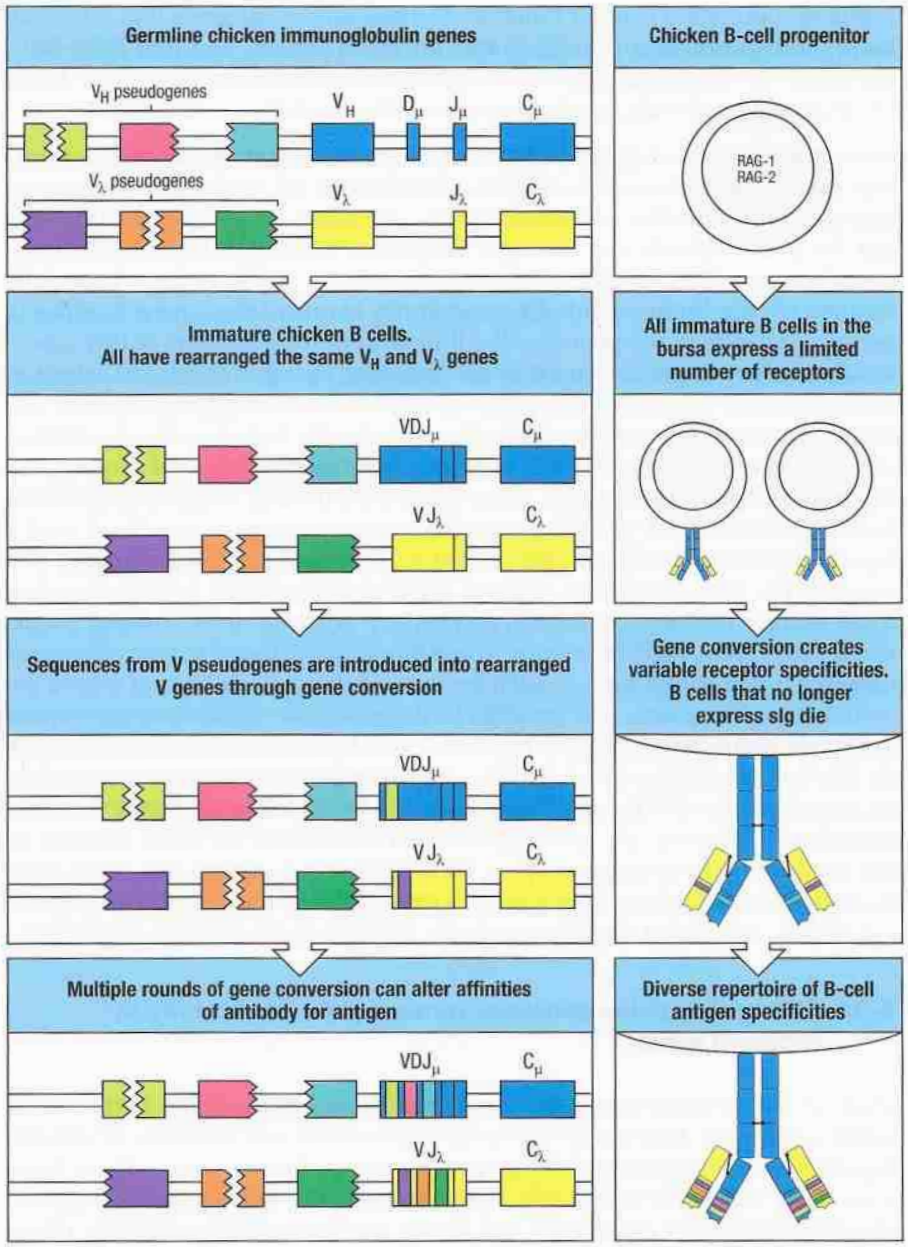

Fig. 5.24 The diversification of chicken immunoglobulins occurs through gene conversion. In chickens, the immunoglobulin diversity that can be created by V(D)J recombination is extremely limited. Initially, there are only one active V, one J, and 15 D gene segments at the chicken heavy-chain locus and one active V and one J gene segment at the single light-chain locus (top left panel). Primary gene rearrangement can thus produce only a very limited number of receptor specificities (second panels). Immature B cells expressing this receptor migrate to the bursa of Fabricius, where the cross-linking of surface immunoglobulin (sIg) induces cell proliferation (second panels). The chicken genome contains numerous pseudogenes with a pre-rearranged VH–D structure. Gene conversion events introduce sequences from these adjacent V gene segment pseudogenes into the expressed gene, creating diversity in the receptors (third panels). Some of these gene conversions will inactivate the previously expressed gene (not shown). If a B cell can no longer express sIg after such a gene conversion, it is eliminated. Repeated gene conversion events can continue to diversify the repertoire (bottom panels).

In Chapter 10, we will see that this same enzyme is involved in class switching and affinity maturation of the antibody response. For gene conversion, it is thought that single-strand cuts in DNA generated by the endonuclease **apurinic/apyrimidinic endonuclease-1 (APE1)** after the actions of AID are the signal that initiates a homology-directed repair process in which a homologous V pseudogene segment is used as the template for the DNA replication that repairs the V-region gene.

In sheep and cows, immunoglobulin diversification is the result of somatic hypermutation, which occurs in an organ known as the ileal Peyer's patch. Somatic hypermutation, independent of T cells and a particular driving antigen, also contributes to immunoglobulin diversification in birds, sheep, and rabbits.

A more fundamentally different organization of immunoglobulin genes is found in the cartilaginous fishes, the most primitive jawed vertebrates. Sharks have multiple copies of discrete V_L-J_L-C_L and V_H-D_H-J_H-C_H cassettes and activate rearrangement within individual cassettes (Fig. 5.25). Although this

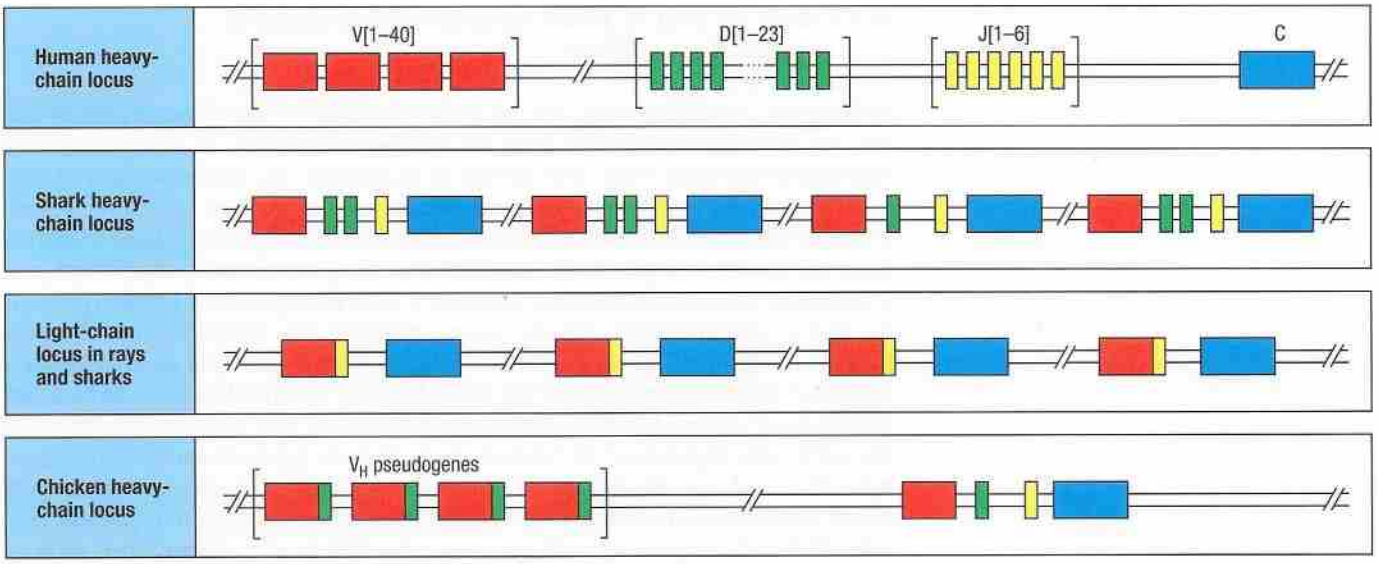

Fig. 5.25 The organization of immunoglobulin genes is different in different species, but all can generate a diverse repertoire of receptors. The organization of the immunoglobulin heavy-chain genes in mammals, in which there are separated clusters of repeated V, D, and J gene segments, is not the only solution to the problem of generating a diverse repertoire of receptors. Other vertebrates have found alternative solutions. In 'primitive' groups, such as the sharks, the locus consists of multiple repeats of a basic unit composed of a V gene segment, one or two D gene segments, a J gene segment, and a C gene segment. A more extreme version of this organization is found in the κ-like light-chain locus of some cartilaginous fishes such as the rays and the carcharhine sharks, in which the repeated unit consists of already rearranged VJ–C genes, from which a random choice is made for expression. In chickens, there is a single rearranging set of gene segments at the heavy-chain locus but there are multiple copies of pre-integrated V_H–D segment pseudogenes. Diversity in this system is created by gene conversion, in which sequences from the V_H–D pseudogenes are copied onto the single rearranged V_H gene.

is somewhat different from the kind of combinatorial gene rearrangement of higher vertebrates, in most cases there is still a requirement for a RAG-mediated somatic rearrangement event. As well as rearranging genes, cartilaginous fishes have multiple 'rearranged' V_L regions (and sometimes rearranged V_H regions) in the germline genome (see Fig. 5.25) and apparently generate diversity by activating the transcription of different copies. Even here, some diversity is also contributed by combinatorial means by the subsequent pairing of heavy and light chains.

This 'germline-joined' organization of the light-chain loci is unlikely to represent an intermediate evolutionary stage, because in that case the heavy-chain and light-chain genes would have had to independently acquire the capacity for rearrangement by convergent evolution. It is much more likely that, after the divergence of the cartilaginous fishes, some immunoglobulin loci became rearranged in the germline of various ancestors through activation of the RAG genes in germ cells, with the consequent inheritance of the rearranged loci by the offspring. In these species, the rearranged germline loci might confer some advantages, such as ensuring rapid responses to common pathogens by producing a preformed set of immunoglobulin chains.

The IgM antibody isotype is thought to go back to the origins of adaptive immunity. It is the predominant form of immunoglobulin in cartilaginous fishes and bony fishes. The cartilaginous fishes also have at least two other heavy-chain isotypes not found in more recently evolved species. One, **IgW**, has a constant region composed of six immunoglobulin domains, whereas the second, **IgNAR**, which we described in Section 4-13, seems to be related to IgW but has lost the first constant-region domain and does not pair with light chains. Instead, it forms a homodimer in which each heavy-chain V domain forms a separate antigen-binding site. IgW seems to be related to IgD (which is first found in bony fishes) and, like IgM, seems to go back to the origin of adaptive immunity.

5-17 Both αβ and γδ T-cell receptors are present in cartilaginous fishes.

Neither the T-cell receptors nor the immunoglobulins have been found in any species evolutionarily earlier than the cartilaginous fishes, in which they have essentially the same form that we see in mammals. The identification of TCR β-chain and δ-chain homologs from sharks and of distinct TCR α, β, γ, and δ chains from a skate show that even at the earliest time that these adaptive immune system receptors can be identified, they had already diversified into at least two recognition systems. Moreover, each lineage shows diversity resulting from combinatorial somatic rearrangement. The identification of many ligands recognized by γδ T cells has helped clarify their role in the immune response. Although a complete list is still lacking, the trend appears to be more similar to a kind of innate sensing rather than the fine peptide specificity of the αβ T cells. Ligands of γδ T cells include various lipids that may derive from microbes and nonclassical MHC class Ib molecules whose expression may be an indication of infection or cellular stress (see Section 6-17). Even certain αβ T cells appear to participate in a form of innate recognition, such as the mucosal associated invariant T cells described in Section 4-21. This could indicate that early in the evolution of RAG-dependent adaptive immunity, the receptors generated by excision of the primordial DNA transposon were useful in innate sensing of infections, and this role has persisted in certain minor T-cell populations to this day. In any case, the very early divergence of these two classes of T-cell receptors and their conservation through subsequent evolution suggests an important early separation of functions.

5-18 MHC class I and class II molecules are also first found in the cartilaginous fishes.

One would expect to see the specific ligands of T-cell receptors, the MHC molecules, emerge at around the same time in evolution as the receptors. Indeed, MHC molecules are present in the cartilaginous fishes and in all higher vertebrates, but, like the T-cell receptors, they have not been found in agnathans or invertebrates. Both MHC class I and class II α-chain and β-chain genes are present in sharks, and their products seem to function in an identical way to mammalian MHC molecules. The key residues of the peptide-binding cleft that interact with the ends of the peptide in MHC class I molecules or with the central region of the peptide in MHC class II molecules are conserved in shark MHC molecules.

Moreover, the MHC genes are also polymorphic in sharks, with multiple alleles of class I and class II loci. In some species, more than 20 MHC class I alleles have been identified so far. For the shark MHC class II molecules, both the class II α and the class II β chains are polymorphic. Thus, not only has the function of the MHC molecules in selecting peptides for presentation evolved during the divergence of the agnathans and the cartilaginous fishes, but the continuous selection imposed by pathogens has also resulted in the polymorphism that is a characteristic feature of the MHC.

Section 4-23 introduced the division between **classical MHC class I genes** (sometimes called class Ia) and the **nonclassical MHC class Ib genes**, which will be discussed in Chapter 6. This division is also present in cartilaginous fishes, because the class I genes of sharks include some that resemble mammalian class Ib molecules. However, it is thought that the shark class Ib genes are not the direct ancestors of the mammalian class Ib genes. For the class I genes, it seems that within each of the five major vertebrate lineages studied (cartilaginous fishes, lobe-finned fishes, ray-finned fishes, amphibians, and mammals), these genes have independently separated into classical and nonclassical loci.

Thus, the characteristic features of the MHC molecules are all present when these molecules are first encountered, and there are no intermediate forms to guide our understanding of their evolution. Although we can trace the evolution of the components of the innate immune system, the origin of the adaptive immune system remains largely mysterious. Although we may not have a sure answer to the question of what selective forces led to RAG-dependent elaboration of adaptive immunity, it has never been clearer that, as Charles Darwin remarked about evolution in general, "from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved."

Summary.

Evolution of RAG-dependent adaptive immunity in jawed vertebrates was once considered a wholly unique and inexplicable 'immunological Big Bang.' However, we now understand that adaptive immunity has also evolved independently at least one other time during evolution. Our close vertebrate cousins, the jawless fishes, have evolved an adaptive immune system built on a completely different basis—the diversification of LRR domains rather than immunoglobulin domains—but otherwise seem to have the essential features of clonal expression of receptors produced through a somatic rearrangement and with a form of immunological memory, all features of an adaptive immune system. We now appreciate that evolution of the RAG-dependent adaptive immune system is probably related to the insertion of a transposon into a member of a primordial immunoglobulin superfamily gene, which must have occurred in a germline cell in an ancestor of the vertebrates. By chance, the transposon terminal sequences, the forerunners of the RSSs, were placed in an appropriate location within this primordial antigen-receptor gene to enable intramolecular somatic recombination, thus paving the way for the full-blown somatic gene rearrangement seen in present-day immunoglobulin and T-cell receptor genes. The MHC molecules that are the ligands for T-cell receptors first appear in the cartilaginous fishes, suggesting coevolution with RAG-dependent adaptive immunity. The transposase genes (the RAG genes) could have already been present and active in some other function in the genome of this ancestor. Both *RAG1* and *RAG2* have very ancient origins, as related sequences have been found in a wide variety of animal genomes.

Summary to Chapter 5.

The antigen receptors of lymphocytes are remarkably diverse, and developing B cells and T cells use the same basic mechanism to achieve this diversity. In each cell, functional genes for the immunoglobulin and T-cell receptor chains are assembled by somatic recombination from sets of separate gene segments that together encode the V region. The substrates for the joining process are arrays of V, D, and J gene segments, which are similar in all the antigen-receptor gene loci. The lymphoid-specific proteins RAG-1 and RAG-2 direct the site-specific cleavage of DNA at RSSs flanking the V, D, and J segments to form double-strand breaks that initiate the recombination process in both T and B cells. These proteins function in concert with ubiquitous DNA-modifying enzymes acting in the double-strand break repair pathway, and with at least one other lymphoid-specific enzyme, TdT, to complete the gene rearrangements. As each type of gene segment is present in multiple, slightly different versions, the random selection of one gene segment from each set is a source of substantial potential diversity. During assembly, the imprecise joining mechanisms at the coding junctions create a high degree of diversity concentrated in the CDR3 loops of the receptor, which lie at the center of the antigen-binding sites. The independent association of the two chains of immunoglobulins

or T-cell receptors to form a complete antigen receptor multiplies the overall diversity available. An important difference between immunoglobulins and T-cell receptors is that immunoglobulins exist in both membrane-bound forms (B-cell receptors) and secreted forms (antibodies). The ability to express both a secreted and a membrane-bound form of the same molecule is due to alternative splicing of the heavy-chain mRNA to include exons that encode different forms of the carboxyl terminus. Heavy-chain C regions of immunoglobulins contain three or four domains, whereas the T-cell receptor chains have only one. Other species have developed strategies to diversify receptors involved in immunity, and the agnathans use a system of VLRs that undergo somatic rearrangement that has some specific similarities to our own adaptive immune system. Adaptive immunity in jawed vertebrates—gnathostomes—appears to have arisen by the integration of a DNA transposon that encoded prototype RAG1/2 genes into a preexisting V-type immunoglobulin-like gene that subsequently diversified to generate T- and B-cell receptor genes.

Discussion Questions

5.1 Antibody heavy-chain V regions are encoded by a series of gene segments that are separated in the genome. After somatic rearrangement, these gene segments can potentially create about 5000 different antibody V_H sequences. Approximately 300 V_L sequences can be generated by somatic rearrangement of light-chain gene segments. After random pairing of one light chain and one heavy chain, approximately 1 million different antibody specificities can be generated. Yet, estimates indicate that the final repertoire of antibodies that can be created by V(D)J recombination is of the order 10^{13} different sequences. How is all of the 'extra' diversity created during antibody heavy- and light-chain gene segment rearrangement?

5.2 Antibody and T-cell receptor gene segment rearrangement is guided by DNA sequences flanking each gene segment. Early studies identified 'the 12/23 rule' on the basis of observations that gene segments flanked by recombination signal sequences (RSSs) containing a 12-bp spacer were always joined to a gene segment flanked by an RSS containing a 23-bp spacer. How does the three-dimensional structure of the RAG-1:RAG-2 complex bound to DNA explain this rule?

5.3 There are both lymphocyte-specific and ubiquitous (that is, expressed in all cell types) enzymes involved in the process of V(D)J recombination. Name two examples of each category of enzyme and describe their function in V(D)J recombination.

5.4 Some inherited immunodeficiency disorders are caused by mutations in genes important in V(D)J recombination. Several of these also cause patients to be hypersensitive to ionizing radiation. What is the reason for the sensitivity to radiation in this class of immunodeficiency patients?

5.5 Mature B cells express membrane-bound IgM and IgD molecules that share the same specificity on their cell surface. How does a B cell express both IgM and IgD heavy-chain proteins with the same V_H sequences present in both?

5.6 Deficiencies in RAG-1 or RAG-2 cause a form of SCID in which patients lack both B cells and T cells. Why is this the case?

5.7 Mature T cells never express both $\alpha\beta$ and $\gamma\delta$ T-cell receptor heterodimers on their surface. What aspect of the T-cell antigen-receptor gene loci accounts for this finding?

5.8 Several invertebrate species have been found to express antigen-binding proteins and cellular receptors with a high degree of diversity similar to the antibody and T-cell receptor repertoires in vertebrates. Yet the antigen-binding proteins in invertebrates bear no resemblance to immunoglobulin proteins or immunoglobulin superfamily members. Describe one of these alternative systems of antigen-binding proteins in an invertebrate and how repertoire diversity is generated in this system.

5.9 In some vertebrate species, such as rabbits and birds, antibody diversity is generated by a mechanism distinct from the V(D)J recombination system used in humans and mice. Describe this mechanism of antibody sequence diversification and name the key enzyme and its function that is required for this process.

Antigen Presentation to T Lymphocytes

6

IN THIS CHAPTER

The generation of αβ T-cell receptor ligands.

The major histocompatibility complex and its function.

Recognition of nonpeptide ligands by unconventional T-cell subsets.

Vertebrate adaptive immune cells possess two types of antigen receptors: the immunoglobulins that serve as antigen receptors on B cells, and the T-cell receptors. While immunoglobulins can recognize native antigens, T cells recognize only antigens that are displayed by MHC complexes on cell surfaces. The conventional **αβ T cells** recognize antigens as peptide:MHC complexes (see Section 4-15). The peptides recognized by αβ T cells can be derived from the normal turnover of self proteins, or from proteins derived from intracellular pathogens such as viruses, or from the extracellular fluids. Various tolerance mechanisms normally prevent self peptides from initiating an immune response; when these mechanisms fail, self peptides can become the target of autoimmune responses, as discussed in Chapter 15. Other classes of T cells, such as **NKT cells**, **MAIT cells**, and **γδ T cells** (see Section 4-23), recognize different types of surface molecules whose expression may indicate infection or cellular stress.

The first part of this chapter describes the cellular pathways used by various types of cells to generate peptide:MHC complexes recognized by αβ T cells. This process participates in adaptive immunity in at least two different ways. In somatic cells, peptide:MHC complexes can signal the presence of an intracellular pathogen for elimination by armed effector T cells. In dendritic cells and B lymphocytes, which may not themselves be infected, peptide:MHC complexes serve to activate antigen-specific effector T cells. We will also introduce mechanisms by which certain pathogens defeat adaptive immunity by blocking the production of peptide:MHC complexes.

The second part of this chapter focuses on the MHC class I and class II genes and their tremendous variability. The MHC molecules are encoded within a large cluster of genes that were first identified by their powerful effects on the immune response to transplanted tissues and were therefore called the major histocompatibility complex (MHC). There are several different MHC molecules in each class, and each of their genes is highly polymorphic, with many variants present in the population. MHC polymorphism has a profound effect on antigen recognition by T cells, and the combination of multiple genes and polymorphism greatly extends the range of peptides that can be presented to T cells in each individual and in populations as a whole, thus enabling individuals to respond to the wide range of potential pathogens they will encounter. The MHC also contains genes other than those for the MHC molecules; some of these genes are involved in the processing of antigens to produce peptide:MHC complexes.

The last part of the chapter discusses the ligands for unconventional classes of T cells. We will examine a group of proteins similar to MHC class I molecules that have limited polymorphism and that were called **nonclassical MHC class I proteins** in the past. Some are encoded within the MHC; others are encoded outside the MHC. These MHC class I–like proteins serve various functions, with some acting as ligands for γδ T-cell receptors or as ligands for NKG2D expressed by T cells and NK cells. We also discuss a special subset of αβ T cells called NKT cells, which recognize nonpeptide ligands, including microbial lipid antigens that are presented by several MHC class I–like proteins.

The generation of αβ T-cell receptor ligands.

The protective function of T cells depends on their recognition of cells harboring intracellular pathogens or that have internalized their products. As we saw in Chapter 4, the ligand recognized by an αβ T-cell receptor is a peptide bound to an MHC molecule and displayed on a cell surface. The generation of peptides from native proteins is commonly referred to as **antigen processing**, while peptide display at the cell surface by the MHC molecule is referred to as **antigen presentation**. We have already described the structure of MHC molecules and seen how they bind peptide antigens in a cleft, or groove, on their outer surface (see Sections 4-15 to 4-20). We will now look at how peptides are generated from the proteins derived from pathogens and how they are loaded onto MHC class I or MHC class II molecules.

6-1 Antigen presentation functions both in arming effector T cells and in triggering their effector functions to attack pathogen-infected cells.

The processing and presentation of pathogen-derived antigens has two distinct purposes: expanding cohorts of effector T cells, and then activating these effector functions at sites where antigens are encountered. MHC class I molecules bind peptides that are recognized by CD8 T cells, and MHC class II molecules bind peptides that are recognized by CD4 T cells, a pattern of recognition determined by specific binding of the TCR and the CD8 or CD4 co-receptor molecules to the respective MHC molecules (see Section 4-21). The importance of this specificity of recognition lies in the different distributions of MHC class I and class II molecules on cells throughout the body and the cellular locations from which their antigens are derived. MHC class I molecules are expressed by nearly all somatic cells (except red blood cells), and consequently, CD8 T cells are primarily responsible for surveillance and cytolysis of somatic cells. Also called **cytotoxic T cells**, effector CD8 T cells kill the cells on which they recognize antigen and help eliminate cells infected with viruses or bacteria that live only in the cytosol. They can also recognize allogeneic MHC class I expressed on organ transplants and cause their rejection or recognize mutated self proteins on cancer cells and help eliminate them.

In contrast, MHC class II molecules are expressed primarily on cells of the immune system, and particularly by dendritic cells, macrophages, B cells, and thymic cortical epithelial cells; they can also be induced on many cells in response to the cytokine IFN-γ. Activated human T cells also express MHC class II molecules. Thus, during their development, CD4 T cells recognize antigens presented by cells in the thymus, and later, they recognize antigens presented only by certain types of immune cells or somatic cells under specific inflammatory conditions. **Effector CD4 T cells** comprise several subsets with different activities. Importantly, naive CD8 and CD4 T cells can become armed effector cells only after encountering their cognate antigen once it has been processed and presented by activated dendritic cells.

In considering antigen processing, it is important to distinguish between the various cellular compartments from which antigens can be derived (Fig. 6.1). These compartments, which are separated by membranes, include the **cytosol** and the various **vesicular compartments** involved in endocytosis and secretion. Peptides derived from the cytosol are transported into the endoplasmic reticulum and either further cut by peptidases or directly loaded onto newly synthesized MHC class I molecules on the same cell for recognition by T cells, as we will discuss later in greater detail. Because viruses and some bacteria replicate in the cytosol or in the contiguous nuclear compartment, peptides

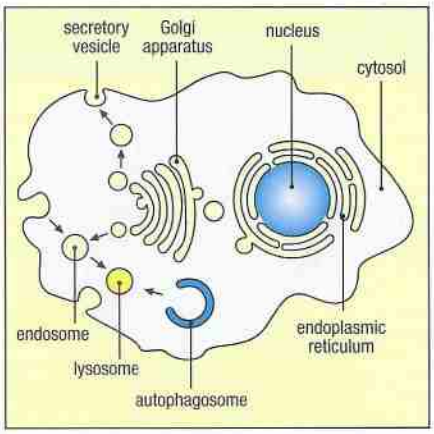

Fig. 6.1 There are two categories of major intracellular compartments, separated by membranes. One compartment is the cytosol, which communicates with the nucleus via pores in the nuclear membrane. The other is the vesicular (also vacuolar) system, which comprises the vesicular compartments: the endoplasmic reticulum, Golgi apparatus, endosomes, lysosomes, and other intracellular vesicles. The vesicular system can be thought of as being continuous with the extracellular fluid. Secretory vesicles bud off from the endoplasmic reticulum and are transported via fusion with Golgi membranes to move vesicular contents out of the cell. Extracellular material is taken up by endocytosis or phagocytosis into endosomes or phagosomes, respectively. The fusion of incoming and outgoing vesicles is important both for pathogen destruction in cells such as neutrophils and for antigen presentation. Autophagosomes surround components in the cytosol and deliver them to lysosomes in a process known as autophagy.

from their components can be loaded onto MHC class I molecules by this process (Fig. 6.2, first panel). This pathway of recognition is sometimes referred to as **direct presentation** and can identify both somatic and immune cells that are infected by a pathogen.

Certain pathogenic bacteria and protozoan parasites can survive ingestion by macrophages and are able to replicate inside the intracellular vesicles of the endosomal–lysosomal system (Fig. 6.2, second panel). Antigens derived from such pathogens are processed for presentation by MHC class II molecules. Similarly, pathogenic bacteria that proliferate outside of cells can be taken up, along with their toxic products, by phagocytosis, receptor-mediated endocytosis, or macropinocytosis into endosomes and lysosomes, where they are broken down by digestive enzymes. Receptor-mediated endocytosis by B cells can efficiently internalize extracellular antigens through B-cell receptors, which are then processed and presented by MHC class II molecules (Fig. 6.2, third panel). Virus particles and parasite antigens in extracellular fluids can also be taken up by these routes and degraded, and their peptides presented to T cells.

Some pathogens may infect somatic cells without directly infecting phagocytes, such as dendritic cells. In this case, dendritic cells must acquire antigens from exogenous sources in order to process and present a pathogen's antigens to T cells. For example, for a virus that infects only epithelial cells, the activation of virus-specific CD8 T cells requires that dendritic cells process viral proteins acquired from the virally infected cells and load peptides derived from them onto MHC class I molecules. This exogenous pathway of loading MHC class I molecules is called **cross-presentation** and is carried out very efficiently by

	Cytosolic pathogens	Intravesicular pathogens	Extracellular pathogens and toxins
			Degraded in	Cytosol	Endocytic vesicles (low pH)	Endocytic vesicles (low pH)
Peptides bind to	MHC class I	MHC class II	MHC class II
Presented to	Effector CD8 T cells	Effector CD4 T cells	Effector CD4 T cells
Effect on presenting cell	Cell death	Activation of macrophage to kill intravesicular bacteria and parasites	Activation of B cells to secrete Ig to eliminate extracellular bacteria/ toxins/viruses

Fig. 6.2 Cells become targets of T-cell recognition by acquiring antigens from either the cytosolic or the vesicular compartments. First panel: Viruses and some bacteria replicate in the cytosolic compartment. Their antigens (shown as red dots) are presented by MHC class I molecules to activate killing by cytotoxic CD8 T cells. Second panel: Other bacteria and some parasites are taken up into endosomes, usually by specialized phagocytic cells such as macrophages. Here they are killed and degraded or in some cases are able to survive and proliferate within the vesicle. Their antigens are presented by MHC class II molecules to activate cytokine production by CD4 T cells. Third panel: Proteins derived from extracellular pathogens may bind to cell-surface receptors and enter the vesicular system by endocytosis, illustrated here for antigens bound by the surface immunoglobulin of B cells. These antigens are presented by MHC class II molecules to CD4 helper T cells, which can then stimulate the B cells to produce antibody.

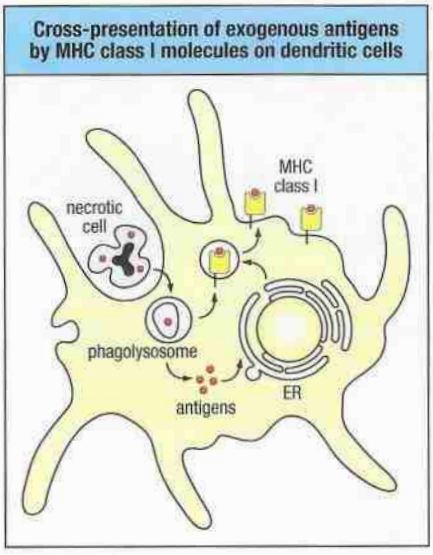

Fig. 6.3 Cross-presentation of extracellular antigens on MHC class I molecules by dendritic cells. Certain subsets of dendritic cells, especially cDC1, are efficient in capturing exogenous proteins from necrotic cells and loading peptides (red) derived from them onto MHC class I molecules. Evidence derived largely from studies of cells *in vitro* suggests that several cellular pathways may be involved. One route may involve the translocation of ingested proteins from the phagolysosome into the cytosol for degradation by the proteasome, with the resultant peptides then passing through a TAP transporter (see Section 6-3) and into the endoplasmic reticulum (ER) or phagosome, where they load onto MHC class I molecules in the usual way. Another route may involve direct transport of antigens into a phagolysosome—without passage through the cytosol—where they are processed into peptides and allowed to be bound to either mature MHC class I molecules or peptide-loading complexes that have been delivered there. These are called the cytosolic and vacuolar (or vesicular) pathways, respectively.

some specialized types of dendritic cells (Fig. 6.3). The activation of naive T cells by this pathway is called **cross-priming**. Cross-presentation and cross-priming are also important in CD8 T cells' responses to many tumors.

For loading peptides onto MHC class II molecules, dendritic cells, macrophages, and B cells are able to capture exogenous proteins via endocytic vesicles and through specific cell-surface receptors. For B cells, this process of antigen capture can include the B-cell receptor. The peptides that are derived from these proteins are loaded onto MHC class II molecules in specially modified endocytic compartments in these antigen-presenting cells, which we will discuss in more detail later. In dendritic cells, this pathway operates to activate naive CD4 T cells to become effector T cells. Macrophages take up particulate material by phagocytosis and mainly present pathogen-derived peptides on MHC class II molecules. In macrophages, such antigen presentation may also indicate the presence of a pathogen within its own vesicular compartment. Effector CD4 T cells, on recognizing antigen, produce cytokines that can stimulate the macrophage to destroy the pathogen. Some intravesicular pathogens have adapted to resist intracellular killing, and the macrophages in which they live require stimulation by cytokines in order to kill these pathogens. This is one of the roles of the T_H1 subset of CD4 T cells, which we will elaborate in Section 11-6. Other CD4 T-cell subsets have roles in regulating other aspects of the immune response. In B cells, antigen presentation by MHC class II molecules may recruit help from CD4 T cells that recognize peptides derived from the same protein recognized and by the surface immunoglobulin of a B cell. The B cell takes up such proteins by endocytosis, processes and presents peptides derived from them on MHC class II molecules, and thereby can activate CD4 T cells that will serve in turn as helper T cells for the production of antibodies against that antigen.

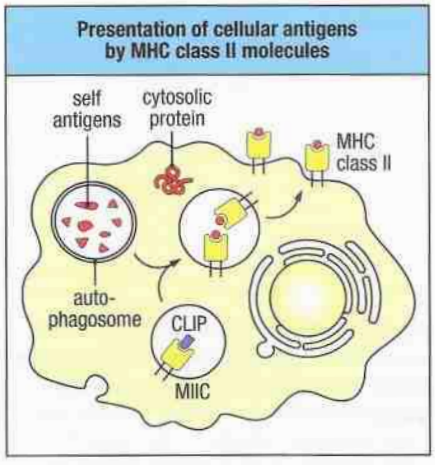

Fig. 6.4 Autophagy pathways can deliver cytosolic antigens for presentation by MHC class II molecules. In the process of autophagy, portions of the cytoplasm are taken into autophagosomes, which are specialized double-membrane vesicles that are fused with endocytic vesicles and eventually with lysosomes, where the contents are catabolized. Some of the resulting peptides of this process can be bound to MHC class II molecules and presented on the cell surface. In dendritic cells and macrophages, this can occur in the absence of activation, so that immature dendritic cells may express self peptides in a tolerogenic context, rather than inducing T-cell responses to self antigens. CLIP, class II–associated invariant chain peptide; MIIC, MHC class II compartment.

Beyond the presentation of exogenous proteins, MHC class II molecules can also be loaded with peptides derived from cytosolic proteins by a ubiquitous pathway of **autophagy**, in which cytoplasmic proteins are delivered into the endocytic system for degradation in lysosomes (Fig. 6.4). This pathway can serve in the presentation of self-cytosolic proteins for the induction of tolerance to self antigens, and also as a means for presenting antigens from pathogens that have accessed the cell's cytosol, such as herpes simplex virus.

6-2 Peptides are generated from ubiquitinated proteins in the cytosol by the proteasome.

Proteins in cells are continually being degraded and replaced with newly synthesized proteins. Much cytosolic protein degradation is carried out by a large, multicatalytic protease complex called the **proteasome** (Fig. 6.5). A typical proteasome is composed of one **20S catalytic core** and two **19S regulatory caps**, one at each end; both the core and the caps are multi-subunit complexes of proteins. The 20S core is a large cylindrical complex of some 28 subunits, arranged in four stacked rings of seven subunits each around a hollow core. The two outer rings are each composed of seven distinct α subunits

and are noncatalytic. The two inner rings of the 20S proteasome core are each composed of seven distinct β subunits. The constitutively expressed **proteolytic subunits are β1, β2, and β5**, which form a part of the catalytic chamber. The 19S regulator is composed of a base containing nine subunits that binds directly to the α ring of the 20S core particle and a lid that has up to 10 different subunits. The association of the 20S core with a 19S cap requires ATP as well as the ATPase activity of many of the cap's subunits. One of the 19S caps binds and delivers proteins into the proteasome, while the other keeps them from exiting prematurely.

Proteins in the cytosol are tagged for degradation via the **ubiquitin–proteasome system (UPS)**. This begins with the attachment of a chain of several ubiquitin molecules to the target protein, a process called **ubiquitination**. First, a lysine residue on the targeted protein is chemically linked to the glycine at the carboxyl terminus of one ubiquitin molecule. Ubiquitin chains are then formed by linking the lysine at residue 48 (K48) of the first ubiquitin to the carboxyl-terminal glycine of a second ubiquitin, and so on until at least four ubiquitin molecules are bound. This K48-linked type of ubiquitin chain is recognized by the 19S cap of the proteasome, which then unfolds the tagged protein so that it can be introduced into the proteasome's catalytic core. There the protein chain is degraded with a general lack of sequence specificity into short peptides, which are subsequently released into the cytosol. The general degradative functions of the proteasome have been co-opted for antigen presentation, so that MHC molecules have evolved to work with the peptides that the proteasome can produce.

The proteasome is the set of cytosolic proteases responsible for generating the majority of MHC I–presented peptides, but it is possible that some peptides are generated by other proteases. Moreover, not only can the proteasome cleave proteins, but it can also splice some resulting peptides back together by the action of a transpeptidase reaction to generate novel fused sequences. Such spliced sequences can be presented on MHC I molecules and be recognized by CD8 T cells.

The constitutive β1, β2, and β5 subunits of the catalytic chamber of the proteasome are sometimes replaced by three alternative catalytic subunits to form the **immunoproteasome**. These induced subunits are called **β1i (or LMP2), β2i (or MECL-1), and β5i (or LMP7)** and are constitutively expressed in dendritic cells and lymphocytes but induced in other cells by interferons. Both β1i and β5i are encoded by the genes *PSMB9* and *PSMB8*, which are located in the MHC locus, whereas β2i is encoded by *PSMB10* outside the MHC locus. Thus, the proteasome can exist both as a constitutive proteasome present in all cells and as the immunoproteasome present in dendritic cells, lymphocytes, and other cells stimulated with interferons. The two types of proteasome produce some non-overlapping peptides. A particular cell will have the standard proteasome with a number of immunoproteasomes that vary with cell type and interferon exposure. The replacement of the β subunits by their interferon-inducible counterparts alters the enzymatic specificity of the proteasome such that there is increased cleavage of polypeptides after hydrophobic and basic residues and decreased cleavage after acidic residues. This produces peptides with carboxyl-terminal residues that are preferred anchor residues for binding to most MHC class I molecules (see Chapter 4) and are also the preferred substrate for transport into the endoplasmic reticulum by a heterodimeric peptide transporter called TAP (see Section 6-3).

Another substitution for a β subunit in the catalytic chamber has been found to occur in cells in the thymus. Epithelial cells of the thymic cortex (**cTECs**) express a unique β subunit, called **β5t**, which is encoded by *PSMB11*. In cTECs, β5t becomes a component of the proteasome in association with β1i and β2i, and this specialized type of proteasome is called the **thymoproteasome**. Mice lacking expression of β5t have reduced numbers of CD8 T cells, indicating that the peptide:MHC complexes produced by the thymoproteasome are important in CD8 T-cell development in the thymus.

Fig. 6.5 Cytosolic proteins are degraded by the ubiquitin–proteasome system into short peptides. The proteasome is composed of a 20S catalytic core, which consists of four multi-subunit rings (see text), and two 19S regulatory caps, one on either end. Proteins (red) that are targeted become covalently tagged with K48-linked polyubiquitin chains (yellow) through the actions of various E3 ligases (see Section 3-7). The 19S regulatory cap recognizes polyubiquitin and draws the tagged protein inside the catalytic chamber; there, the protein is degraded, giving rise to small peptide fragments that are released back into the cytoplasm.

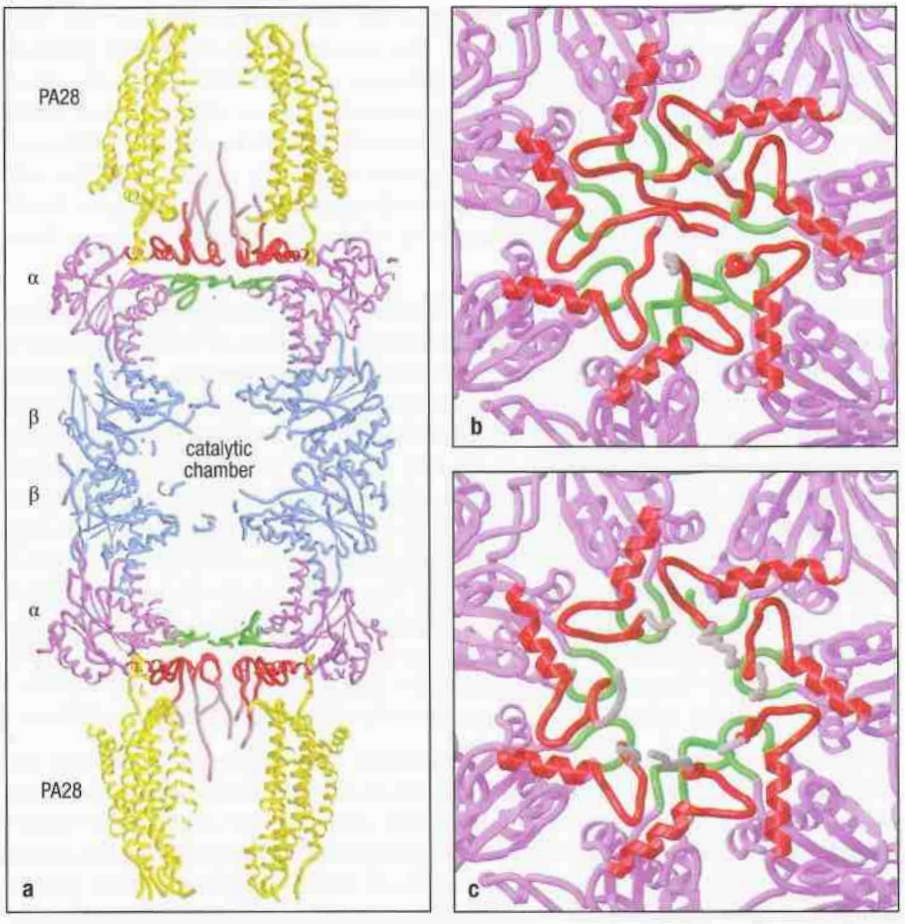

Fig. 6.6 The PA28 proteasome activator binds to either end of the proteasome. Panel a: In this side-view cross section, the heptamer rings of the PA28 proteasome activator (yellow) interact with the α subunits (pink) at either end of the core proteasome (the β subunits that make up the catalytic cavity of the core are in blue). Within this region is the α-annulus (green), a narrow ringlike opening that is normally blocked by other parts of the α subunits (shown in red). Panel b: A close-up view from the top, looking into the α-annulus without PA28 bound. Panel c: With the same perspective, the binding of PA28 to the proteasome changes the conformation of the α subunits, moving those parts of the molecule that block the α-annulus, and opening the end of the cylinder. For simplicity, PA28 is not shown.

Interferon-γ (IFN-γ) can further influence the production of some antigenic peptides by inducing expression of the **PA28 proteasome-activator complex** that binds to the proteasome. PA28 is a six- or seven-membered ring composed of two proteins, PA28α and PA28β, both of which are induced by IFN-γ. The PA28 ring can bind to either end of the 20S proteasome core in place of the 19S regulatory cap (Fig. 6.6). The exact function of the PA28:20S proteasome complex is still unclear, but it may increase the presentation of some peptides. PA28 does not affect rates of protein hydrolysis by the proteasome but may reduce the size of peptides generated.

Translation of self or pathogen-derived mRNAs in the cytoplasm generates not only properly folded proteins but also a significant quantity—possibly up to 30%—of peptides and proteins that are known as **defective ribosomal products (DRiPs)**. These include peptides translated from introns in improperly spliced mRNAs, translations of frameshifts, improperly folded cytoplasmic proteins, and membrane or secreted proteins that fail to enter the endoplasmic reticulum. Such proteins are tagged by ubiquitin for degradation by the proteasome. This seemingly wasteful process might help to generate peptide substrates from self proteins and proteins derived from pathogens for eventual presentation by MHC class I proteins.

6-3 Peptides from the cytosol are transported by TAP into the endoplasmic reticulum and further processed before binding to MHC class I molecules.

The polypeptide chains of proteins destined for the cell surface, such as the two chains of MHC molecules, are translocated during synthesis into the lumen of the endoplasmic reticulum, where two chains fold correctly and assemble with

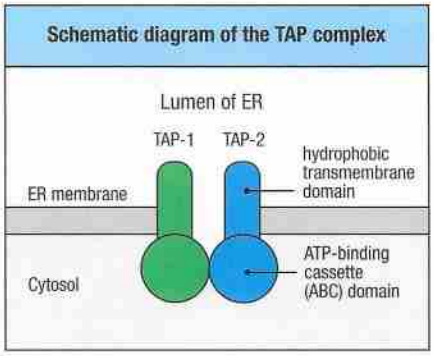
each other. This means the peptide-binding site of the MHC class I molecule is formed in the lumen of the endoplasmic reticulum and is never exposed to the cytosol. However, the antigen fragments that bind to MHC class I molecules are typically derived from proteins made in the cytosol. This raises the question: How are these peptides able to bind to MHC class I molecules and be delivered to the cell surface?

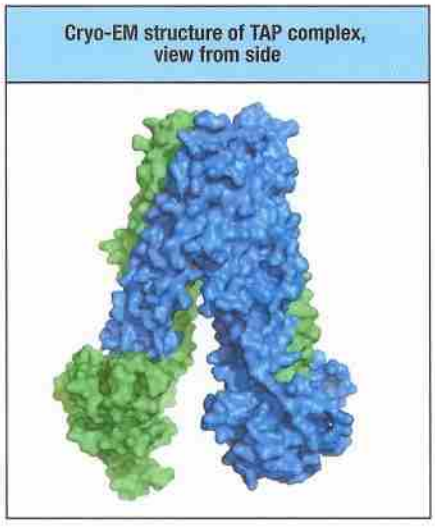
The answer was discovered through studies of mutant cell lines that had a defect in antigen presentation by MHC class I molecules. These cells expressed far fewer MHC class I proteins than normal on their surface despite normal synthesis of these molecules in the cytoplasm. The addition of synthetic peptides to the culture medium restored surface expression of MHC class I proteins, and it was hypothesized that these cells may have a defect in supplying peptides to MHC class I molecules during their assembly. These mutant cells were discovered to have defects in two genes that were members of the **ATP-binding cassette (ABC)** family of proteins that mediate the ATP-dependent transport of ions, sugars, amino acids, and peptides across membranes.

The defective genes were named **Transporters associated with antigen processing-1 and -2 (*TAP1* and *TAP2*)**, and their protein products are normally associated with the endoplasmic reticulum membrane. Transfection of the mutant cells with correct versions of the defective genes restored the presentation of peptides by MHC class I molecules. The two TAP proteins form a heterodimer in the membrane (Fig. 6.7), and mutations in either TAP gene can prevent antigen presentation by MHC class I molecules. The genes *TAP1* and *TAP2* are located in the MHC locus (see Section 6-10), near *PSMB9* and *PSMB8*, and their basal level of expression is further enhanced by interferons produced in response to viral infection, similar to MHC class I and β1i, β2i, and β5i subunits of the proteasome. This induction results in increased delivery of cytosolic peptides into the endoplasmic reticulum. When this delivery of peptides is disrupted, as in *TAP*-mutant cells, newly synthesized MHC class I molecules are retained in a partially folded state in the endoplasmic reticulum. Rare human individuals with immunodeficiency due to defects in *TAP1* and *TAP2* also have few MHC class I molecules on their cell surfaces, a condition known as **MHC class I deficiency**.

Microsomal vesicles from nonmutant cells can mimic the endoplasmic reticulum in assays *in vitro* by internalizing peptides that then bind to MHC class I molecules present in the lumen of the microsome. In contrast, vesicles from TAP-1–deficient or TAP-2–deficient cells do not take up peptides. Peptide transport into normal microsomes requires ATP hydrolysis, confirming that the TAP-1:TAP-2 complex is an ATP-dependent peptide transporter. The TAP complex will transport peptides of between 8 and 16 amino acids in length and prefers to transport peptides that have hydrophobic or basic residues at the carboxyl terminus. Such residues at the carboxyl terminus are precisely the ones preferentially generated by the proteasome and needed for binding to MHC class I molecules (see Section 4-18). In addition to its carboxyl-terminal residue preference, the TAP transporter has a bias against proline in the first three amino acid residues; otherwise, there is no other known peptide-sequence specificity. Cytosolic peptides are short lived, and the vast majority

MHC Class I Deficiency





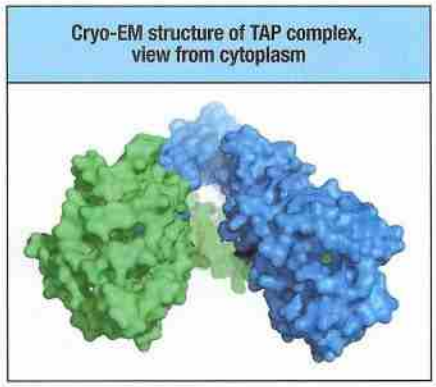


Fig. 6.7 TAP-1 and TAP-2 form a peptide transporter in the endoplasmic reticulum membrane. Upper panel: TAP-1 and TAP-2 are individual polypeptide chains, each with one hydrophobic and one ATP-binding domain. The two chains assemble into a heterodimer to form a four-domain transporter typical of the ATP-binding cassette (ABC) family. The hydrophobic transmembrane domains have multiple transmembrane regions (not shown here). The ATP-binding domains lie within the cytosol, whereas the hydrophobic domains project through the membrane into the lumen of the endoplasmic reticulum (ER) to form a channel through which peptides can pass. The middle and lower panels show surface representations of the TAP-1:TAP-2 heterodimer as determined by cryo-electron microscopy (cryo-EM), viewed from the side (middle panel) and from the cytoplasm (lower panel), the latter revealing a hollow channel through which peptides can pass.

of peptides generated by the proteasome are eventually destroyed. The discovery of TAP explained how viral peptides from proteins synthesized in the cytosol gain access to the lumen of the endoplasmic reticulum and are swiftly presented by MHC class I molecules.

The carboxyl terminus of peptide antigens appears to be produced by cleavage in the proteasome. However, the amino terminus of peptides that are too long to bind MHC class I molecules can be trimmed by an enzyme called the **endoplasmic reticulum aminopeptidase associated with antigen processing (ERAAP)**, also called **ERAP1**, and in humans by a second enzyme, **ERAP2**. Like other components of the antigen-processing pathway, expression of ERAP1 is increased by IFN-γ stimulation. ERAP1 strongly prefers peptides that are 9–16 residues in length, precisely those that are efficiently transported by TAP into the endoplasmic reticulum, but spares peptides of 8–9 amino acids. Mice lacking ERAP1 have an altered repertoire of peptides loaded onto MHC class I molecules. Although the loading of some peptides is not affected by the absence of ERAP1, other peptides fail to load normally, and many unstable and immunogenic peptides not normally present are found bound to MHC molecules on the cell surface, leading to defects in antigen presentation. Polymorphisms in the human ERAP1 gene are significant risk factors in some autoimmune diseases.

6-4 Newly synthesized MHC class I molecules are retained in the endoplasmic reticulum until they bind a peptide.

Binding a peptide is an important step in the assembly of a stable MHC class I molecule. The folding and assembly of a complete MHC class I molecule (see Fig. 4.16) requires that the MHC class I α chain, or heavy chain, associate first with β_2-microglobulin and then with peptide. This process involves a number of accessory proteins with chaperone-like functions. Only after binding with peptide is the MHC class I molecule released from the endoplasmic reticulum and transported to the cell surface.

Newly synthesized MHC class I α chains that enter the endoplasmic reticulum membranes bind to **calnexin**, a general-purpose chaperone protein that retains the MHC class I molecule in a partly folded state (Fig. 6.8). Calnexin also associates with partly folded T-cell receptors, immunoglobulins, and MHC class II molecules, and so has a central role in the assembly of many immunological as well as non-immunological proteins. When β_2-microglobulin binds to the α chain, the partly folded MHC class I α:β_2-microglobulin heterodimer dissociates from calnexin and binds to an assembly of proteins called the MHC class I **peptide-loading complex (PLC)** (Fig. 6.9). One component of the PLC—**calreticulin**—is similar to calnexin and probably also has a general chaperone function, like calnexin. A second component of the complex is the TAP-associated protein **tapasin**, encoded by a gene within the MHC. Tapasin forms a bridge between MHC class I molecules and TAP, allowing the partly folded α:β_2-microglobulin heterodimer to await the transport of a suitable peptide from the cytosol. A third component of this complex is the chaperone **ERp57**, a thiol oxidoreductase that forms a stable disulfide-linked heterodimer with tapasin (Fig. 6.9). While being covalently bound to tapasin, ERp57 plays a structural role in making additional interaction with calreticulin. Tapasin seems to be a component of the PLC that is specific to antigen processing, while calnexin, ERp57, and calreticulin bind various other glycoproteins assembling in the endoplasmic reticulum and seem to be part of the cell's general quality-control machinery. TAP itself is the final component of the PLC, and it delivers peptides to the partially folded MHC class I molecule.

ANIMATION 6.1

The loading of peptides into newly synthesized MHC class I relies on the glycoprotein quality-control machinery of the endoplasmic reticulum. This complex system of enzymes detects and modifies the state of *N*-linked glycans placed

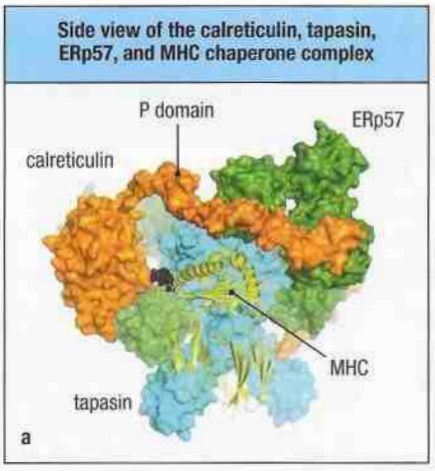
Fig. 6.8 MHC class I molecules do not leave the endoplasmic reticulum unless they bind peptides. Newly synthesized MHC class I α chains assemble in the endoplasmic reticulum (ER) with the membrane-bound protein calnexin. When this complex binds β_2-microglobulin (β_2m), the MHC class I α:β_2m heterodimer dissociates from calnexin, and the partly folded MHC class I molecule then binds to the TAP-associated protein tapasin. Two MHC:tapasin complexes may bind with the TAP dimer at the same time. The chaperone molecules ERp57 (which forms a heterodimer with tapasin) and calreticulin also bind to form the MHC class I peptide-loading complex. The MHC class I molecule is retained within the ER until released by the binding of a peptide, which completes the folding of the MHC molecule. Even in the absence of infection, there is a continual flow of peptides from the cytosol into the ER. Defective ribosomal products (DRiPs) and proteins marked for destruction by K48-linked polyubiquitin (yellow triangles) are degraded in the cytoplasm by the proteasome to generate peptides (red circles and teardrops) that are transported into the lumen of the endoplasmic reticulum by TAP. Some of these peptides will bind to MHC class I molecules. The aminopeptidase ERAAP (ERAP1) trims some peptides at their amino termini, allowing peptides that are too long (red teardrops) to bind to MHC class I molecules and thereby increasing the repertoire of potential peptides for presentation. Once a peptide has bound to the MHC molecule, the peptide:MHC complex leaves the endoplasmic reticulum and is transported through the Golgi apparatus and finally to the cell surface.

on newly synthesized proteins. The initial complex glycans placed on the MHC class I molecule are trimmed by enzymes into a **monoglucosylated glycan** that is the substrate for binding to calreticulin of the PLC. While bound to the PLC, the empty MHC molecule is receptive to binding peptides. Peptides binding with low affinity are continually exchanged for peptides of higher affinity in a process called **peptide editing**. This process continues until a peptide binds that allows for proper folding of the MHC class I molecule when it is released from the PLC. Properly folded peptide:MHC complexes are recognized by the enzyme **glucosidase II (GlsII)**, which then fully deglucosylates the MHC molecule. In this state, the peptide:MHC complex is no longer a substrate for binding to calreticulin, and it leaves the endoplasmic reticulum and is transported to the cell surface.

Recently, a second protein was discovered that functions in quality control of peptide:MHC complexes. This protein, called **TAPBPR** (encoded by the human TAPBPL gene), acts in the Golgi as a secondary sensor for proper protein folding in cooperation with the enzyme **UDP-glucose:glycoprotein glucosyltransferase 1 (UGT1)**. When TAPBPR binds an imperfectly folded peptide:MHC complex, it directs UGT1 to re-glucosylate the MHC, which causes the MHC to be transported back to the endoplasmic reticulum for further peptide editing by the PLC.



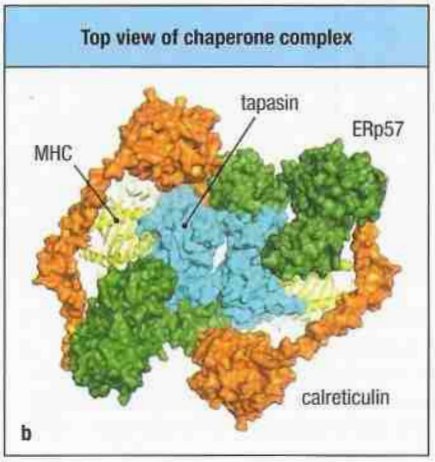


Fig. 6.9 The MHC class I peptide-loading complex includes the chaperones calreticulin, ERp57, and tapasin. This model shows side (a) and top (b) views of the peptide-loading complex (PLC) oriented as it extends from the luminal surface of the endoplasmic reticulum. The newly synthesized MHC class I and β_2-microglobulin are shown as yellow ribbons, with the α helices of the MHC peptide-binding groove clearly identifiable. The MHC and tapasin (blue) would be tethered to the membrane of the endoplasmic reticulum by carboxyl-terminal extensions not shown here. Tapasin and ERp57 (green) form a heterodimer linked by a disulfide bond, and tapasin makes contacts with the MHC molecule that stabilize the empty conformation of the peptide-binding groove. The function of tapasin and ERp57 is to edit peptides that bind to the MHC class I molecule. Calreticulin (orange), like the calnexin it replaces (see Fig. 6.8), binds to the monoglucosylated *N*-linked glycan at asparagine 86 of the immature MHC molecule. The long, flexible P domain of calreticulin extends around the top of the peptide-binding groove of the MHC molecule to make contact with ERp57. The transmembrane region of tapasin (not shown) associates the PLC with TAP (see Fig. 6.8), bringing the empty MHC molecules into proximity with peptides arriving into the endoplasmic reticulum from the cytosol.

Proteins that fail to fold properly in the endoplasmic reticulum are eventually translocated back into the cytosol and degraded by the proteasome via a quality-control pathway known as **endoplasmic reticulum–associated protein degradation (ERAD)**. ERAD comprises several general cellular pathways that involve the recognition and delivery of misfolded proteins to a **retrotranslocation complex**, which unfolds and translocates them across endoplasmic reticulum membrane into the cytosol. The proteins are ubiquitinated during this process and so are targeted to the ubiquitin–proteasome system for eventual degradation. We shall not delve deeply into the details of ERAD here, because these pathways are not unique to MHC class I assembly or antigen processing. However, we will see in Chapter 13 how many viral pathogens co-opt the ERAD pathways to block assembly of MHC class I molecules as a way to evade recognition by CD8 T cells.

In uninfected cells, peptides derived from self proteins fill the peptide-binding groove of the mature MHC class I molecules and are carried to the cell surface. In normal cells, MHC class I molecules are retained in the endoplasmic reticulum for some time, which suggests that they are present in excess of peptide. This is important for the immunological function of MHC class I molecules, which must be immediately available to transport viral peptides to the cell surface if the cell becomes infected. In order for MHC class I molecules to display peptides derived largely from cytosolic proteins, it is important that peptides not dissociate and allow extracellular peptides to bind in the empty peptide-binding site. Fortunately, loss of peptides from MHC class I molecules causes them to dissociate from β_2-microglobulin and be internalized and degraded. Thus, empty MHC class I molecules are quickly lost from the cell surface, helping ensure that primed T cells target infected cells while sparing surrounding healthy cells.

6-5 Dendritic cells use cross-presentation to present exogenous proteins on MHC class I molecules so as to prime CD8 T cells.

The pathway described above explains how proteins synthesized in the cytosol can generate peptides that become displayed as complexes with MHC class I molecules on the cell surface. This pathway allows for the detection and destruction of pathogen-infected cells by cytotoxic T cells. But these cytotoxic T cells must first be activated and expanded by interacting with dendritic cells that express the same peptide:MHC class I complexes produced on infected cells. However, many pathogens exhibit a restricted **tropism** for different cell types, and not all viruses will infect dendritic cells. To help induce responses against such pathogens, some dendritic cells are able to generate peptide:MHC class I complexes from antigens that are derived from extracellular sources through a process called cross-presentation.

Cross-presentation was first observed in studies of **minor histocompatibility antigens**, which are polymorphic non-MHC molecules that can elicit strong responses between mice of different genetic backgrounds. In other words, polymorphic proteins from one background harbor peptides that are recognized as foreign by T cells in a second background. These studies used two different genetic backgrounds of mice, B10 and BALB, which differed in many such minor histocompatibility antigens. When spleen cells from B10 mice of MHC type H-2^b were injected into BALB mice of MHC type H-$2^{b\times d}$ (which express both b and d MHC types), the BALB mice generated cytotoxic T cells reactive against minor antigens of the B10 background. Some of these cytotoxic T cells recognized minor antigens presented by (or restricted by) the H-2^b B10 cells used for immunization (see Section 4-15). This result is expected if BALB T cells were directly activated by B10 antigen-presenting cells. But other cytotoxic T cells recognized minor B10 antigens presented only by H-2^d MHC cells. This meant that these CD8 T cells had been activated *in vivo* by minor B10 antigens presented by the BALB host's own H-2^d molecules. In other words, minor histocompatibility antigens from the original immunizing B10 cells must have been transferred to the BALB host's dendritic cells and processed for MHC class I presentation. We now know that cross-presentation by MHC class I molecules occurs not only for antigens on tissue or cell grafts, as in the original experiment described above, but also for viral and bacterial antigens, as well as tumor antigens.

The capacity for cross-presentation is not equally distributed across all antigen-presenting cells. The antigen-presenting cells that are responsible for activation and expansion of naive T cells are the conventional dendritic cells (cDCs), which exist in both humans and mice as two major lineages, now called cDC1 and cDC2. These two lineages rely on different factors for their development and express distinct sets of functional surface proteins, discussed in Chapter 9. In human and mouse, the cDC1 lineage is the major cross-presenting dendritic cell and is required for CD8 T-cell responses to many viruses and to tumors. This subset requires the transcription factor **BATF3** for its development, and mice lacking a functional BATF3 gene lack cDC1 and are also unable to generate normal CD8 T-cell responses to many viruses, including herpes simplex virus.

The biochemical pathways for cross-presentation by cDC1 *in vivo* are still unclear, but there is evidence supporting at least two pathways. In the cytosolic pathway, proteins captured by phagocytic receptors and taken into endosomes are transported into the cytosol by unknown mechanisms and degraded by the proteasome into peptides that then pass through TAP into the endoplasmic reticulum. Some evidence supports a **vacuolar pathway**, in which peptides are generated by unknown mechanisms within the endocytic compartment and loaded onto MHC class I molecules in phagosomes. In each case, one important specialization of cDC1 for cross-presentation is the efficient capture of cell-associated antigens by surface receptors. One such receptor is **CLEC9A**, which is selectively expressed by cDC1 and binds to actin filaments exposed on necrotic cells. This pathway may direct the efficient uptake and processing of viral proteins from cells killed during viral infections for cross-presentation to CD8 T cells.

6-6 Peptide:MHC class II complexes are generated in acidified endocytic vesicles from proteins obtained through endocytosis, phagocytosis, and autophagy.

The immunological function of MHC class II molecules is to bind peptides generated in the intracellular vesicles of dendritic cells, macrophages, and B cells, and to present these peptides to CD4 T cells. The purpose of this pathway is different for each cell type. Dendritic cells primarily are concerned with activating and expanding naive CD4 T cells, while macrophages and B cells

elicit various forms of helper activities from these activated CD4 T cells. For example, the intracellular vesicles of macrophages are the sites of replication for several types of pathogens, including the protozoan parasite *Leishmania* and the mycobacteria that cause leprosy and tuberculosis. Because these pathogens reside in membrane-enclosed vesicles, the proteins of these pathogens are not usually accessible to proteasomes in the cytosol. Instead, proteins derived from the pathogens are degraded by intravesicular proteases into peptide fragments that can bind to MHC class II molecules that pass through this compartment on their way from the endoplasmic reticulum to the cell surface. In this compartment, peptide:MHC class II complexes are formed and are then delivered to the cell surface, where they can be recognized by CD4 T cells. Section 11-6 describes in great detail how this interaction helps macrophages to contain and eliminate these intracellular pathogens.

Antigen processing for MHC class II molecules begins when extracellular pathogens and proteins are internalized into endocytic vesicles (Fig. 6.10). Proteins that bind to surface immunoglobulin on B cells and are internalized by receptor-mediated endocytosis are processed by this pathway. Larger particulate materials, such as fragments of dead cells, are internalized by phagocytosis, particularly by macrophages and dendritic cells. Soluble proteins, such as secreted toxins, are taken up by macropinocytosis. These proteins are delivered to endosomes, which become increasingly acidic as they progress into the interior of the cell, eventually fusing with lysosomes. Acidification of endosomes and lysosomes results from the action of a multimeric protein complex called a **V-type ATPase**. This complex resides on the cytosolic side of endosomes and lysosomes and contains membrane-associated components that allow the energy of ATP hydrolysis to drive protons from the cytosol into the endosome and lysosome, leading to their acidification.

Endosomes and lysosomes contain proteases, known as acid proteases, that are activated at low pH. Drugs such as chloroquine that prevent acidification of endosomes also inhibit the presentation of intravesicular antigens, suggesting that acid proteases are responsible for processing such antigens. These proteases include the cysteine proteases—so called because they use a cysteine in their catalytic site—known as **cathepsins** B, S, and L, of which L is the most active. Cathepsins S and L may be the predominant proteases in the processing of vesicular antigens; mice that lack cathepsin B or cathepsin D process antigens normally, whereas mice with no cathepsin S show some deficiencies, including in the vacuolar pathway of cross-presentation. Asparagine endopeptidase (AEP), a cysteine protease cleaving after asparagines, is important for processing some antigens, such as the tetanus toxin antigen for MHC class II presentation, but is not required in all cases where antigens contain asparagine residues near their relevant epitopes. It is likely that the overall

Fig. 6.10 Peptides that bind to MHC class II molecules are generated in acidified endocytic vesicles. In the case illustrated here, extracellular foreign antigens (red), such as bacteria or bacterial antigens, have been taken up by an antigen-presenting cell such as a macrophage or an immature dendritic cell (first panel). In other cases, the source of the peptide antigen may be bacteria or parasites that have invaded the cell to replicate in endocytic/phagocytic vesicles. In both cases, the antigen-processing pathway is the same. The pH of the early endosome containing the engulfed pathogens is neutral, unlike the acidic pH of the lysosome, which is acidic and contains active protease (second panel). By the action of a V-type ATPase (green), a multimeric assembly of many subunits (not shown), H^+ ions are delivered into the early endosome, thereby activating proteases within the vesicle to degrade the engulfed material (third panel). At some point on their pathway to the cell surface, newly synthesized MHC class II molecules pass through such acidified vesicles and bind peptide fragments of the antigen, transporting the peptides to the cell surface (fourth panel).

repertoire of peptides produced within the vesicular pathway reflects the activities of the many proteases present in endosomes and lysosomes. The breaking of intramolecular disulfide bonds also facilitates the proteolysis of proteins, which is carried out by the enzyme **IFN-γ–induced lysosomal thiol reductase (GILT)** present in endosomes. The various endosomal proteases act in a largely redundant and nonspecific manner to digest regions of the polypeptide that have become accessible to proteolysis by denaturation and previous steps of degradation. The peptides generated vary in sequence and abundance throughout the endocytic pathway, so that MHC class II molecules can bind and present many different peptides from these compartments. Self peptides bound to MHC class II molecules arise from common proteins in the cytosol, including cell membrane proteins. Cytosolic proteins can be processed for MHC class II presentation by the natural process of protein turnover known as autophagy, in which damaged organelles and cytosolic proteins are delivered to lysosomes for degradation. Here their peptides could encounter MHC class II molecules present in the lysosome membranes, and the resulting peptide:MHC class II complex could be transported to the cell surface via endolysosomal tubules (see Fig. 6.4). Autophagy has been shown to be involved in the processing of the Epstein–Barr virus nuclear antigen 1 (EBNA-1) for presentation on MHC class II molecules. Such presentation enables cytotoxic CD4 T cells to recognize and kill B cells infected with Epstein–Barr virus.

6-7 The invariant chain directs newly synthesized MHC class II molecules to acidified intracellular vesicles.

The biosynthetic pathway for MHC class II molecules begins with their translocation into the endoplasmic reticulum. However, the endoplasmic reticulum also contains peptides transported there by TAP as well as unfolded and partly folded polypeptide chains. To prevent premature binding of these peptides to newly synthesized MHC class II molecules, a specific membrane protein known as the MHC class II–associated **invariant chain (Ii, CD74)** is expressed in dendritic cells, macrophages, and B cells. Ii is a type II membrane glycoprotein; its amino terminus resides in the cytosol, and its transmembrane region spans the membrane of the endoplasmic reticulum (Fig. 6.11). The remainder of Ii and its carboxyl terminus reside within the endoplasmic reticulum. Ii has a unique cylindrical domain that mediates formation of stable Ii trimers. Near

Fig. 6.11 The invariant chain is cleaved to leave a peptide fragment, CLIP, bound to the MHC class II molecule. A model of the trimeric invariant chain bound to MHC class II αβ heterodimers is shown on the left. The CLIP portion is shown in purple, the rest of the invariant chain is shown in green, and the MHC class II molecules are shown in yellow (model, and leftmost of the three panels). In the endoplasmic reticulum, the invariant chain (Ii) binds to MHC class II molecules with the CLIP section of its polypeptide chain lying along the peptide-binding groove. After transport into an acidified vesicle, Ii is cleaved, initially just at one side of the MHC class II molecule (center panel), first by non-cysteine proteases to give a remaining portion of Ii known as the leupeptin-induced peptide LIP22 (not shown) and then by cysteine protease to give the LIP10 fragment shown. LIP10 retains the transmembrane and cytoplasmic segments that contain the signals that target Ii:MHC class II complexes to the endosomal pathway. Subsequent cleavage (right panel) of LIP10 leaves only a short peptide still bound by the MHC class II molecule; this peptide is the CLIP fragment.

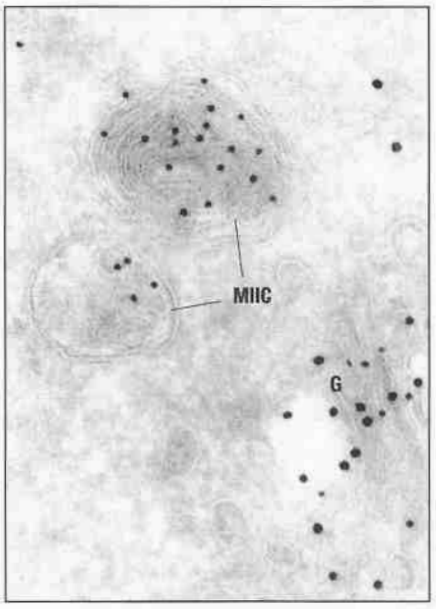

Fig. 6.12 **MHC class II molecules are loaded with peptide in a late endosomal compartment.** MHC class II molecules are transported from the Golgi apparatus (labeled G in this electron micrograph of an ultrathin section of a B cell) to the cell surface via intracellular vesicles each of which is called an MHC class II compartment (MIIC). These vesicles have a complex morphology, showing internal vesicles and sheets of membrane. This image used antibodies labeled with different-sized gold particles to identify the presence of both MHC class II molecules (visible as small dark spots) and the invariant chain (large dark spots). Large and small spots are seen in the Golgi, indicating both proteins are present there. In contrast, only MHC class II molecules are detectable in the MIIC. This compartment is thought to be a late endosome, an acidified compartment of the endocytic system (pH 4.5–5) in which the invariant chain is cleaved and peptide loading occurs. Magnification ×135,000.

this domain, Ii contains a peptide sequence, the **class II–associated invariant chain peptide (CLIP)**, with which each Ii subunit of the trimer binds noncovalently to an MHC class II αβ heterodimer. Each Ii subunit binds to an MHC class II molecule with CLIP lying within the peptide-binding groove, thus blocking the groove and preventing the binding of either peptides or partly folded proteins. The binding site of an MHC class II molecule is relatively open compared to the binding site of an MHC class I molecule. This allows MHC class II molecules to allow the CLIP region of Ii to pass through their binding sites more easily. While this complex is being assembled in the endoplasmic reticulum, its component parts are associated with calnexin. Only when a nine-chain complex—three Ii chains, three α chains, and three β chains—has been assembled is the complex released from calnexin for transport out of the endoplasmic reticulum. As part of the nine-chain complex, the MHC class II molecules cannot bind peptides or unfolded proteins, so that peptides present in the endoplasmic reticulum are not usually presented by MHC class II molecules. There is evidence that in the absence of Ii, many MHC class II molecules become aggregated and are retained in the endoplasmic reticulum as complexes with misfolded proteins.

Trafficking of membrane proteins is controlled by cytosolic sorting tags. In this regard, Ii has a second function, which is to target delivery of the MHC class II molecules to a low-pH endosomal compartment where peptide loading can occur. The complex of MHC class II αβ heterodimers with Ii trimers is retained for 2–4 hours in this compartment (see Fig. 6.11). During this time, the Ii molecule undergoes an initial cleavage by acid proteases to remove the trimerization domain, generating a truncated 22-kDa fragment of Ii called **LIP22**. LIP22 is further cleaved by cysteine proteases into a 10-kDa fragment called **LIP10**, which is composed of CLIP at one end and a transmembrane region at the other. The CLIP segment binds to the MHC class II molecule while its transmembrane region retains it in the proteolytic compartment. A subsequent cleavage of LIP10 releases CLIP, which remains bound to the MHC class II molecule. This cleavage is carried out by cathepsin S in most MHC class II–positive cells but by cathepsin L in thymic epithelial cells. Because CLIP does not carry the Ii-encoded signals that retain the complex in the endocytic compartment, the MHC:CLIP complex is now free to escape this compartment, but it cannot yet bind other peptides.

Newly synthesized MHC class II molecules are brought toward the cell surface in vesicles, most of which fuse with incoming endosomes at some point. However, some MHC class II:Ii complexes can first be transported to the cell surface and reinternalized into endosomes. In each case, MHC class II:Ii complexes enter the endosomal pathway, where they encounter and bind peptides derived from either internalized pathogen proteins or self proteins. Initially, specialized endosomal compartments were thought to exist for antigen-presenting cells. One was an early endosomal compartment in dendritic cells that was called the **CIIV (MHC class II vesicle)**. Another, a late endosomal compartment containing Ii and MHC class II molecules, was called the **MHC class II compartment, or MIIC** (Fig. 6.12). The current view is that MHC class II molecules use many common endocytic compartments, including lysosomes, to allow for the exchange of CLIP for other peptides. MHC class II molecules that do not bind peptide after dissociation from CLIP are unstable in the acidic pH after fusion with lysosomes, and they are rapidly degraded.

6-8 The MHC class II–like molecules HLA-DM and HLA-DO regulate exchange of CLIP for other peptides.

To allow other peptides to bind to the MHC class II molecule, CLIP must either dissociate or be displaced. Antigen-presenting cells possess a mechanism that facilitates this process, which was discovered by studies of mutant human

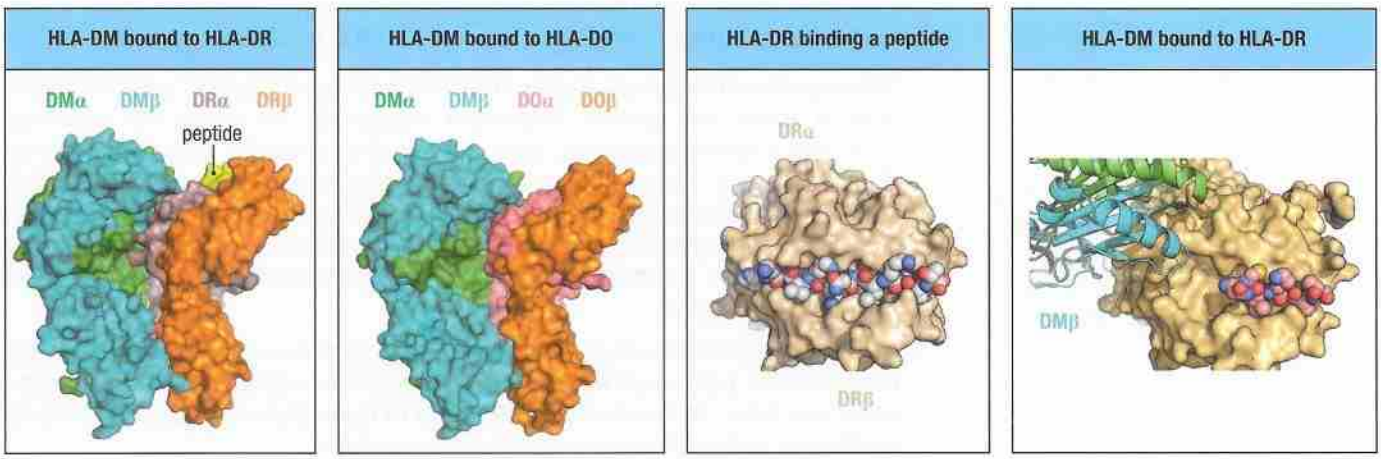
Fig. 6.13 HLA-DM facilitates the loading of antigenic peptides onto MHC class II molecules. First panel: The invariant chain (Ii) binds to newly synthesized MHC class II molecules and blocks peptides from binding class II molecules in the endoplasmic reticulum and during their transport to acidified endosomes. Second panel: In late endosomes, proteases cleave the invariant chain, leaving CLIP bound to the MHC class II molecules. Third panel: Pathogens and their proteins are broken down into peptides within acidified endosomes, but these peptides cannot bind to MHC class II molecules that are occupied by CLIP. Fourth panel: The class II–like molecule HLA-DM binds to MHC class II:CLIP complexes, catalyzing the release of CLIP and the binding of antigenic peptides.

B-cell lines with a defect in antigen presentation. MHC class II molecules in these mutant cells assemble correctly with Ii and seem to follow the normal vesicular route, but fail to bind peptides derived from internalized proteins and often arrive at the cell surface with the CLIP peptide still bound. The defect in these cells lies in an MHC class II–like molecule called **HLA-DM** in humans (**H-2DM** in mice). The HLA-DM genes, *HLA-DMA* and *HLA-DMB*, encode an α chain and a β chain, respectively, which form a heterodimer closely resembling other MHC class II molecules. The HLA-DM molecule is not present at the cell surface, however, but is found predominantly in the endosomal compartment that contains Ii and MHC class II molecules. HLA-DM binds to and stabilizes empty MHC class II molecules and catalyzes the release of CLIP, thus allowing the binding of other peptides to the empty MHC class II molecule (Fig. 6.13). The HLA-DM molecule does not contain the open groove found in other MHC class II molecules, so it does not bind peptides. Instead, HLA-DM binds to the α chain of the MHC class II molecule near the region of the floor of the peptide-binding site (Fig. 6.14). This binding induces changes in the

Fig. 6.14 HLA-DM and HLA-DO regulate loading of peptides into MHC class II molecules. First panel: The HLA-DM dimer, composed of α (green) and β (turquoise) chains, binds to the HLA-DR MHC class II molecule (side view). HLA-DM contacts the MHC molecule near the peptide-binding groove where the peptide amino terminus would reside. Second panel: HLA-DO binds to HLA-DM in a similar configuration as HLA-DR, thus blocking HLA-DM's peptide-editing activity. Third panel: Top view of HLA-DR with bound peptide in the absence of HLA-DM. Fourth panel: Top view of HLA-DR with HLA-DM bound. The amino-terminal end of the MHC peptide-binding groove is open and devoid of bound peptide, enabling peptide exchange.



ANIMATION 6.2

structure of the MHC class II molecule and holds this part of the peptide-binding groove in a partially 'open' configuration (see Fig. 6.14, right panel). In this way, HLA-DM catalyzes the release of CLIP from MHC class II molecules and the exchange for other peptides contained in the endosomal compartment.

In the presence of a mixture of peptides capable of binding to MHC class II molecules, HLA-DM forms a stable complex that lacks a bound peptide. Peptides rapidly bind to and then release from this complex, but only high-affinity peptides can induce DM dissociation from MHC class II proteins. Antigens presented by MHC class II molecules may have to persist on the surface of antigen-presenting cells for some days before encountering T cells able to recognize them. The ability of HLA-DM to remove unstably bound peptides, sometimes called peptide editing (see Section 6-4), ensures that the peptide:MHC class II complexes displayed on the surface of the antigen-presenting cell can survive long enough to stimulate the appropriate CD4 T cells. During this process, it is likely that some peptides are captured first as longer polypeptides that undergo amino-terminal trimming by exopeptidases, further increasing the number of possible peptides that can be bound.

Binding of longer polypeptides is probably more prominent in early endosomal compartments where antigen degradation is more limited. Allowing the binding of epitopes contained in long polypeptides also helps protects them from degradation.

A second atypical MHC class II molecule, called **HLA-DO** in humans (**H-2O** in mice), is produced in thymic epithelial cells, B cells, and dendritic cells. This molecule is a heterodimer of the HLA-DOα chain and the HLA-DOβ chain. HLA-DO is not present at the cell surface, being found only in intracellular vesicles, and it does not seem to bind peptides. HLA-DO acts as a negative regulator of HLA-DM. HLA-DO binds to HLA-DM in the same manner as MHC class II molecules (see Fig. 6.14), and it must be bound to HLA-DM in order to leave the endoplasmic reticulum. When the DM–DO dimer reaches an acidified endocytic compartment, HLA-DO appears to dissociate slowly from HLA-DM, which is then free to catalyze peptide editing for MHC class II molecules. Moreover, IFN-γ increases the expression of HLA-DM, but not of the HLA-DOβ chain. Thus, during inflammatory responses, IFN-γ produced by T cells and NK cells can increase the expression of HLA-DM, and so overcome the inhibitory effects of HLA-DO. The loss of HLA-DO in mice does not dramatically alter adaptive immunity but does cause a spontaneous production of autoantibodies with age. Proteins captured by the B-cell receptor (BCR) are normally delivered to acidic endosomal compartments where, in the absence of HLA-DO, HLA-DM facilitates the loading of peptides from these proteins onto MHC class II molecules. But loss of HLA-DO may allow loading of peptides derived from proteins not captured by the BCR. Further, because thymic epithelial cells function in the selection of developing CD4 T cells, their expression of HLA-DO may influence the repertoire of self peptides that these T cells encounter at different stages, as discussed further in Chapter 8.

The peptide editing conferred by HLA-DM and the removal of unstable MHC class II molecules provide important safeguards. To reveal the presence of an intracellular pathogen, the peptide:MHC complex must be stable at the cell surface. If peptides were to dissociate too readily, an infected cell could escape detection, and if peptides could too easily be acquired from other cells, then healthy cells might be mistakenly targeted for destruction. Tight binding of peptides to MHC molecules reduces the chance of these unwanted outcomes.

Just as specialized mechanisms for loading peptides onto MHC molecules have evolved, pathogens have evolved strategies to inhibit the loading of peptides onto MHC molecules. We will return to these topics in Chapter 13 when we discuss pathogen immunoevasion mechanisms.

6-9 Cessation of MHC class II antigen processing occurs after dendritic-cell activation through reduced expression of the MARCH-1 E3 ligase.

To enhance the presentation of peptides derived from pathogens, there is a specific mechanism that prolongs the lifetime of peptide:MHC complexes being formed at the same time as innate signals are received indicating possible infection. Dendritic cells that have not yet been activated by infection carry out active surveillance of the antigens in their location; for example, through macropinocytosis of soluble proteins. Peptides derived from such proteins are continually processed and loaded onto MHC class II molecules for expression on the cell surface. These peptide:MHC complexes are continually being endocytosed from the cell surface. They can be recycled to the surface again, but the majority is degraded by ubiquitination and proteasomal degradation. To support ubiquitination, MHC class II molecules contain a conserved lysine residue in the cytoplasmic tails of the β chain; this lysine residue is a target of an **E3 ligase** (see Section 3-7) called **membrane-associated ring finger (C3HC4) 1, or MARCH-1**, expressed in B cells, dendritic cells, and macrophages. MARCH-1 is expressed constitutively in B cells and induced by the cytokine IL-10 in other cells. It resides in the membrane of a recycling endosomal compartment, where it ubiquitinates the cytoplasmic tail of MHC class II molecules, leading to their eventual degradation in lysosomes, thereby regulating their steady-state level of expression (Fig. 6.15). MARCH-1-dependent degradation targets even high-affinity peptide:MHC complexes, so that the peptides represented on the cell surface are continually renewed. Thymic epithelial cells (TECs) also express MHC class II molecules but use MARCH-8 to regulate its degradation. In TECs, the membrane protein CD83 binds to MARCH-8 and prevents its degradation of MHC class II. Mice lacking CD83 have reduced expression of MHC class II protein on the surface of TECs, causing reduced positive selection of CD4 T cells (see Section 6-13 and Chapter 8). This effect illustrates why fine-tuning surface expression and half-life of MHC II molecules is important.

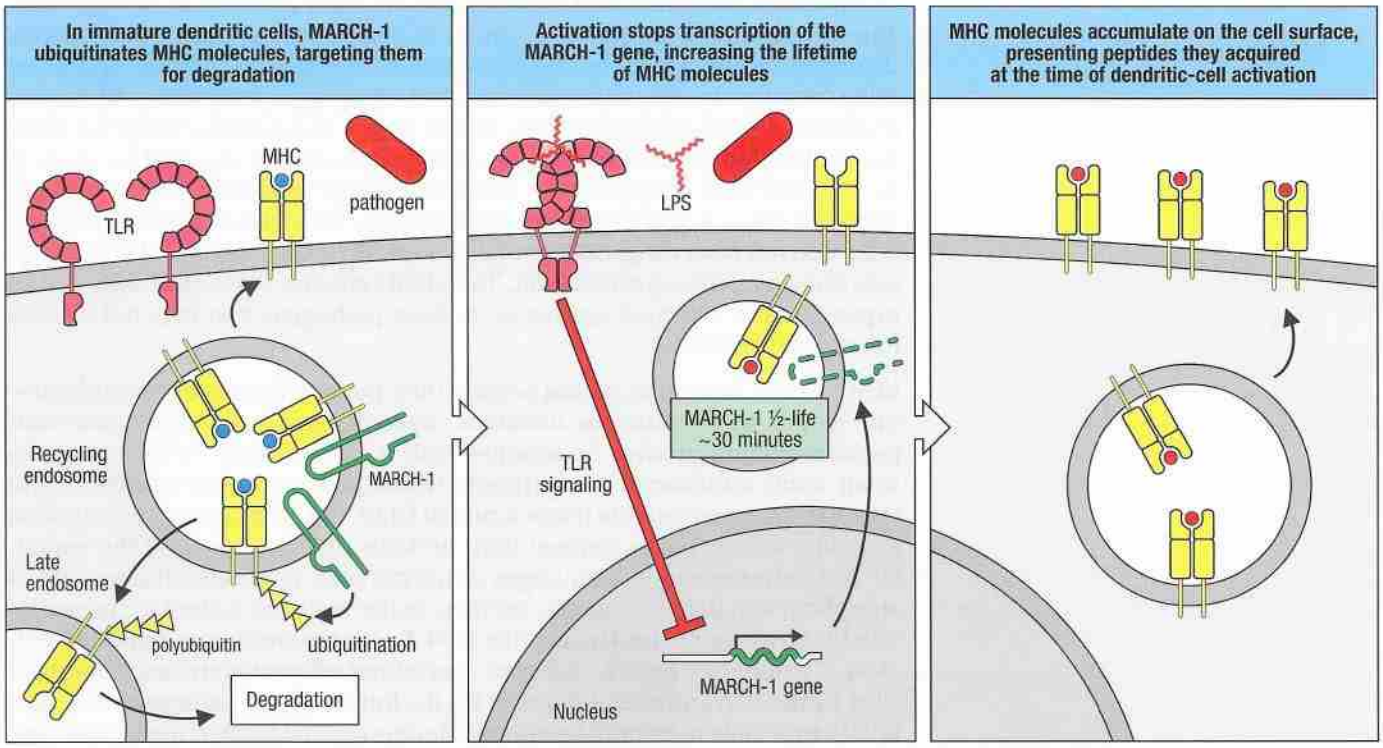


Fig. 6.15 Activation of dendritic cells reduces MARCH-1 expression, thus increasing the lifetime of MHC molecules. Before activation by innate recognition of pathogens, dendritic cells express the membrane-associated E3 ligase MARCH-1, which resides in the recycling endosomes compartment. There it attaches K48-linked ubiquitin chains to the β chain of MHC class II molecules. This causes MHC molecules to move out of the recycling endosomes and eventually to be degraded, leading to a reduced overall half-life and level of MHC expression on the cell surface. Signals emanating from innate sensors, such as TLR-4, reduce the level of MARCH-1 mRNA, and with the half-life of MARCH-1 now being short, MHC molecules are free to accumulate on the cell surface. Because innate signaling also triggers acidification of endocytic compartments and activates caspases associated with antigen processing, the MHC molecules that accumulate on the cell surface will bear peptides from the pathogens captured around the time of innate activation of the dendritic cells.

When dendritic cells sense the presence of a pathogen in a peripheral tissue, they must first migrate to local lymph nodes in order to activate naive T cells (see Section 9-8); this may take many hours. Because continuous recycling limits the lifetime of peptide:MHC complexes on the cell surface, pathogen-derived peptide:MHC complexes might be lost during this migration, preventing T-cell activation. To prevent this situation, activated dendritic cells undergo a process of maturation in which transcription of the MARCH-1 gene is shut off. Because the MARCH-1 protein half-life is only around 30 minutes, activated dendritic cells soon accumulate peptide:MHC complexes on their cell surface produced at the time of encounter with pathogen. Another gene turned off during dendritic-cell maturation is the transcriptional activator CIITA (see Section 6-10), which is required for expression of MHC class genes. Shutting off CIITA therefore helps prevent the production of new MHC molecules after the dendritic cell leaves the site of infection.

In addition to regulating MHC class II expression in dendritic cells, MARCH-1 similarly regulates expression in dendritic cells of the co-stimulatory molecule (see Section 1-15) **CD86** (or **B7-2**), which like MHC class II molecules is also regulated by ubiquitination. This means by the time dendritic cells arrive at lymph nodes, they express peptides derived from the pathogens that activated them and have higher CD86 levels that provide signals for greater CD4 T-cell activation. However, we will see in Chapter 13 that viral pathogens have taken advantage of this pathway by producing MARCH-1–like proteins, which primarily down-regulate MHC class I molecules in the endoplasmic reticulum as a means of evading adaptive immunity.

Summary.

The ligand recognized by the T-cell receptor is a peptide bound to an MHC molecule. MHC class I and MHC class II molecules acquire peptides at different intracellular sites and activate CD8 and CD4 T cells, respectively. Infected cells presenting peptides derived from virus replication in the cytosol are thus recognized by cytotoxic CD8 T cells, which are specialized to kill any cells displaying foreign antigens. MHC class I molecules are synthesized in the endoplasmic reticulum and typically acquire their peptides at this location. The peptides loaded onto MHC class I molecules are derived from proteins degraded in the cytosol by the proteasome, transported into the endoplasmic reticulum by the heterodimeric ATP-binding protein TAP, and further processed by the aminopeptidase ERAP1 before being loaded onto the MHC molecules. Peptide binding to MHC class I molecules is required for them to be released from chaperones in the endoplasmic reticulum and to travel to the cell surface. A specific type of dendritic cell, the cDC1, is able to load peptides derived from exogenous proteins onto MHC class I molecules in a process known as cross-presentation. This ability ensures that CD8 T cells can be expanded and activated against even those pathogens that may not directly infect dendritic cells.

MHC class II molecules do not acquire their peptide ligands in the endoplasmic reticulum, because the invariant chain (Ii) first inserts CLIP into their peptide-binding groove. Association with Ii targets these MHC molecules to an acidic endosomal compartment where active proteases cleave Ii, and HLA-DM helps to catalyze dissociation of CLIP. The MHC molecules can then associate with peptides derived from proteins that have entered the vesicular compartments of macrophages, dendritic cells, or B cells. The process of autophagy can deliver cytosolic proteins to the vesicular system for presentation by MHC class II molecules. The CD4 T cells that recognize peptide:MHC class II complexes have a variety of specialized effector activities. Subsets of CD4 T cells activate macrophages to kill the intravesicular pathogens they harbor, help B cells to secrete immunoglobulins against foreign molecules, and

regulate immune responses. Dendritic cells possess mechanisms that help prolong the lifetime of peptide:MHC complexes produced at the time of infection. MARCH-1 expressed by immature dendritic cells causes the continual turnover of peptide:MHC class II molecules. MARCH-1 expression is shut off when a dendritic cell senses infection, leading to increased lifetime and levels of peptide:MHC class II molecules representative of antigens present when pathogens were initially detected.

The major histocompatibility complex and its function.

The function of MHC molecules is to bind peptide fragments derived from pathogens and display them on the cell surface for recognition by the appropriate T cells. The consequences are almost always deleterious to the pathogen—virus-infected cells are killed, macrophages are activated to kill bacteria living in their intracellular vesicles, and B cells are activated to produce antibodies that eliminate or neutralize extracellular pathogens. Thus, there is strong selective pressure in favor of any pathogen that has mutated in such a way that it escapes presentation by an MHC molecule.

Two separate properties of the MHC make it difficult for pathogens to evade immune responses in this way. First, the MHC is **polygenic**: it contains several different MHC class I and MHC class II genes, so that every individual possesses a set of MHC molecules with different ranges of peptide-binding specificities. Second, the MHC is highly **polymorphic**; that is, there are multiple variants, or alleles, of each gene within the population as a whole. The MHC genes are, in fact, the most polymorphic genes known. In this part of the chapter we describe the organization of the genes in the MHC and discuss how the variation in MHC molecules arises. We also consider how the effect of polygeny and polymorphism on the range of peptides that can be bound contributes to the ability of the immune system to respond to the multitude of different and rapidly evolving pathogens.

6-10 Many proteins involved in antigen processing and presentation are encoded by genes within the MHC.

The MHC is located on chromosome 6 in humans and chromosome 17 in the mouse and extends over at least 4 million base pairs. In humans, it contains more than 200 genes. As work continues to define the genes within and around the MHC, it becomes difficult to establish precise boundaries for this genetic region, which is now thought to span as many as 7 million base pairs. The genes encoding the α chains of MHC class I molecules and the α and β chains of MHC class II molecules are linked within the complex. Figure 6.16 shows the general organization of the MHC class I and class II genes in human and mouse. In humans, these genes are called **human leukocyte antigen (HLA)** genes, because they were first discovered through antigenic differences between white blood cells from different individuals; in the mouse they are known as the **H-2 genes**. The mouse MHC class II genes were in fact first identified as genes that controlled whether an immune response was made to a given antigen and were originally called **Ir (immune response) genes**. Consequently, the mouse MHC class II A and E genes were referred to as *I-A* and *I-E* in the past. Although this terminology could be confused with MHC class I genes, it is still in use. Several genes encoding proteins primarily dedicated to antigen presentation are located outside the MHC, including genes for β_2-microglobulin, invariant chain, TAPBPR, cathepsin S, and MARCH-1.

Fig. 6.16 The genetic organization of the major histocompatibility complex (MHC) in humans and mice. The organization of the MHC genes is shown. In humans, the cluster is called HLA (short for human leukocyte antigen) and is on chromosome 6, and in mice, it is called H-2 (for histocompatibility) and is on chromosome 17. The organization is similar in both species, with separate clusters of MHC class I genes (red) and MHC class II genes (yellow). In mice, the MHC class I gene *H-2K* has been translocated relative to the human MHC, splitting the class I region in two. Both species have three main class I genes, which are called *HLA-A*, *HLA-B*, and *HLA-C* in humans, and *H-2K*, *H-2D*, and *H-2L* in the mouse. These encode the α chain of the respective MHC class I proteins, HLA-A, HLA-B, and so on. The other subunit of an MHC class I molecule, β_2-microglobulin, is encoded by a gene located on a different chromosome—chromosome 15 in humans and chromosome 2 in the mouse. The class II region includes the genes for the α and β chains (designated *A* and *B*) of the MHC class II molecules HLA-DR, -DP, and -DQ (*H-2A* and *H-2E* in the mouse). Also in the MHC class II region are the genes for the TAP-1:TAP-2 peptide transporter, the PSMB (or LMP) genes that encode proteasome subunits, the genes encoding the DMα and DMβ chains (*DMA* and *DMB*), the genes encoding the α and β chains of the DO molecule (*DOA* and *DOB*, respectively), and the gene encoding tapasin (*TAPBP*). The so-called class III genes encode various other proteins with functions in immunity (see Fig. 6.17). Several genes that encode proteins primarily or solely dedicated to antigen presentation but are located outside the MHC include genes for TAPBPR, cathepsin S, and MARCH-1.

There are three class I α-chain genes in humans, called *HLA-A*, *-B*, and *-C*. There are also three pairs of MHC class II α- and β-chain genes, called *HLA-DR*, *-DP*, and *-DQ*. In many people, however, the HLA-DR cluster contains an extra β-chain gene whose product can pair with the DRα chain. This means the three sets of genes can give rise to four types of MHC class II molecules. All the MHC class I and class II molecules can present peptides to T cells, but each protein binds a different range of peptides (see Sections 4-18 and 4-19). Thus, the presence of several different genes for each MHC class means that any one individual is equipped to present a much broader range of peptides than if only one MHC molecule of each class were expressed at the cell surface.

Figure 6.17 shows a more detailed map of the human MHC region. Many genes within this locus participate in antigen processing or antigen presentation or have other functions related to the innate or adaptive immune response. The two TAP genes lie in the MHC class II region near the proteasome PSMB8 and PSMB9 genes, whereas the gene encoding tapasin (*TAPBP*) lies at the edge of the MHC nearest the centromere. The genetic linkage of the MHC class I genes, whose products deliver cytosolic peptides to the cell surface, with the TAP, tapasin, and proteasome (*PSMB8*, *PSMB9*, *LMP2*, and *LMP5*) genes, whose products deliver cytosolic peptides into the endoplasmic reticulum, suggests that the entire MHC has been selected during evolution for antigen processing and presentation.

When cells are treated with the interferons IFN-α, -β, or -γ, there is a marked increase in the transcription of MHC class I α-chain and β_2-microglobulin genes and of the immunoproteasome, tapasin, and TAP genes. Type I interferons (IFN-α and IFN-β) are produced early in viral infections as part of the innate immune response (see Section 3-7), while IFN-γ is produced during T_H1 responses (see Section 9-14). The increase in MHC expression they produce helps all cells to process viral proteins and present the resulting virus-derived peptides on their surface (except for red blood cells). On dendritic cells, this helps to activate the appropriate T cells and initiate the adaptive immune response to the virus. The coordinated regulation of the genes encoding these components may be facilitated by the linkage of many of them in the MHC.

The HLA-DMA and HLA-DMB genes encoding the subunits of the HLA-DM molecule are clearly related to the MHC class II genes, as are the HLA-DOA and HLA-DOB genes encoding the subunits of HLA-DO. However, unlike

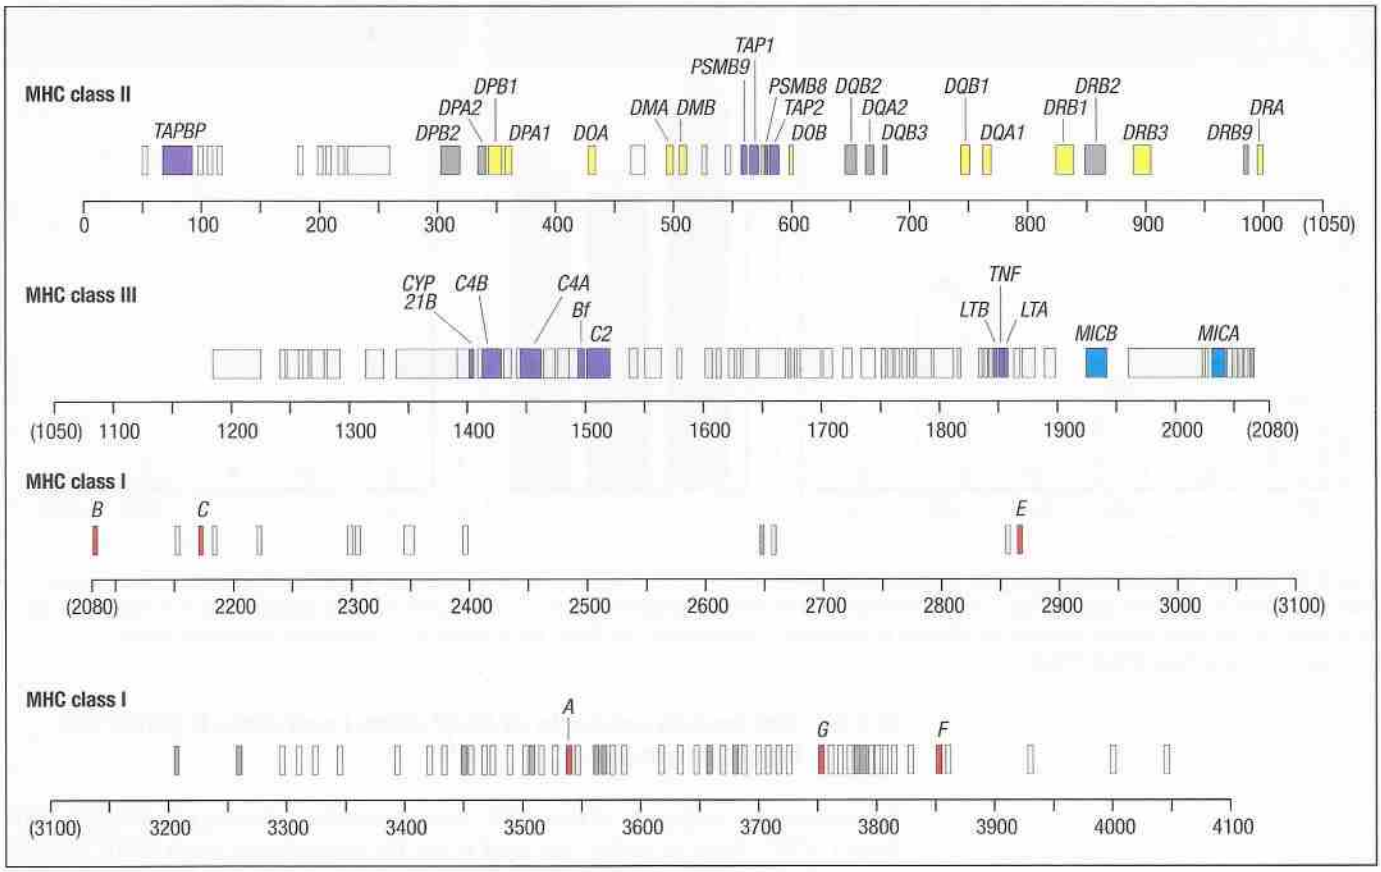

Fig. 6.17 Detailed map of the human MHC. The organization of the class I, class II, and class III regions of the human MHC is shown, with approximate genetic distances given in thousands of base pairs. Most of the genes in the class I and class II regions are mentioned in the text. The additional genes indicated in the class I region (for example, *E*, *F*, and *G*) are class I–like genes encoding class Ib molecules; the additional class II genes are pseudogenes. The genes shown in the class III region encode the complement proteins C4 (two genes, shown as *C4A* and *C4B*), C2, and factor B (shown as *Bf*), as well as the cytokines tumor necrosis factor-α (*TNF*) and lymphotoxin (*LTA*, *LTB*). Closely linked to the C4 genes is the gene encoding 21-hydroxylase (shown as *CYP 21B*), an enzyme involved in steroid biosynthesis. Immunologically important functional protein-coding genes identified in the text are color coded: the MHC class I genes are shown in red, except for the MHC class Ib (MIC) genes, which are shown in blue; these are distinct from the other class I–like genes and are under different transcriptional control. The immunologically important MHC class II genes are shown in yellow. Genes in the MHC region that have immune functions but are not related to the MHC class I and class II genes are shown in purple. Genes in dark gray are pseudogenes related to immune-function genes. Unnamed genes unrelated to immune function are shown in light gray.

conventional MHC genes, the genes encoding HLA-DM and HLA-DO are nonpolymorphic. These genes are found near the TAP and PSMB8/9 genes in the MHC class II region (see Fig. 6.16). Gene expression of the classical MHC class II proteins, along with the invariant chain, HLA-DMA, HLA-DMB, and HLA-DOA, but not HLA-DOB, is coordinately increased by IFN-γ, produced by T_H1 cells, CD8 T cells, and NK cells. This form of regulation allows dendritic cells and macrophages to increase processing of intravesicular antigens when presenting to T cells and NK cells. Expression of all these molecules is induced by IFN-γ (but not by IFN-α or -β) via the production of a protein known as **MHC class II transactivator (CIITA)**, which is a transcriptional co-activator of MHC class II genes. An absence of CIITA causes severe immunodeficiency due to the nonproduction of MHC class II molecules, a condition called **MHC class II deficiency**. Finally, the MHC contains many **'nonclassical' MHC genes**, so called because, while they resemble MHC genes in structure, their products do not function in presenting peptides to conventional αβ T cells. Many of these genes are now referred to as MHC class Ib genes, and their protein products have a variety of different functions, which we will describe later in Section 6-16, after we discuss the conventional MHC genes.

MHC Class II Deficiency

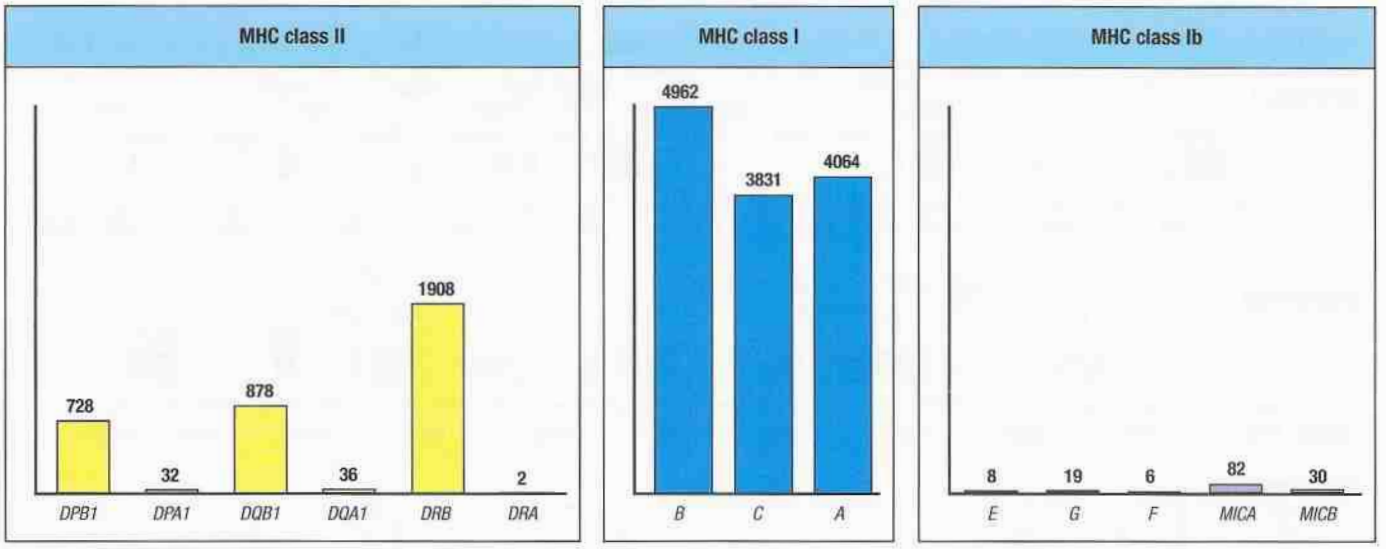

Fig. 6.18 Human MHC genes are highly polymorphic. With the notable exception of the DRα locus, which is functionally monomorphic, each gene locus has many alleles. The number of functional proteins encoded is less than the total number of alleles. Shown in this figure as the heights of the bars are the number of different HLA proteins assigned by the WHO Nomenclature Committee for Factors of the HLA System as of September 2018.

6-11 The protein products of MHC class I and class II genes are highly polymorphic.

Because of the polygeny of the MHC, every person expresses at least three different MHC class Ia molecules and three (or sometimes four) MHC class II molecules on his or her cells. In fact, the number of different MHC molecules expressed by most people is greater because of the extreme polymorphism of the MHC (Fig. 6.18).

The term **polymorphism** comes from the Greek *poly*, meaning many, and *morphe*, meaning shape or structure. As used here, it means within-species variation at a gene, and thus in the gene's protein product; the variant genes that can occupy the locus are termed **alleles**. For several MHC class I and class II genes, there are more than 1000 alleles in the human population, vastly more than for any other gene in the genome. Because there are so many allelic variants present in the human population, there is only a small chance that an individual will have the same allele for a particular MHC gene on both homologous chromosomes; most individuals will be **heterozygous** for the genes encoding MHC class I and class II molecules. The particular combination of MHC alleles found on a single chromosome is known as an **MHC haplotype**. Expression of MHC alleles is **codominant**, meaning that the protein products of both of the alleles at a locus are expressed equally in the cell, and both gene products can present antigens to T cells. The number of known MHC alleles that do not code for a functional protein is remarkably small. The extensive polymorphism at each locus thus has the potential to double the number of different MHC molecules expressed in an individual and thereby increase the diversity already available through polygeny (Fig. 6.19). In fully heterozygous individuals, further diversity of MHC class II molecules arises from different allelic forms of the α chain pairing with the various allelic forms of the β chain.

The polymorphic nature of the MHC class II proteins causes their affinity for binding Ii and CLIP to vary among different MHC class II allotypes. Some allotypes do not require cathepsin S and/or HLA-DM to allow peptide binding and can replace LIP10 and CLIP with peptides without the sequence of events described in the several previous sections of this chapter. Thus some MHC class II alleles may be able to bind peptides/polypeptides in compartments where cathepsin S and HLA-DM activity or abundance is low, further increasing the repertoire of antigens available for sampling by MHC molecules.

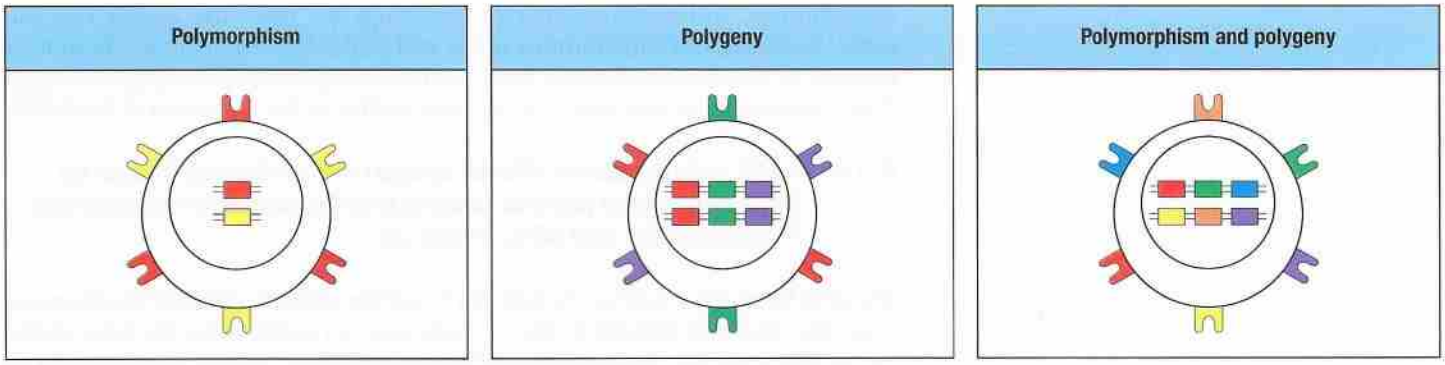

Fig. 6.19 Polymorphism and polygeny both contribute to the diversity of MHC molecules expressed by an individual. The high polymorphism of the classical MHC genes ensures diversity in MHC gene expression in the population as a whole. However, no matter how polymorphic a gene is, no individual can express more than two alleles at a single gene locus. Polygeny, the presence of several different related genes with similar functions, ensures that each individual produces a number of different MHC molecules. The combination of polymorphism and polygeny produces the diversity of MHC molecules seen both within an individual and in the population at large. Not shown in this figure are additional variations that result from the pairing of different alleles of α and β chains in the assembly of MHC class II molecules.

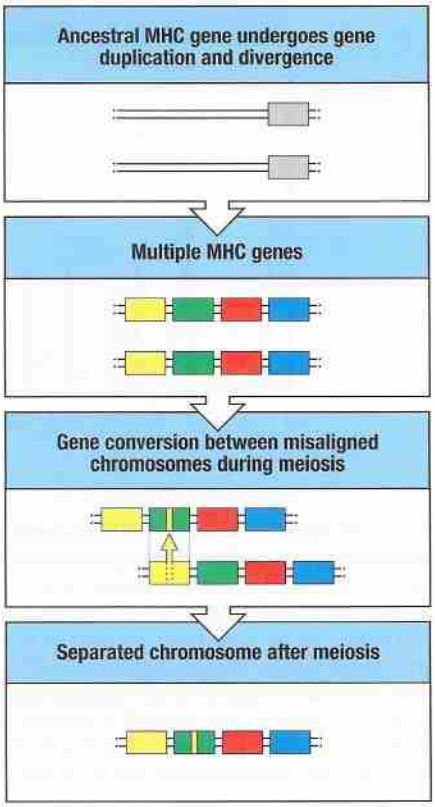
Because most individuals are heterozygous, most matings will produce offspring that receive one of four possible combinations of the parental MHC haplotypes. Thus siblings are also likely to differ in the MHC alleles they express, there being one chance in four that an individual will share both haplotypes with a sibling. Sharing of alleles between unrelated individuals is even less frequent. Cells expressing different MHC alleles from a host are highly immunogenic. Therefore, one consequence of this extensive polymorphism is the difficulty of finding suitable donors for tissue transplantation, even among siblings (see Chapter 15).

All MHC class I and II proteins are polymorphic to a greater or lesser extent, with the exception of the DRα chain and its mouse homolog, Eα. These chains do not vary in sequence between different individuals and are said to be **monomorphic**. This might indicate a functional constraint that prevents variation in the DRα and Eα proteins, but no such special function has been found. Many mice, both domestic and wild, have a mutation in the Eα gene that prevents synthesis of the Eα protein. They thus lack cell-surface H-2E molecules, so if H-2E does have a special function it is unlikely to be essential.

MHC polymorphisms at individual MHC genes seem to have been strongly selected by evolutionary pressures. Several genetic mechanisms contribute to the generation of new alleles. Some new alleles arise by point mutations and others by gene conversion, a process in which a sequence in one gene is replaced, in part, by sequences from a different gene (Fig. 6.20. The effects of selective pressure in favor of polymorphism can be seen clearly in the pattern of point mutations in the MHC genes. Point mutations can be classified as replacement substitutions, which change an amino acid, or silent



Ancestral MHC gene undergoes gene duplication and divergence
Multiple MHC genes

Separated chromosome after meiosis

Fig. 6.20 Gene conversion can create new alleles by copying sequences from one MHC gene to another. Multiple MHC genes of generally similar structure were derived over evolutionary time by duplication of an unknown ancestral MHC gene (gray) followed by genetic divergence. Further interchange between these genes can occur by a process known as gene conversion, in which sequences can be transferred from part of one gene to a similar gene. For this to happen, the two genes must become apposed during meiosis. This can occur as a consequence of the misalignment of the two paired homologous chromosomes when there are many copies of similar genes arrayed in tandem—somewhat like buttoning in the wrong buttonhole. During the process of crossing-over and DNA recombination, a DNA sequence from one chromosome is sometimes copied to the other, replacing the original sequence. In this way, several nucleotide changes can be inserted all at once into a gene and can cause several simultaneous amino acid changes in the gene product. Because of the similarity of the MHC genes to each other and their close linkage, gene conversion has occurred many times in the evolution of MHC alleles.

substitutions, which simply change the codon but leave the amino acid the same. Replacement substitutions occur within the MHC at a higher frequency relative to silent substitutions than would be expected, providing evidence that polymorphism has been actively selected for in the evolution of the MHC.

6-12 MHC polymorphism affects antigen recognition by T cells by influencing both peptide binding and the contacts between the T-cell receptor and MHC molecule.

The next few sections describe how MHC polymorphisms benefit the immune response and how pathogen-driven selection can account for the large number of MHC alleles. The products of individual MHC alleles, often known as protein **isoforms**, can differ from one another by up to 20 amino acids, making each variant protein quite distinct. Most of the differences are localized to exposed surfaces of the extracellular domain farthest from the membrane, and to the peptide-binding groove in particular (Fig. 6.21). We have seen that peptides bind to MHC class I and class II molecules through the interaction of specific anchor residues with peptide-binding pockets in the peptide-binding groove (see Sections 4-18 and 4-19). Non-anchor peptide residues can vary between all 20 amino acids. Many of the polymorphisms in MHC molecules alter the amino acids that line these pockets and thus change the pockets' binding specificities. This in turn changes the anchor residues of peptides that can bind to each MHC isoform. The set of anchor residues that allows binding

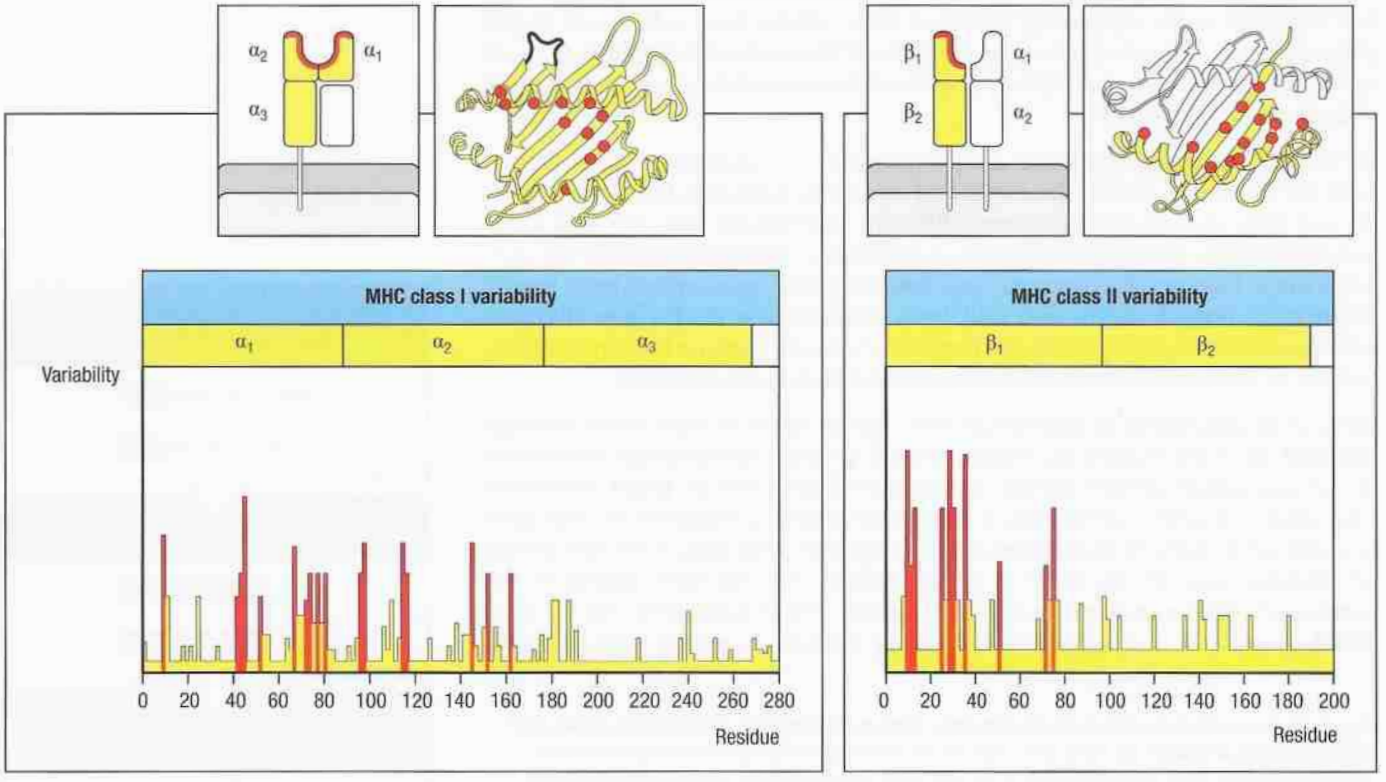

Fig. 6.21 Allelic variation in MHC molecules occurs predominantly within the peptide-binding region. Variability plots of the amino acid sequences of MHC molecules show that the variation arising from genetic polymorphism is restricted to the amino-terminal domains (α_1 and α_2 domains of MHC class I molecules and α_1 and β_1 domains of MHC class II molecules). The amino acid sequence is indicated across the bottom of each graph. Regions of high variability are indicated in red. Shown at the top are ribbon diagrams and schemata of the domains that form the peptide-binding groove and the MHC surface that interacts with the T-cell receptor (TCR). Allelic variability is clustered in specific sites within the amino-terminal domains, lying in positions that line the peptide-binding groove, either on the floor of the groove or inward from the walls, and on the helical surface that interacts with the TCR. For the MHC class II molecule, the variability of the HLA-DR alleles is shown. For HLA-DR, and its homologs in other species, the α chain is essentially invariant and only the β chain shows significant polymorphism (see Fig. 6.18). This is the exception; the α chains of HLA-DP and HLA-DQ are highly polymorphic.

to a given isoform of an MHC class I or class II molecule is called a **sequence motif**, and this can be used to predict peptides within a protein that might bind that variant (Fig. 6.22). Such predictions may be very important in designing peptide vaccines, as we will see in Chapter 16, where we discuss recent progress in cancer immunotherapy.

In rare cases, the processing of a protein does not generate any peptides with a suitable sequence motif for binding to any of the MHC molecules expressed by an individual. This individual fails to respond to the antigen. Such failures in responsiveness to simple antigens were first reported in inbred animals and were called Ir (immune response) gene defects. These defects were mapped to genes within the MHC long before the structure or

Fig. 6.22 Different allelic variants of an MHC class I molecule bind different peptides. Shown are cutaway views of (a) ovalbumin peptide bound to the mouse H-2K^b MHC class I molecule and (b) influenza nucleoprotein (NP) peptide bound to the H-2K^d MHC class I molecule. The solvent-accessible surface of the MHC molecules is shown as a blue dotted surface. Class I MHC molecules typically have six pockets in the peptide-binding groove, which are conventionally called A–F. The bound peptides, shown as space-filling models, fit into the peptide-binding groove, with side chains from the anchor residues extending to fill the pockets. H-2K^b is binding SIINFEKL (single-letter amino acid code), a peptide of eight residues (P1–8) from ovalbumin, and H-2K^d is binding TYQRTRALV, a peptide of nine residues (P1–9) from the influenza nucleoprotein. Anchor residues (shown in yellow) may be primary or secondary in their influence on peptide binding. For H-2K^b, the sequence motif is determined by two primary anchors, P5 and P8; the C pocket binds the P5 side chain of the peptide [a tyrosine (Y) or a phenylalanine (F)], and the F pocket binds the P8 residue [a nonaromatic hydrophobic side chain from leucine (L), isoleucine (I), methionine (M), or valine (V)]. The B pocket binds P2, a secondary anchor residue in H-2K^b. For H-2K^d, the sequence motif is primarily determined by the two primary anchors, P2 and P9. The B pocket accommodates a tyrosine side chain. The F pocket binds leucine, isoleucine, or valine. Beneath the structures are shown sequence motifs from peptides that are known to bind to the MHC molecule. CSP, circumsporozoite antigen; ERK4, extracellular signal-related kinase 4; HBV, hepatitis B virus; JAK1, Janus kinase 1; LCMV, lymphocytic choriomeningitis virus; NS2, NS2 protein; P198, modified tumor-cell antigen; *P. berghei*, *Plasmodium berghei*; *P. yoelii*, *Plasmodium yoelii*; VSV, vesicular stomatitis virus. An extensive collection of motifs can be found at http://www.syfpeithi.de.

function of MHC molecules was understood, and they were the first clue to the antigen-presenting function of MHC molecules. We now understand that Ir gene defects are common in inbred strains of mice because the mice are **homozygous** at all their MHC gene loci, which limits the range of peptides they can present to T cells. Ordinarily, MHC polymorphism guarantees a sufficient number of different MHC molecules in a single individual to make this type of nonresponsiveness unlikely, even to relatively simple antigens such as small toxins.

Early evidence linking Ir gene defects to the MHC was genetic; the MHC genotype determined whether guinea pigs could produce a T-cell response against a particular polypeptide. Likewise, mice of one MHC genotype could make antibody in response to a particular antigen, whereas mice of a different MHC genotype, but otherwise genetically identical, could not. The MHC genotype was somehow controlling the ability of the immune system to detect or respond to specific antigens. For their discovery of the MHC's relationship to Ir genes, Baruj Benacerraf, with George Davis Snell and Jean Dausset, were awarded the 1980 Nobel Prize.

However, it was not clear at the time how the immune responses were controlled by MHC molecules. Later experiments showed that the antigen specificity of T-cell recognition was controlled by MHC molecules. The immune responses affected by the Ir genes were known to depend on T cells, and this led to a series of experiments in mice to ascertain how MHC polymorphism might control T-cell responses. The earliest of these experiments showed that T cells could be activated only by macrophages or B cells that shared MHC alleles with the mouse in which the T cells originated. This was the first evidence that antigen recognition by T cells depends on the presence of specific MHC molecules in the antigen-presenting cell—the phenomenon we now know as **MHC restriction**.

We first mentioned MHC restriction in Section 4-20 in the context of the crystal structure of the T-cell receptor bound to peptide:MHC complexes. But the phenomenon of MHC restriction was discovered much earlier and is illustrated by the studies of virus-specific cytotoxic T cells carried out by Peter C. Doherty and Rolf M. Zinkernagel, for which they received the Nobel Prize in 1996. When mice are infected with a virus, they generate cytotoxic T cells that kill the virus-infected cells while sparing both uninfected cells and cells infected with unrelated viruses. The cytotoxic T cells are thus virus specific. The additional and striking outcome of these experiments was the demonstration that the ability of cytotoxic T cells to kill virus-infected cells was also affected by the polymorphism of MHC molecules. Cytotoxic T cells induced by viral infection in mice of MHC genotype a (MHC^a) would kill any MHC^a cell infected with that virus. But these same T cells would not kill cells of MHC genotype b, or c, and so on, even if they were infected with the same virus. In other words, cytotoxic T cells kill cells infected by virus only if those cells express the same MHC by which the T cells were primed. Because the MHC genotype 'restricts' the antigen specificity of the T cells, this effect was called MHC restriction. Together with the earlier studies on both B cells and macrophages, this work showed that MHC restriction is a critical feature of antigen recognition by all functional classes of T cells.

We now know that MHC restriction is due to the fact that the binding specificity of an individual T-cell receptor is not for its peptide antigen alone but for the complex of peptide and MHC molecule, as discussed in Section 4-15. MHC restriction is explained in part by the fact that different MHC molecules bind different peptides. In addition, some of the polymorphic amino acids in MHC molecules are located in the α helices that flank the peptide-binding groove but have side chains oriented toward the exposed surface of the peptide:MHC complex that can directly contact the T-cell receptor (see Figs. 6.21 and 4.28). In retrospect, then, it is not surprising

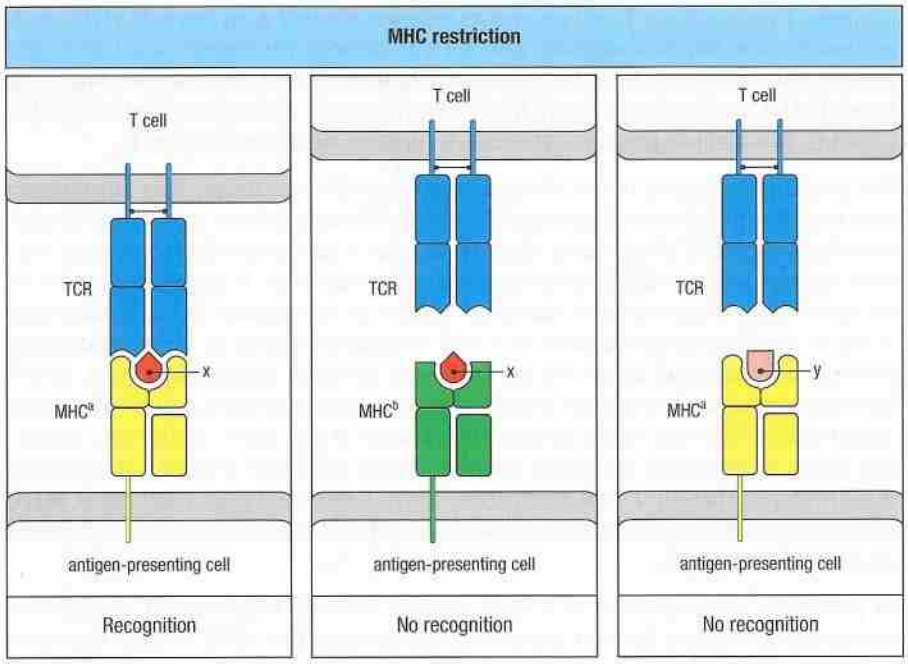

Fig. 6.23 T-cell recognition of antigens is MHC restricted. The antigen-specific T-cell receptor (TCR) recognizes a complex consisting of an antigenic peptide and a self MHC molecule. One consequence of this is a T cell specific for peptide x and an MHC molecule that is the product of a particular MHC allele, MHC^a (left panel), will usually not recognize the complex of peptide x bound to a different MHC allele product, MHC^b (center panel), or the complex of a different peptide, peptide y, bound to MHC^a (right panel). The co-recognition of a foreign peptide and an MHC molecule is known as MHC restriction because the particular MHC allele product is said to restrict the ability of the T cell to recognize antigen. This restriction is the result of the TCR binding the surface of the MHC and its bound peptides, which are highly variable because of MHC polymorphisms.

that T cells can distinguish between a peptide bound to MHC^a and the same peptide bound to MHC^b. This restricted recognition may sometimes be caused both by differences in the conformation of the bound peptide imposed by the different MHC molecules and by direct recognition of polymorphic amino acids in the MHC molecule itself. Thus, the specificity of a T-cell receptor is defined both by the peptide it recognizes and by the MHC molecule bound to it (Fig. 6.23).

6-13 Alloreactive T cells recognizing nonself MHC molecules are very abundant.

The discovery of MHC restriction also helped to explain the otherwise puzzling phenomenon of recognition of nonself MHC in the rejection of organs and tissues transplanted between members of the same species. Transplanted organs from donors bearing MHC molecules that differ from those of the recipient—even by as little as one amino acid—are rapidly rejected owing to the presence in any individual of large numbers of T cells that react to nonself, or **allogeneic**, MHC molecules. Early studies on T-cell responses to allogeneic MHC molecules used the **mixed lymphocyte reaction**, in which T cells from one individual are mixed with lymphocytes from a second individual. If the T cells of this individual recognize the other individual's MHC molecules as 'foreign,' the T cells will divide and proliferate. The lymphocytes from the second individual are usually prevented from dividing by irradiation or treatment with the cytostatic drug mitomycin C. Such studies have shown that roughly 1–10% of all T cells in an individual will respond to stimulation by cells from another, unrelated, member of the same species. This type of T-cell response is called an **alloreaction or alloreactivity**, because it represents the recognition of allelic polymorphisms in MHC molecules.

Before the role of the MHC molecules in antigen presentation was understood, it was a mystery why so many T cells should recognize nonself MHC molecules, as there is no reason that the immune system should have evolved a defense against tissue transplants. Once it was realized that T-cell receptors have evolved to recognize foreign peptides in combination with polymorphic MHC molecules, alloreactivity became easier to explain. We now know of at least two processes that can contribute to the high frequency of alloreactive T cells. The first is the process of **positive selection**. When developing in the

thymus, T cells whose T-cell receptors interact weakly with the self MHC molecules receive survival signals, and so are favored for representation in the peripheral repertoire. It is thought that T-cell receptors that interact with one type of MHC molecule are more likely to cross-react with other (nonself) MHC variants. We discuss positive selection in greater detail in Chapter 8.

But positive selection is not the only basis for alloreactivity. This conclusion was implied by observations that T cells artificially driven to mature in animals lacking MHC class I and class II, in which positive selection in the thymus cannot occur, still display frequent alloreactivity. It appears that T-cell receptor genes encode the inherent ability to recognize MHC molecules. X-ray crystallographic studies of T-cell receptors bound to MHC molecules provide a structural basis for an inherent binding interaction (Fig. 6.24). Specific amino acid residues within the germline-encoded region of certain TCRβ genes interact with conserved features of the MHC molecule, implying a type of germline-encoded affinity. Given the large number of variable-region sequences in T-cell receptors, each T-cell receptor may bind MHC molecules in its own idiosyncratic way using both germline-encoded regions and variable regions.

In principle, alloreactivity of T cells against nonself MHC might depend on recognizing either a foreign peptide antigen bound to MHC or just the nonself MHC molecule alone; these options were called 'peptide-dependent' and 'peptide-independent' allorecognition. But as the number of individual alloreactive T-cell clones studied has increased, it seems that most alloreactive T cells actually recognize both; that is, most individual alloreactive T-cell clones respond to a foreign MHC molecule only when a particular peptide is bound to it. In this sense, the structural basis of allorecognition may be quite similar to normal MHC-restricted peptide recognition and dependent on contacts with both peptide and MHC molecule (see Fig. 6.23, left panel), but in this case, the MHC molecule is foreign. In practice, alloreactive responses against a transplanted organ are likely to represent the combined activity of many different alloreactive T cells. While it is not possible to determine what peptides from the donor might be involved in recognition by the alloreactive T cells, these would be an example of the minor histocompatibility antigens described in

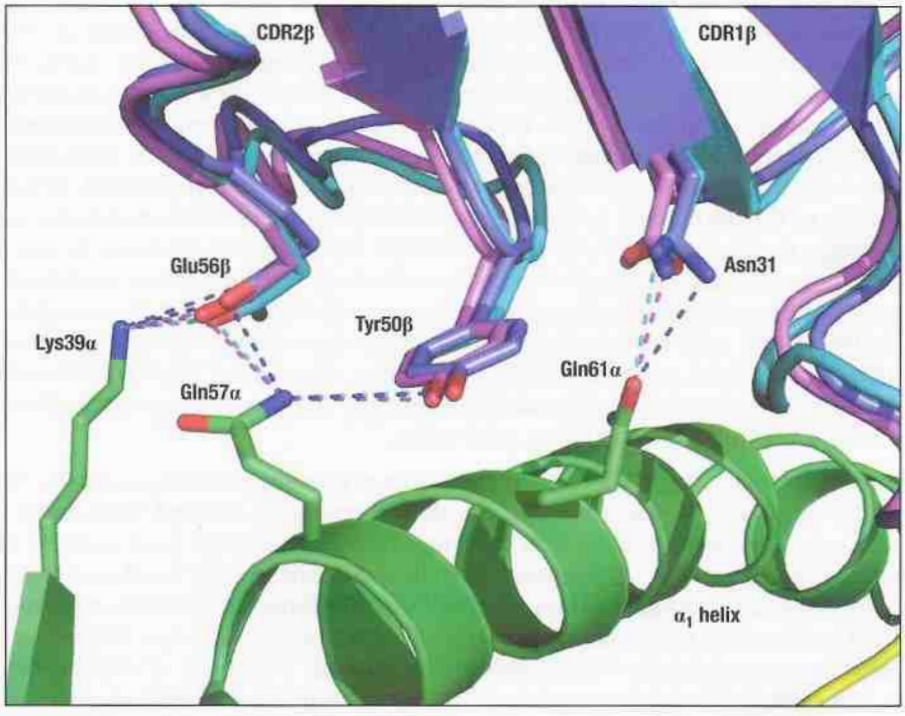

Fig. 6.24 Germline-encoded residues in CDR1 and CDR2 of V-region genes confer on T-cell receptors an inherent affinity for MHC molecules. Shown is the structure for several T-cell receptors bound to a class II MHC molecule. Conserved residues (Lys39, Gln57, and Gln61) within the α_1 helix of the MHC (green) make an extended hydrogen-bonded network with germline-encoded and nonpolymorphic residues located in the CDR1 (Asn31) and CDR2 (Glu56, Tyr50) regions of the V_β 8.2 gene, respectively. The configuration of these contacts is very similar between different structures, implying that the germline sequence of the CDR1 and CDR2 confers an inherent bias for T-cell receptor affinity for MHC.

Section 6-5. We will return to alloreactivity when we discuss organ transplantation in more detail in Chapter 15.

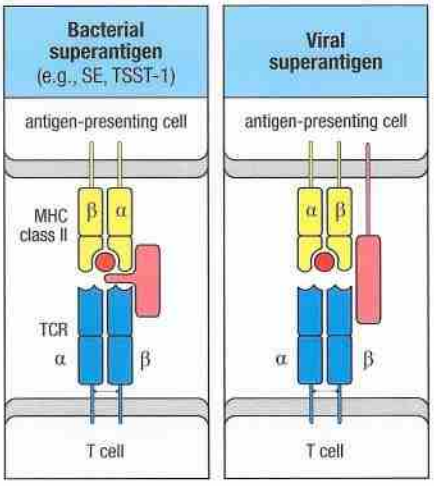
6-14 Many T cells respond to superantigens.

Superantigens are a distinct class of antigens that stimulate a primary T-cell response similar in magnitude to a response to allogeneic MHC molecules. Such responses were first observed in mixed lymphocyte reactions using lymphocytes from strains of mice that were MHC-identical but otherwise genetically distinct. The antigens provoking this reaction were originally designated as **minor lymphocyte stimulating (Mls) antigens**, and it seemed reasonable to suppose that they might be functionally similar to the MHC molecules themselves. We now know that this is not true. The Mls antigens in these mouse strains are encoded by retroviruses, such as the mouse mammary tumor virus, that have become stably integrated at various sites in the mouse chromosomes. Superantigens are produced by many different pathogens, including bacteria, mycoplasmas, and viruses, and the responses they provoke are helpful to the pathogen rather than the host.

Mls proteins act as superantigens because they have a distinctive mode of binding to both MHC and T-cell receptor molecules that enables them to stimulate very large numbers of T cells. Superantigens are unlike other protein antigens in that they are recognized by T cells without being processed into peptides that are captured by MHC molecules. Indeed, fragmentation of a superantigen destroys its biological activity, which depends on binding as an intact protein to the outside surface of an MHC class II molecule that has already bound peptide. In addition to binding MHC class II molecules, superantigens are able to bind the V_β region of many T-cell receptors (Fig. 6.25). Bacterial superantigens bind mainly to the V_β CDR2 loop and, to a lesser extent, to the V_β CDR1 loop and an additional loop called the hypervariable 4 (or HV4) loop. The HV4 loop is the predominant binding site for viral superantigens, at least for the Mls antigens encoded by the endogenous mouse mammary tumor viruses. Thus, the α-chain V region and the CDR3 of the β chain of the T-cell receptor have little effect on superantigen recognition, which is determined largely by the germline-encoded V gene segments that encode the expressed V_β chain. Each superantigen is specific for one or a few of the different V_β gene products, of which there are 20–50 in mice and humans; a superantigen can thus stimulate 2–20% of all T cells.

This mode of stimulation does not prime an adaptive immune response specific for the pathogen. Instead, it causes a massive production of cytokines by CD4 T cells, the predominant responding population of T cells. These cytokines have two effects on the host: systemic toxicity and suppression of the adaptive immune response. Both these effects contribute to microbial pathogenicity. Among the bacterial superantigens are the **staphylococcal enterotoxins (SEs)**, which cause food poisoning, and the **toxic shock syndrome toxin-1 (TSST-1)** of *Staphylococcus aureus*, the etiologic principle in **toxic shock syndrome**, which can be caused by a localized infection with toxin-producing strains of the bacterium. The role of viral superantigens in human disease is less clear.

Toxic Shock Syndrome



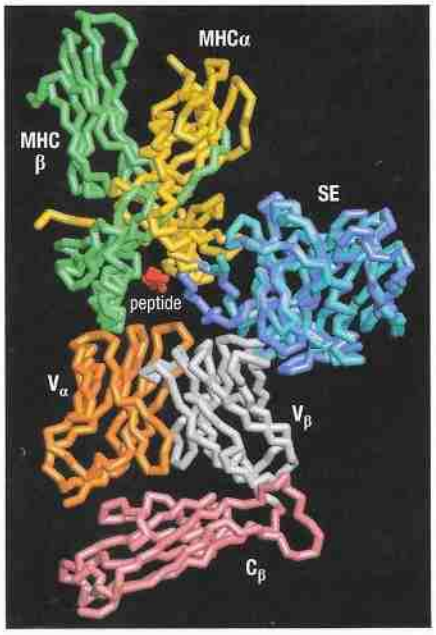


Fig. 6.25 Superantigens bind directly to T-cell receptors and to MHC molecules. Superantigens can bind independently to MHC class II molecules and to T-cell receptors. As shown in the top panels, the superantigens (red bars) can bind to the V_β domain of the T-cell receptor (TCR), away from the complementarity-determining regions, and to the outer faces of the MHC class II molecule, outside the peptide-binding site. In the bottom panel, a reconstruction of the interaction between a T-cell receptor, an MHC class II molecule, and a staphylococcal enterotoxin (SE) superantigen is shown by superimposing separate structures of an enterotoxin:MHC class II complex onto an enterotoxin:T-cell receptor complex. The two enterotoxin molecules (actually SEC3 and SEB) are shown in turquoise and blue, binding to the α chain of the MHC class II molecule (yellow) and to the β chain of the T-cell receptor (colored gray for the V_β domain and pink for the C_β domain).

6-15 MHC polymorphism extends the range of antigens to which the immune system can respond.

Most polymorphic genes encode proteins that vary by only one or a few amino acids, whereas the allelic variants of MHC proteins differ from each other by up to 20 amino acids. The extensive polymorphism of the MHC proteins has almost certainly evolved to outflank the evasive strategies of pathogens. The requirement that pathogen antigens must be presented by an MHC molecule provides two possible ways in which pathogens could evolve to evade detection. One is through mutations that eliminate from the pathogen's proteins all peptides able to bind MHC molecules. The Epstein–Barr virus provides an example. There are small isolated populations in southeast China and Papua New Guinea in which about 60% of the people carry the HLA-A11 allele. Many isolates of the Epstein–Barr virus obtained from these populations have mutations in a dominant peptide epitope normally presented by HLA-A11; the mutant peptides no longer bind to HLA-A11 and cannot be recognized by HLA-A11–restricted T cells. This strategy is clearly much less successful if there are many different MHC molecules, and the polygeny of the MHC may have evolved in response.

In addition, in large outbred populations, polymorphism at each locus can greatly increase the number of different MHC molecules expressed by an individual, as most individuals will be heterozygotes. Polymorphism has the additional advantage that individuals in a population will differ in the combinations of MHC molecules that they express and will therefore present different sets of peptides from each pathogen. This makes it unlikely that all individuals in a population will be equally susceptible to a given pathogen, and its spread will therefore be limited. The fact that exposure to pathogens over an evolutionary timescale can select for particular MHC alleles is indicated by the strong association of the HLA-B53 allele with recovery from a potentially lethal form of malaria. This allele is very common in people from West Africa, where malaria is endemic, and rare elsewhere, where lethal malaria is uncommon.

Similar arguments apply to a second strategy by which pathogens could evade recognition. Pathogens that can block the presentation of their peptides by MHC molecules can avoid the adaptive immune response. Adenoviruses encode a protein that binds to MHC class I molecules in the endoplasmic reticulum and prevents their transport to the cell surface, thus preventing the recognition of viral peptides by cytotoxic CD8 T cells. This viral MHC-binding protein interacts with a polymorphic region of the MHC class I molecule, as some allelic variants are retained in the endoplasmic reticulum by the adenoviral protein, whereas others are not. Increasing the variety of MHC molecules expressed reduces the likelihood that a pathogen will be able to block presentation by all of them and completely evade an immune response.

These arguments raise a question: If having three MHC class I loci is better than having one, why are there not far more? The probable explanation is that each time a distinct MHC molecule is added to the repertoire, all T cells that can respond to self peptides bound to that MHC molecule must be removed to maintain self-tolerance. It seems that the number of MHC genes present in humans and mice is about optimal to balance the advantages of presenting an increased range of foreign peptides with the disadvantages of losing T cells from the repertoire.

Summary.

The major histocompatibility complex (MHC) of genes consists of a linked set of genetic loci encoding many of the proteins involved in antigen presentation to T cells, most notably the MHC class I and class II glycoproteins (the MHC molecules) that present peptides to the T-cell receptor. The outstanding feature

of the MHC molecules is their extensive polymorphism. This polymorphism is of critical importance in antigen recognition by T cells. A T cell recognizes antigen as a peptide bound by a particular allelic variant of an MHC molecule and will not recognize the same peptide bound to other MHC molecules. This behavior of T cells is called MHC restriction. Most MHC alleles differ from one another by multiple amino acid substitutions, and these differences are focused on the peptide-binding site and the surface-exposed regions that make direct contact with the T-cell receptor. At least three properties of MHC molecules are affected by MHC polymorphism: the range of peptides bound; the conformation of the bound peptide; and the direct interaction of the MHC molecule with the T-cell receptor. Thus, the highly polymorphic nature of the MHC has functional consequences, and the evolutionary selection for this polymorphism suggests that it is critical to the role of the MHC molecules in the immune response. Powerful genetic mechanisms generate the variation that is seen among MHC alleles, and a compelling argument can be made that selective pressure to maintain a wide variety of MHC molecules in the population comes from infectious agents. As a consequence, the immune system is highly individualized—each individual responds differently to a given antigen.

Recognition of nonpeptide ligands by unconventional T-cell subsets.

So far we have focused on how peptide:MHC complexes—the ligands for αβ T cells—are generated. We now turn to the question of how other types of T cells recognize their ligands and how these ligands are generated. Our current knowledge in this area is still incomplete, and this is perhaps most apparent in the area of γδ T cells, where a growing list of ligands for individual γδ T cells suggests an innate-like pattern of recognition. The recent discovery that mucosal-associated invariant T cells (MAIT cells; see Section 4-21) recognize microbial metabolites when they are presented by a nonpolymorphic MHC class I–like molecule solved a long-standing mystery regarding the specificity of this particular T-cell subset. Another subset, the invariant NKT cells, provides a system for detecting and responding to lipid rather than peptide antigens. These unconventional T cells respond rapidly, without the need for clonal expansion, and therefore operate somewhere between innate and adaptive immunity. In this part of the chapter, we will discuss the ligands they recognize and what is known about how they are generated or expressed.

6-16 A variety of genes with specialized functions in immunity are also encoded in the MHC.

In addition to the highly polymorphic 'classical' MHC class Ia proteins described earlier, there is a group of structurally related MHC class I–like proteins, the so-called 'nonclassical' MHC or MHC class Ib proteins. Some of these are encoded by genes located within the MHC, and others reside outside the MHC. By comparison with MHC class Ia proteins, MHC class Ib genes show little polymorphism. Many of these have yet to be assigned a function, and their exact number varies greatly among species and even among members of the same species. Like MHC class I proteins, many, but not all, associate with β_2-microglobulin when expressed on the cell surface. Their expression on cells is variable, both in the amount present at the cell surface and in tissue distribution. The characteristics of several MHC class Ib gene products are shown in Fig. 6.26.

One mouse MHC class Ib molecule, **H2-M3**, can present peptides with *N*-formylated amino termini, which is of interest because all bacteria initiate protein synthesis with *N*-formylmethionine (fMet). Cells infected with cytosolic bacteria can be killed by CD8 T cells that recognize *N*-formylated

	Class Ib molecule						Receptors or interacting proteins			
	Human	**Mouse**	**Expression pattern**	**Associates with β_2m**	**Poly-morphism**	**Ligand**	**T-cell receptor**	**NK receptor**	**Other**	**Biological function**
MHC encoded	HLA-C (class Ia)		Ubiquitous	Yes	High	Peptide	TCR	KIRs		Activate T cells Inhibit NK cells
		H2-M3	Limited	Yes	Low	fMet peptide	TCR			Activate CTLs with bacterial peptides
		T22 T10	Splenocytes	Yes	Low	None	γδ TCR			Regulation of activated splenocytes
	HLA-E	Qa-1	Ubiquitous	Yes	Low	MHC leader peptides (Qdm)		NKG2A NKG2C		NK-cell inhibition
	HLA-F		Widely expressed	Yes	Low	Peptide?		LILRB1 LILRB2		Unknown
	HLA-G		Maternal–fetal interface	Yes	Low	Peptide	TCR	LILRB1 LILRB2		Modulate maternal–fetal interaction
	MIC-A MIC-B		Widely expressed	No	Moderate	None		NKG2D		Stress-induced activation of NK cells, γδ and CD8 T cells
		TL	Small intestine epithelium	Yes	Low	None	CD8ααα			Potential modulation of T-cell activation
		M10	Vomeronasal neurons	Yes	Low	Unknown			Vomeronasal receptor V2R	Pheromone detection
Non-MHC encoded	ULBPs	MULT1, H60, Rae1	Limited	No	Low	None		NKG2D		Induced NK-cell–activating ligand
	MR1	MR1	Ubiquitous	Yes	None	Riboflavin metabolites (vit B_2, vit B_9)	αβ TCR			Control of antimicrobial response
	CD1a–CD1e	CD1d	Lymphocytes	Yes	None	Lipids glycolipids	αβ TCR			Activate T cells against bacterial lipids
		Mill1 Mill2	Ubiquitous	Yes?	Low	Unknown	Unknown			Unknown
	HFE	HFE	Liver and gut	Yes	Low	None			Transferrin receptor	Iron homeostasis
	FcRn	FcRn	Maternal–fetal interface	Yes	Low	None			Fc (IgG)	Shuttle maternal IgG to fetus (passive immunity)
	ZAG	ZAG	Bodily fluid	No	None	Fatty acid				Lipid homeostasis
	EPCR	EPCR	Endothelial cells	No	Low		γδ TCR		Protein C	Blood coagulation

Fig. 6.26 Mouse and human MHC class Ib proteins and their functions. MHC class Ib proteins are encoded both within the MHC region and on other chromosomes. The functions of some MHC class Ib proteins are unrelated to the adaptive immune response, but many have a role in innate immunity by interacting with receptors on NK cells (see the text and Section 3-25). HLA-C, which is a classical MHC molecule (class Ia), is included here because, in addition to presenting peptides to T-cell receptors, all HLA-C isoforms interact with the KIR class of NK-cell receptors to regulate NK-cell function in the innate immune response. CTLs are cytotoxic T lymphocytes. FcRn, the neonatal Fc receptor, is discussed in Chapters 5 and 10, and TL (thymus leukemia antigen) is discussed in Chapter 12. The role of Mill1 (MHC I–like leukocyte 1) and Mill2 is still under investigation.

bacterial peptides bound to H2-M3. Whether an equivalent MHC class Ib molecule exists in humans is not known.

Two other closely related mouse MHC class Ib genes, ***T22*** and ***T10***, are expressed by activated lymphocytes and are recognized by a subset of γδ T cells. Although the precise purpose remains unclear, it has been proposed that this interaction allows γδ T cells to regulate activated lymphocytes expressing T22 and T10 proteins.

The other genes that map within the MHC include some that encode complement components (for example, C2, C4, and factor B) and some that encode cytokines (for example, tumor necrosis factor and lymphotoxin)—all of which have important functions in immunity. These genes lie in the so-called 'MHC class III' region (see Fig. 6.17).

Many studies have established associations between susceptibility to certain diseases and particular alleles of MHC genes (see Chapter 15), and we now have considerable insight into how polymorphism in the classical MHC class I and class II genes can affect disease resistance or susceptibility. Most MHC-influenced traits or diseases are known or suspected to have an immunological cause, but this is not so for all of them: some genes residing within the MHC have no known or suspected immunological function. For example, the class Ib gene *M10* encodes a protein that functions in the vomeronasal organ as a chaperone to escort certain types of pheromone receptors to the cell surface. *M10* could potentially influence mating preference, a trait that has been linked to the MHC region in rodents.

The gene ***HFE***, encoding the **hemochromatosis protein**, lies some 4 million base pairs from HLA-A. Its protein product is expressed in cells of the intestinal tract and acts in iron metabolism by regulating the uptake of dietary iron into the body. It seems to interact with the transferrin receptor and decrease the receptor's affinity for iron-loaded transferrin. Individuals defective for this gene have an iron-storage disease, **hereditary hemochromatosis**, in which an abnormally high level of iron is retained in the liver and other organs. Mice lacking β_2-microglobulin have defective expression of all class I molecules and thus also show a similar iron overload. Another MHC gene with a nonimmune function encodes the enzyme **21-hydroxylase**, which, when deficient, causes congenital adrenal hyperplasia and, in severe cases, salt-wasting syndrome. Even where a disease-related gene is clearly homologous to immune-system genes, as is the case with *HFE*, the disease mechanism may not be immune related. Disease associations mapping to the MHC must therefore be interpreted with caution, in the light of a detailed understanding of its genetic structure and the functions of its individual genes. Much remains to be learned about the significance of all the genetic variation localized within the MHC. For instance, the human complement component 4 (C4) comes in two versions, C4A and C4B, not to be confused with the C4 convertase cleavage products C4a and C4b, and different individuals have variable numbers of the gene for each type in their genomes, but the adaptive significance of this genetic variability is not well understood.

6-17 Specialized MHC class I molecules act as ligands for the activation and inhibition of NK cells and unconventional T-cell subsets.

In Sections 3-24 to 3-27, we introduced NK cells and briefly discussed their activation by members of the MIC gene family expressed by humans. These MHC class Ib genes are regulated differently from MHC class Ia genes and are induced in response to cellular stress (such as heat shock). There are seven MIC genes, but only two are expressed and produce protein products, **MIC-A and MIC-B** (see Fig. 6.26). They are expressed in fibroblasts and epithelial cells, particularly in intestinal epithelial cells, and have a role in

innate immunity or in the induction of immune responses in circumstances in which interferons are not produced. The MIC-A and MIC-B proteins are recognized by the NKG2D receptor expressed by NK cells. But NKG2D is also expressed by γδ T cells and some CD8 T cells, and it can activate these cells to kill MIC-expressing targets. NKG2D is an 'activating' member of the NKG2 family of NK-cell receptors (see Fig. 3.40); its cytoplasmic domain lacks the inhibitory sequence motif found in other members of this family, which act as inhibitory receptors (see Section 3-26). NKG2D is coupled to the adaptor protein DAP10, which transmits the signal into the interior of the cell by interacting with and activating intracellular phosphatidylinositol 3-kinase.

Even more distantly related to MHC class I genes is a small family of proteins known in humans as the **UL16-binding proteins (ULBPs**; UL16 is a human cytomegalovirus protein) or the **RAET1** proteins (see Fig. 6.26); the homologous proteins in mice are known as Rae1 (retinoic acid early inducible 1) and H60. These proteins also bind NKG2D (see Section 3-27). They seem to be expressed under conditions of cellular stress, such as when cells are infected with pathogens or have undergone transformation to tumor cells. By expressing ULBPs, stressed or infected cells can bind and activate NKG2D molecules expressed on NK cells, γδ T cells, and cytotoxic CD8 αβ T cells, and so be recognized and eliminated.

The human MHC class Ib molecule HLA-E and its mouse counterpart Qa-1 (see Fig. 6.26) have an unusual and somewhat puzzling role in cell recognition by NK cells and CD8 T cells. HLA-E and Qa-1 bind a very restricted subset of nonpolymorphic peptides, called **Qa-1 determinant modifiers (Qdm)**, which are derived from the leader peptides of other HLA class I molecules. These peptide:HLA-E complexes can bind to the inhibitory receptor NKG2A:CD94 expressed on NK cells, and so should inhibit the cytotoxic activity of NK cells. This function might seem redundant, because expression of other MHC class I molecules by cells should prevent NK-cell activation (see Section 3-25). Nonetheless, it has been shown that Qa-1 expression by activated CD4 T cells protects them from lysis by NK cells, and so Qa-1 expression by other host cells may provide them with additional protection from being killed by NK cells. HLA-E and Qa-1 can also bind leader peptides from the heat-shock protein Hsp60, and CD8 T cells that are specific for these complexes have been identified in mice and humans. Some recent evidence suggests that CD8 T cells restricted by HLA-E/Qa-1 may help maintain self-tolerance by killing or suppressing potentially autoreactive T cells.

In Section 3-26, we introduced the **killer cell immunoglobulin-like receptors (KIRs)** expressed by human NK cells. Members of the KIRs recognize the classical class Ia MHC molecules HLA-A, -B, and -C, which present a diverse repertoire of peptides to CD8 T cells. HLA-C is specialized for regulating NK cells in humans, as all HLA-C alleles express proteins that bind KIRs, while only a few HLA-A and HLA-B alleles do so. Although KIRs interact with the same face of the MHC class I molecule as do T-cell receptors, the KIRs bind only at one end, and not over the whole area recognized by the T-cell receptor. KIRs themselves are highly polymorphic, and they have undergone rapid evolution in humans.

Two other MHC class Ib molecules, HLA-F and HLA-G (see Fig. 6.26), can also inhibit cell killing by NK cells. HLA-G is expressed on fetus-derived placental cells that migrate into the uterine wall. These cells express no classical MHC class I molecules and cannot be recognized by CD8 T cells, but, unlike other cells lacking such proteins, they are not killed by NK cells. This seems to be because HLA-G is recognized by two other inhibitory receptors on NK cells, the leukocyte immunoglobulin-like receptor subfamily B member 1 (LILRB1; also called ILT-2 or LIR-1) and by LILRB2.

HLA-G expressed by placental cells prevents their being killed by NK cells. HLA-F is expressed in a variety of tissues, although it is usually not detected at the cell surface, except, for example, on some monocyte cell lines or on virus-transformed lymphoid cells. HLA-F is also thought to interact with LILRB1.

6-18 Members of the CD1 family of MHC class I–like molecules present lipid-based antigens to NKT cells.

Some MHC class I-like genes map outside the MHC region. One small family of such genes is called **CD1** and is expressed on dendritic cells, monocytes, thymocytes, and lymphocytes including T and B cells. Humans have five CD1 genes, CD1a through e, whereas mice and rats have only two highly homologous versions of CD1d, namely CD1d1 and CD1d2. CD1 proteins can present antigens to T cells, but they have two features that distinguish them from classical MHC class I molecules. The first is that CD1, although similar to an MHC class I molecule in its subunit organization and association with β_2-microglobulin, behaves like an MHC class II molecule. It is not retained within the endoplasmic reticulum by association with the TAP complex but is targeted to vesicles, where it binds its ligand. The second unusual feature is that, unlike MHC class I, CD1 molecules have a hydrophobic pocket specialized for binding hydrocarbon alkyl chains. This confers CD1 molecules an ability to bind and present a variety of lipid-based antigens.

CD1 molecules are classified into group 1, comprising CD1a, CD1b, and CD1c, and group 2, containing only CD1d; CD1e is considered intermediate. CD1d expression is constitutive, while expression of all others is inducible during immune responses. Group 1 molecules bind various **microbial glycolipids**, phospholipids, and **lipopeptide antigens**, such as the mycobacterial membrane components mycolic acid, glucose monomycolate, phosphoinositol mannosides, and lipoarabinomannan (Fig. 6.27). CD1d molecules can bind self lipid antigens such as **sphingolipids** and **diacylglycerols** but also microbial lipid-based antigens, for example from *Borrelia burgdorferi*, the agent that causes Lyme disease.

Structural studies show that the CD1 molecule has a deep binding groove into which the glycolipid antigens bind (Fig. 6.28). Unlike the binding of peptide to MHC, in which the peptide takes on a linear, extended conformation, CD1 molecules bind their antigens by anchoring the alkyl chains in the hydrophobic groove, which orients the variable hydrophilic parts of these molecules, such as a phosphate or carbohydrate group, to protrude from the binding groove, allowing recognition by the T-cell receptors on CD1-restricted T cells. In contrast to other CD1 molecules, CD1e is not bound to the cell membrane and so is not recognized by T cells but may act in the transfer of intracellular lipids.

The T cells that recognize lipids presented by CD1 molecules can vary in their expression of the co-receptors CD4 and CD8; some express CD4, but others are negative for CD4 and CD8 expression. Most of the T cells recognizing lipids presented by group 1 CD1 molecules have a diverse repertoire of $\alpha\beta$ receptors and respond to these lipids presented by CD1a, CD1b, and CD1c. CD1d-restricted T cells are less diverse, with many using the same TCRα chain

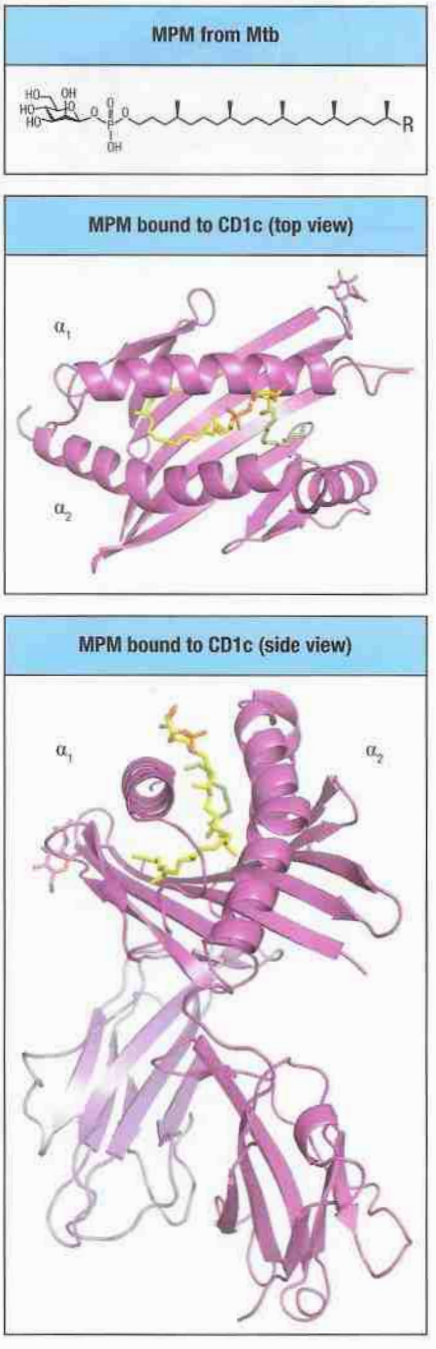

Fig. 6.27 CD1c binds microbial lipids for presentation to iNKT cells. Top panel: The structure of mannosyl-β1-phosphomycoketides (MPMs) from the cell walls of *Mycobacterium tuberculosis* (Mtb) (R = C_7H_{15}) and *M. avium* (R = C_5H_{11}). Middle panel: MPM (stick figure) bound to CD1c (purple) as viewed from the top, facing the surface of the cell bearing CD1c. Bottom panel: Side view of MPM bound to CD1c. The general resemblance with peptide:MHC complexes is apparent. Note: The long acyl chain of MPM extends deep into the binding groove of CD1c, to beneath the α_1 helical domain.

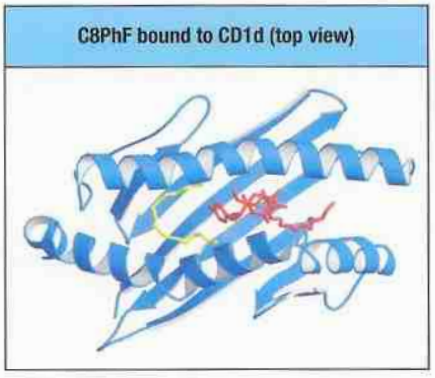

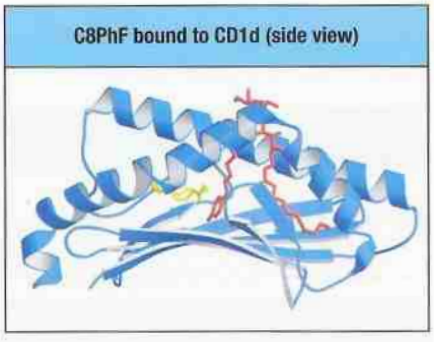

Fig. 6.28 Structure of CD1 binding to a lipid antigen. Shown are top and side views of the structure of mouse CD1d bound to C8PhF, a synthetic lipid that is an analog of α-GalCer. The helical side chains of CD1d (blue) form a binding pocket that is generally similar in shape to the binding pockets of MHC class I and class II molecules. However, the C8PhF (red) ligand binds to CD1 molecules in a distinctly different conformation from that of peptides. The two long alkyl side chains extend deep inside the binding groove (see side view), where they make contacts with hydrophobic residues. This orientation of the alkyl side chains places the carbohydrate component of α-GalCer to the outer surface of CD1, where it can be recognized by the T-cell receptor. In addition, the CD1 molecule contains an endogenous lipid molecule (yellow) derived from cellular sources and which binds to a distinct region within the groove and prevents a large pocket adjacent to the α-GalCer–binding region from collapsing. The ability to incorporate additional ligands into the binding groove may provide flexibility to CD1d in accommodating a variety of exogenous glycosphingolipids from microorganisms.

(Vα24-Jα18 in humans). Many also express NK-cell receptors, such as NK1.1. In fact, CD1d-restricted T cells were originally called **invariant NKT (iNKT) cells**. However, CD1d-restricted T cells have a diverse TCRβ repertoire, and some are now known to have a more diverse TCRα chain repertoire as well. A new nomenclature uses **type 1 NKT cells** to refer to CD1d-restricted T cells with a restricted TCRα chain and **type 2 NKT cells** to refer to those with a more diverse TCRα repertoire. A recently discovered population of CD1b-restricted human T cells uses a near-invariant TCRα chain (Vα1–2 and Jα9). These cells, which recognize the mycobacterial lipid antigen glucose monomycolate, are called **GEM** (germline-encoded mycolyl lipid-reactive) T cells.

One ligand recognized by CD1d-restricted NKT cells is **α-galactosylceramide (α-GalCer)**, which was isolated from an extract of marine sponge. Related glycosphingolipids are produced by various bacteria, including *Bacteroides fragilis*, which is present in the normal human microbiota. When α-galactosylceramide is bound to CD1d, it forms a structure that is recognized by many NKT cells. Unlike conventional αβ T cells that require several days of activation and expansion in order to acquire effector function, NKT cells can produce cytokines rapidly after they recognize lipid-based antigens presented by CD1d molecules. In this way, they are similar to innate lymphocytes such as NK cells. Their recognition of limited types of antigens is also a characteristic of cells of the innate immune system.

Similar to the theme of loading peptides onto classical MHC proteins from various cellular locations, the various CD1 proteins are transported differently through the endocytic compartments, providing them with access to different lipid antigens. Transport is regulated by an amino acid sequence motif at the terminus of the cytoplasmic domain of the CD1 protein through interaction with the adaptor-protein (AP) complexes AP-2 and AP-3. CD1a lacks this binding motif and moves to the cell surface, where it is transported only through the early endocytic compartment. CD1b, CD1c, and CD1d have motifs that interact with the adaptor AP-2 and are transported through early and late endosomes. CD1b and mouse CD1d bind AP-2 and AP-3 and can be transported through late endosomes, lysosomes, and the MIIC. Thus, CD1 proteins can bind lipids delivered into and processed within the endocytic pathway, such as by the internalization of mycobacteria or the ingestion of mycobacterial glycolipids (such as lipoarabinomannans), mediated by mannose receptors.

CD1a is highly expressed on human **Langerhans cells**, a specialized immune cell that has similarities to macrophages and dendritic cells and which resides in the epidermis. The epidermis is protected in part by the production of sebum, containing various lipids, including wax esters and squalene (see Section 2-2). CD1a-restricted T cells survey human skin for the "headless" lipid-based antigens presented by the CD1a expressed by Langerhans cells, which may indicate a breach of skin tissue. CD1a-restricted T cells also respond to injury caused by bee and wasp venom, presumably in response to ligands generated by the venom's lipid-modifying phospholipases.

MHC class Ib genes evolved before the divergence of cartilaginous fishes from the vertebrate line and are likely to have homologs in all vertebrates. Other MHC class I genes have evolved independently into classical and nonclassical loci within the vertebrate lineages that have been studied (for example, cartilaginous fishes, lobe-finned fishes, ray-finned fishes, amphibians, and mammals). Sequence data have also revealed homologs of the mammalian MHC class I and MHC class II gene families in virtually all jawed vertebrates including sharks, bony fishes, reptiles, and birds. In contrast, CD1 genes may not be as old as other MHC class Ib genes. They have been found only in a subset of these animal groups and appear to be missing in fishes. This pattern of CD1 occurrence in the genomes of living species suggests the emergence of CD1 in an early terrestrial vertebrate.

6-19 The nonclassical MHC class I molecule MR1 presents microbial riboflavin metabolites to MAIT cells.

Another nonclassical MHC class I–like molecule is **MR1 (MHC-related protein 1)**. MR1 is the most highly conserved MHC class I antigen-presenting molecule across many mammalian species and is linked to the CD1 genes on human chromosome 1, suggesting an important function. MR1 associates with β_2-microglobulin and is encoded outside the MHC. The function of MR1 was originally known only in relation to a conserved population of $\alpha\beta$ T cells known as mucosal-associated invariant T cells (MAIT cells), which we introduced in Section 4-21. MAIT cells are uniquely characterized by expression of an invariant α chain of the T-cell receptor, specifically human $V_\alpha 7.2$ and $J_\alpha 33$, and in mouse, $V_\alpha 19$, $J_\alpha 33$, or occasionally $J_\alpha 12$ or $J_\alpha 20$. These α chains pair with a limited number of V_β chains, typically $V_\beta 2$ or $V_\beta 13$. MAIT cells are very abundant in human tissues and can compose up to 10% of lymphocytes in peripheral blood and up to 40% of lymphocytes in liver. They are also present in mesenteric lymph nodes and the mucosa of the intestine, lungs, and all locations where other T cells reside.

When MAIT cells were identified in the 1990s, it was unclear what ligand, if any, they recognized. Studies indicated that development of MAIT cells required MR1 and that they could be activated by a wide spectrum of microbes, including diverse bacteria and yeast. Structural studies of the MR1 protein uncovered an important clue: The MR1 protein produced by cell lines *in vitro* was yellow; chemical analysis revealed that a small molecule, the folate derivative 6-formylpterin (6-FP) was covalently bound to Lys43 of the MR1 protein. Further X-ray crystallographic studies showed that 6-FP bound within the central groove of the MR1 molecule. However, most MAIT cells were not activated by cells expressing the 6-FP:MR1 complex, suggesting that other molecules might be the physiological ligands that activate MAIT cells. Analysis of MR1 proteins that were refolded in the presence of supernatants from cultures of *Salmonella enterica* ssp. *typhimurium* eventually led to the identification of several riboflavin (vitamin B_2) metabolites that are formed by biosynthetic pathways in most bacteria and yeast. One key antigen for MAIT-cell activation is the short-lived metabolite 5-(2-oxopropylideneamino)-6-d-ribitylaminouracil (5-OP-RU) formed by microbial biosynthetic pathways. These metabolites, captured from the extracellular environment or from phagosomes harboring bacteria, find their way to the endoplasmic reticulum, where empty MR1 is being retained. There they bind and stabilize MR1, induce its surface expression, and cause activation of MAIT cells. Thus, the surface expression of MR1 is a sensor of microbial riboflavin metabolism, and MAIT cells are activated in response to infection by organisms that produce it. Like NKT cells, MAIT cells use a TCR assembled by somatic gene rearrangement to recognize a molecular structure that falls within the definition of a PAMP (pathogen-associated molecular pattern; see Section 3-1). Also like NKT cells, MAIT cells produce cytokines rapidly after activation, without the need for priming and expansion by dendritic cells.

6-20 γδ T cells can recognize a variety of diverse ligands.

γδ T cells and αβ T cells have been known to be distinct developmental lineages almost since the T-cell receptor genes were identified. But unlike αβ T cells, the function of γδ T cells has remained somewhat obscure, due primarily to difficulty in identifying the ligands they recognize. Yet the abundance of γδ T cells across vertebrate species, their rapid expansion to form more than 50% of the blood lymphocytes during infections, and their abundant cytokine production all argue for an important role in immunity. They are also the cell type that most favorably correlates with a good prognosis in human tumors. Over time, many different ligands recognized by γδ T-cell clones have been identified (Fig. 6.29), and their diversity suggests that, like NKT cells and MAIT cells, they play an intermediate role in the spectrum of innate versus adaptive immunity.

In Section 4-23, we discussed how one γδ T-cell receptor binds to the nonclassical MHC class I molecule T22. Instead of binding centrally over the MHC binding groove, similar to an αβ T-cell receptor, the γδ T-cell receptor interacts obliquely from one side of the T22 molecule. However, fewer than 1% of γδ T cells recognize this ligand. Other antigens recognized by murine γδ T cells are the protein **phycoerythrin (PE)** from algae, the inner mitochondrial membrane lipid **cardiolipin**, glycoprotein I (gI) of herpes simplex virus, and a peptide derived from the hormone insulin. Other antigens that can activate human γδ T cells are the nonclassical MHC class I proteins MIC-A and **ULBP4** and the **endothelial protein C receptor (EPCR)**, which is expressed by endothelial cells. Like MIC-A and ULBPs, EPCR appears to be induced by stress, such as infection of cells by cytomegalovirus, suggesting that reactive γδ T cells could serve in an innate capacity similar to that of NK cells activated by stress-induced nonclassical MHC class Ib molecules. Also, some γδ T cells can recognize α-galactosylceramide and the sulfated glycolipid sulfatide (3-*O*-sulfogalactosylceramide) presented by CD1d. A subset of γδ T cells

Ligands that activate γδ T cells		
Ligands	**Species**	**γδ subset**
T22, T10	Mouse	Various
H2-E (MHC class II)	Mouse	Clones
Phycoerythrin (PE)	Mouse	Various
Cardiolipin	Mouse	Various
Keratinocytes	Mouse	DETC $V_\gamma5V_\delta1$
HSV-gI	Mouse	Clone
Skint-1	Mouse	$V_\gamma5V_\delta1$
MIC-A/MIC-B	Human	Clones
ULBP4	Human	$V_\gamma9V_\delta2$
CD1-sulfatide, CD1d-αGalCer	Human	$V_\delta1$
EPCR (endothelial protein C receptor)	Human	Clones
Phosphoantigens, amino-bisphosphonates, BTN3A1	Human	$V_\gamma9V_\delta2$
Alkylamines	Human	$V_\gamma9V_\delta2$

Fig. 6.29 Ligands that activate γδ T cells.

expressing a Vγ9Vδ2 TCR respond to small phosphate-containing antigens (for example, hydroxymethyl but-2-enyl pyrophosphate) in a manner requiring a cell-surface receptor BTN3A1, a member of the **butyrophilin (BTN)** family. BTNs are type 1 cell-surface transmembrane proteins having two or more extracellular immunoglobulin domains; humans have 11 BTN family members. The mechanism of antigen presentation by BTNs to γδ T cells is still a matter of active research, but some evidence suggests that different BTNs may function in heterodimeric pairs.

Several other antigens can activate human γδ T cells (see Fig. 6.29), although there is still limited structural information about their interaction with the T-cell receptor, and even reservations about whether such an interaction is always the basis for activation. Among these activating antigens is **Skint-1** (selection and upkeep of intraepithelial T cells 1), an immunoglobulin superfamily member related to the butyrophilins that is expressed by thymic epithelial cells and by keratinocytes. Skint-1 seems to be required in mice for the generation of a subset of Vγ5Vδ1 T cells that develop in the thymus and home to the skin to become **dendritic epidermal T cells (DETCs)**. Some evidence suggests a direct interaction between Skint-1 and the γδ T-cell receptor, although structural studies are not yet available. Conceivably, DETCs localize to the skin because their T-cell receptor recognizes Skint-1 expressed by keratinocytes. There DETCs might provide a 'transitional' mode of immune defense, becoming activated through innate receptors that are triggered locally during infections.

Summary.

Antigen presentation to various nonconventional T-cell subsets and γδ T cells generally does not involve the generation of peptide:MHC complexes. Instead, these cells recognize surface proteins, such as ULBPs and RAET1 proteins (which may indicate cellular stress, transformation, or intracellular infection), or nonpeptide antigens; NKT cells recognize various microbial glycolipids presented by CD1 molecules; and MAIT cells recognize microbe-specific riboflavin metabolites presented by MR1. The MHC region contains many genes whose structure is closely related to the MHC class I molecules—the so-called nonclassical, or class Ib, MHC. Some of these genes serve purposes that are unrelated to the immune system, but many are involved in recognition by activating and inhibitory receptors expressed by NK cells, γδ T cells, and αβ T cells. MHC class I–like proteins called CD1 molecules are encoded outside the MHC region. CD1a, CD1c, and CD1d can bind lipids and glycolipid antigens for presentation to NKT cells. The T-cell population called MAIT cells, which are abundant in humans, recognizes vitamin B_2 metabolites presented by the MR1 MHC class I–like molecule, suggesting that the MAIT cells have a 'transitional' role between innate and adaptive immunity. Likewise, many antigens that activate γδ T cells may be indicators of stress or infection, and these cells are able to generate cytokines that amplify immune-defense pathways.

Summary to Chapter 6.

T-cell receptors on conventional αβ T cells recognize peptides bound to MHC molecules. In the absence of infection, MHC molecules are occupied by self peptides, which do not normally provoke a T-cell response because of various tolerance mechanisms. But during infections, pathogen-derived peptides bind to MHC molecules and are displayed on the cell surface, where they can be recognized by T cells that have been previously activated and armed for the specific peptide:MHC complex. Naive T cells become activated when they encounter their specific peptide antigen presented by MHC molecules of activated dendritic cells. MHC class I molecules in most cells bind to peptides

derived from proteins that have been synthesized and then degraded in the cytosol of the same cell. Some dendritic cells, the cDC1 subset, can capture exogenous antigens using cell-surface receptors such as CLEC9A and process them for loading onto MHC class I molecules. This process of cross-presentation is important for priming CD8 T cells to many viral infections as well as to antigens expressed by tumors.

Through assembly with the invariant chain (Ii), MHC class II molecules bind peptides derived from proteins degraded in endocytic vesicles, including extracellular proteins that are internalized, or endogenous intracellular proteins that are delivered to endosomes by autophagy or other protein-targeting mechanisms. Stable peptides are bound after a process of peptide editing in the endocytic compartment involving HLA-DM and HLA-DO. CD8 T cells recognize peptide:MHC class I complexes and are activated to kill cells displaying foreign peptides derived from cytosolic pathogens, such as viruses. CD4 T cells recognize peptide:MHC class II complexes expressed by dendritic cells, macrophages, or B cells; naive CD4 T cells become activated when recognizing antigen on dendritic cells, and activated CD4 T cells provide help when recognizing antigen presented to macrophages and B cells.

For each class of MHC molecule, there are several genes arranged in clusters within a larger region known as the major histocompatibility complex (MHC). Within the MHC, the genes encoding MHC molecules are closely linked to genes involved in the degradation of proteins into peptides, the formation of the peptide:MHC complex, and the transport of these complexes to the cell surface. Because the varied genes for the MHC class Ia and class II molecules are highly polymorphic and are expressed in a codominant fashion, each individual expresses a number of different MHC class Ia and class II molecules. Each different MHC molecule can bind stably to a range of different peptides, and thus the MHC repertoire of each individual can recognize and bind many different peptide antigens. Because the T-cell receptor binds a combined peptide:MHC ligand, T cells show MHC-restricted antigen recognition, such that a given T cell is specific for a particular peptide bound to a particular MHC molecule.

Unconventional T-cell subsets include NKT cells, MAIT cells, and γδ T cells, which recognize nonpeptide ligands of various types. CD1 molecules bind self lipids and pathogen-derived lipid-based antigens and present them to NKT cells. MAIT cells recognize microbial-specific riboflavin metabolites presented by MR1. γδ T cells are activated by a diverse array of ligands, including MHC class Ib molecules and EPCR, that are induced by infection or cellular stress. These unconventional T-cell subsets function in the transitional area between innate and adaptive immunity, relying on a repertoire of receptors produced by somatic gene rearrangement but recognizing ligands in a manner somewhat similar to the way PAMPs are recognized by TLRs and other fully innate receptors.

Discussion Questions

6.1 MHC class I and class II molecules are structurally and functionally homologous, yet have dissimilar pathways of assembly and delivery to the cell surface. (a) Describe how these differences in assembly and delivery are related to the different functions of class I and class II molecules. (b) What kinds of cells typically recognize antigens presented by MHC class I molecules? What kinds of cells present antigens to these cells, and what is the purpose in each case? (c) What types of cells present antigens on MHC class II molecules, and for what purpose(s)?

6.2 Different types of antigen-presenting cells carry out cross-presentation and MHC class II processing to varying degrees of efficiency. (a) What would the theoretical consequence be for the loss of cross-presentation by dendritic cells? (b) What would the theoretical consequence be for the loss of MHC class II antigen processing?

6.3 Many of the proteins encoded within the MHC exist in the population in multiple forms, or allelic variants. (a) What genetic events give rise to this variation, and what are the functional consequences? (b) In some cases, particular combinations of alleles of the different MHC genes are found to be present at far higher frequency than chance would predict. What are the possible mechanisms that could explain this finding? (c) MHC proteins are the most polymorphic proteins known. What benefit, if any, does this provide and how?

6.4 Many genes outside the MHC region encode proteins that are structurally and functionally related to class I MHC proteins. (a) Discuss the cell types that recognize various 'nonclassical' MHC proteins and what their functions are. (b) Discuss the kinds of ligands that are presented by various members of these proteins. (c) Compare and contrast the nature of the ligands with the ligand recognized by the TLR proteins, and describe their role in the immune response.

PART III
THE DEVELOPMENT OF MATURE LYMPHOCYTE RECEPTOR REPERTOIRES

7 Lymphocyte Receptor Signaling
8 The Development of B and T Lymphocytes

Lymphocyte Receptor Signaling

7

IN THIS CHAPTER

General principles of signal transduction and propagation.

Antigen receptor signaling and lymphocyte activation.

Co-stimulatory and inhibitory receptors modulate antigen receptor signaling in T and B lymphocytes.

T and B lymphocytes are cells of the adaptive immune system, each of which expresses a unique antigen receptor. After exiting the thymus (T cells) and bone marrow (B cells), these cells circulate through the blood, the lymph, and the secondary lymphoid organs, where they survey antigen-presenting cells for their specific antigen. Once that antigen is encountered, signals from the antigen receptor stimulate several downstream pathways, activating enzymes that promote the conversion of nondividing naive lymphocytes into activated cells that reorganize their actin cytoskeleton, activate transcription factors, and synthesize a wide range of new proteins. As a result of these events, naive T and B cells undergo rapid cell division and differentiate into armed effector cells, thus expanding lymphocyte populations during an immune response and equipping these cells with the machinery to combat infections (Fig. 7.1).

We begin by discussing some general principles of intracellular signaling and then outline the pathways activated when a naive lymphocyte encounters its specific antigen. Next, we briefly discuss the co-stimulatory signaling that is necessary to activate naive T cells and, in most cases, naive B cells. In this last part of the chapter we also discuss inhibitory receptors and their roles in down-regulating signaling pathways in T and B cells.

General principles of signal transduction and propagation.

In this part of the chapter we review briefly some general principles of receptor action and signal transduction that are common to many of the pathways discussed here. All cell-surface receptors that have a signaling function either are transmembrane proteins themselves or form parts of protein complexes that link the extracellular environment and the interior of the cell. Different classes of receptors transduce extracellular signals in a variety of ways. A common theme among the receptors covered in this chapter is that ligand binding results in the activation of an intracellular enzymatic activity.

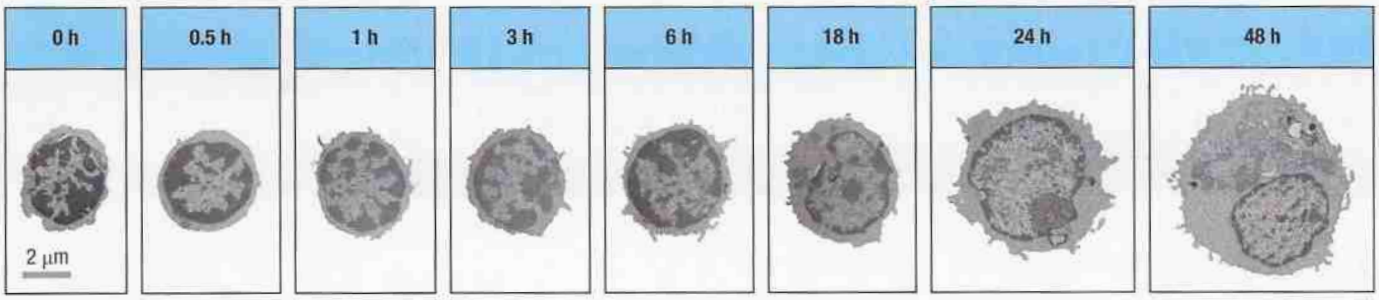

Fig. 7.1 Lymphocyte activation converts small nondividing cells into effector cells. Transmission electron microscopy was used to view resting naive T cells before and after stimulation with anti-CD3 antibodies. Among the changes that can be seen are the increased size of the cell, the expanded volume of the cell cytoplasm, and the decondensation of the chromatin in the cell nucleus.

7-1 Transmembrane receptors convert extracellular signals into intracellular biochemical events.

The enzymes most commonly associated with receptor activation are the **protein kinases**, enzymes that catalyze the covalent attachment of a phosphate group to a protein, a reversible process called **phosphorylation**. In animals, protein kinases phosphorylate proteins on tyrosine, serine, or threonine, and more rarely, on histidine. In the case of the antigen receptors on B lymphocytes and T lymphocytes, the transmembrane receptors themselves have no intrinsic enzymatic activity. Instead these receptors associate with intracellular **protein tyrosine kinases**. Ligand binding to the extracellular domain of such receptors causes tyrosine phosphorylation of intracellular proteins, including the cytoplasmic domains of the receptor subunits.

For many cytokine receptors, ligand binding causes dimerization or clustering of individual receptor molecules, bringing the associated kinases together and enabling them to phosphorylate the cytoplasmic tail of adjacent receptors—thus initiating an intracellular signal. In the case of the lymphocyte antigen receptors, association with cytoplasmic tyrosine kinases occurs after ligand binding but is unlikely to be due to a simple clustering mechanism. Instead, the actions of co-receptors are required: these bring cytoplasmic tyrosine kinases into proximity with the cytoplasmic regions of the antigen receptor, a complex process that we will describe later.

Signaling is usually not a simple 'on or off' switch. Depending on the affinity of the receptor for the ligand, the abundance of the ligand, the concentrations of intracellular signaling components, and a complex network of positive- and negative-feedback pathways, receptor activation and downstream signaling occur when a minimum threshold determined by all of these factors is exceeded. These features are often merged into the simple term 'signal strength.' It is important to keep in mind that variations in signal strength will determine the magnitude of cellular responses—some will be all-or-nothing, whereas others will increase as the strength of signaling increases (Fig. 7.2).

T-cell receptor strength				
None	Low	Medium low	Medium high	High
–	+	++	+++	+++
–	++	+++	+++	+++
–	+	+	++	+++
–	–	–	++	+++
–	–	–	–	++
–	–	–	–	+++
Expression: Low → High				

Fig. 7.2 Antigen receptor signaling can produce varying patterns of gene expression. Receptor-stimulated signaling responses in lymphocytes are complex networks of positive- and negative-feedback pathways that can produce various outcomes. An example illustrated here is a set of genes, each one represented by a row of boxes. Depending on the strength of stimulation through the T-cell receptor, each gene shows a unique pattern of expression.

The role of protein kinases in cell signaling is not confined to receptor activation, as they act at many different stages in intracellular signaling pathways. Protein kinases figure largely in cell signaling because phosphorylation and **dephosphorylation**—the removal of a phosphate group—are the means of regulating the activity of many enzymes, transcription factors, and other proteins. Equally important to the workings of signaling pathways is the fact that phosphorylation generates sites on proteins to which other signaling proteins can bind.

Phosphate groups are removed from proteins by a large class of enzymes called **protein phosphatases**. Like protein kinases, protein phosphatases can also be soluble cytosolic proteins or transmembrane receptors. Different classes of protein phosphatases remove phosphate groups from phosphotyrosine or

from phosphoserine/phosphothreonine, or both (as in dual-specificity phosphatases). Specific dephosphorylation by phosphatases is one important means of regulating signaling pathways by resetting a protein to its original state and thus switching signaling off. Dephosphorylation does not always inhibit a protein's activity. In many instances the removal of a particular phosphate group by a specific phosphatase is needed to activate an enzyme. In other cases, the extent of phosphorylation of an enzyme determines its activity and represents a balance between the activity of kinases and phosphatases.

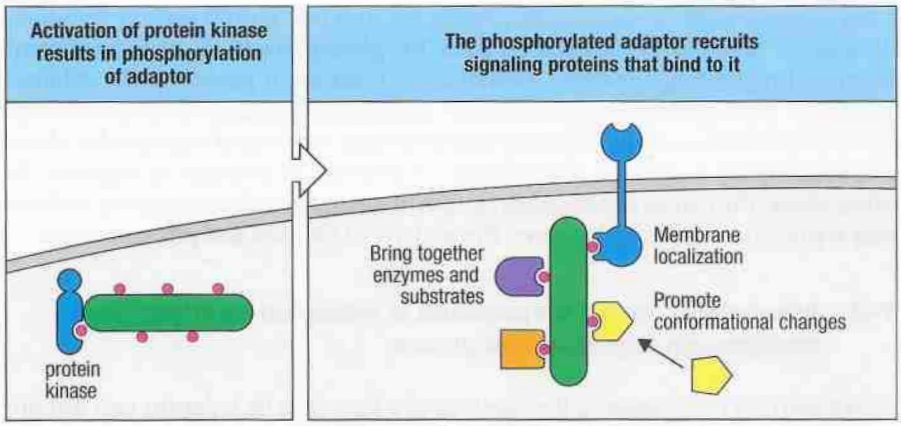
7-2 Intracellular signal propagation is mediated by large multiprotein signaling complexes.

As we learned in Chapter 3, the binding of a ligand to its receptor can initiate a cascade of biochemical events involving intracellular proteins that sequentially act in a signaling pathway. The unique enzymes and other components assembled into a particular multiprotein receptor complex will determine the specific biochemical and cellular changes that result from each segment of the pathway. These components may be shared by several receptor pathways or they may be exclusive to one receptor pathway, thus allowing distinct signaling pathways to be built up from a relatively limited number of components. The assembly of multi-subunit signaling complexes involves specific interactions of a number of distinct types of **protein-interaction domains**, or **protein-interaction modules**, carried by the signaling proteins. Signaling proteins in general contain at least one such protein-interaction domain, but many contain multiple domains. Figure 7.3 gives a few examples of such domains.

For the pathways considered in this chapter, an important mechanism underlying the formation of signaling complexes is the phosphorylation of protein tyrosine residues. Phosphotyrosines are binding sites for a number of protein-interaction domains, including the **SH2 (Src homology 2) domain** (see Fig. 7.3). SH2 domains, built from approximately 100 amino acids, are present in many intracellular signaling proteins, where they are frequently linked to enzymatic or other functional domains. SH2 domains recognize the phosphorylated tyrosine (pY) and, typically, the amino acid three positions away (pYXXZ, where X is any amino acid and Z is a specific amino acid); they bind in a sequence-specific fashion, with different SH2 domains preferring different combinations of amino acids. In this way, the unique SH2 domain of a signaling molecule can promote inducible and specific association with a protein that contains the appropriate pY-containing

Protein domain	Found in	Ligand class	Example of ligand
SH2	Lck, ZAP-70, Fyn, Src, Grb2, PLC-γ, STAT, Cbl, Btk, Itk, SHIP, Vav, SAP, PI3K, Syk, Lyn	phosphotyrosine	pYXXZ
SH3	Lck, Fyn, Src, Grb2, Btk, Itk, Tec, Fyb, Nck, Gads	proline	PXXP
PH	Tec, PLC-γ, Akt, Btk, Itk, Sos	phosphoinositides	PIP_3
PX	$P40^{phox}$, $P47^{phox}$, PLD	phosphoinositides	PI(3)P
PDZ	CARMA1	C termini of proteins	IESDV, VETDV
C1	RasGRP, PKC-θ	membrane lipid	diacylglycerol (DAG) phorbol ester
NZF	TAB2	polyubiquitin (K63-linked)	polyubiquitinated RIP, TRAF6, or NEMO
G domain	Ras, Rho, Cdc42, Rap1	guanine nucleotide	GTP, GDP

Fig. 7.3 Signaling proteins interact with each other and with lipid signaling molecules via modular protein domains. A few of the most common protein domains used by immune-system signaling proteins are listed, together with some proteins that contain them and the general class of ligand bound by the interaction domain. The right-hand column lists specific examples of a protein motif (in single-letter amino acid code) or, for the phosphoinositide-binding domains, the particular phosphoinositide that they bind. All these domains are used in many other nonimmune signaling pathways as well.



Activation of protein kinase results in phosphorylation of adaptor
The phosphorylated adaptor recruits signaling proteins that bind to it
protein kinase
Bring together enzymes and substrates
Membrane localization
Promote conformational changes

Fig. 7.4 Assembly of signaling complexes is mediated by adaptor proteins. Assembly of signaling complexes is an important aspect of signal transduction. This is often achieved through adaptor proteins. In some cases, adaptor proteins have numerous sites of phosphorylation that function to bring many different signaling proteins together. Adaptors may also function to promote membrane localization, to bring enzymes into close proximity with their substrates, and to induce conformational changes in proteins that regulate their functions. Some adaptor proteins function more simply, bringing two different proteins together.

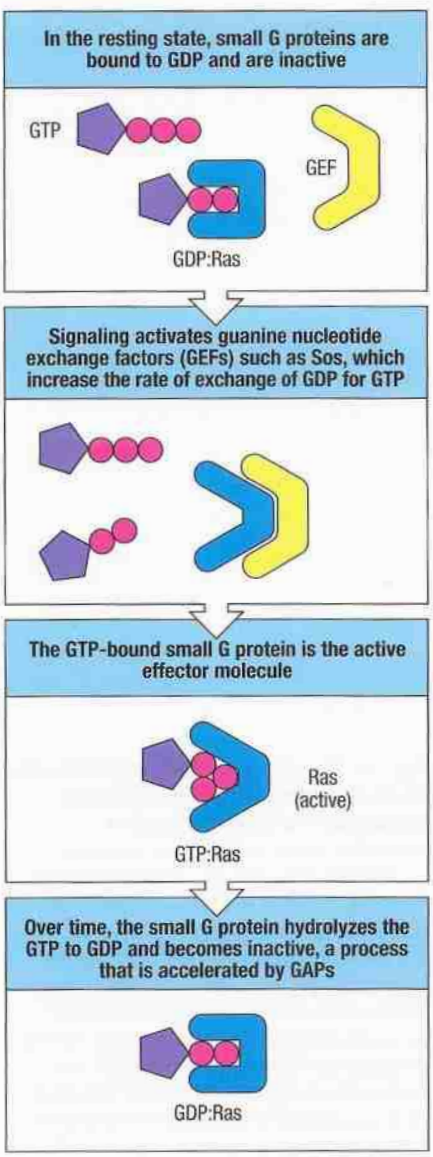
amino acid sequence, an interaction that only occurs after tyrosine phosphorylation of the SH2 domain's binding partner.

Tyrosine kinase–associated receptors can assemble multiprotein signaling complexes by using proteins called **adaptors**. Adaptors lack enzymatic activity, and they function by recruiting other proteins into a signaling complex so that interactions among these proteins can take place (Fig. 7.4). The adaptor proteins Grb2 and Gads, for example, each contain an SH2 domain and two copies of another module called the SH3 domain. This arrangement of modules can be used to link tyrosine phosphorylation of a receptor to molecules acting in the next stage of signaling. As we will see later, antigen receptor signaling pathways make extensive use of this mechanism to assemble a variety of distinct multiprotein complexes, each of which functions to activate a different enzyme that contributes to overall lymphocyte responses.

7-3 Small G proteins act as molecular switches in many different signaling pathways.

Another biochemical mechanism important in the signaling pathways leading from many tyrosine kinase–associated receptors is the use of monomeric GTP-binding proteins known as **small G proteins, or small GTPases**. The small GTPases are distinct from the larger heterotrimeric G proteins associated with G protein–coupled receptors such as the chemokine receptors discussed in Chapter 3. The superfamily of small GTPases comprises more than 100 different proteins, and many are important in lymphocyte signaling. One of these, **Ras**, is involved in many pathways leading to cell proliferation. Other small GTPases include Rac, Rho, and Cdc42, which control changes in the actin cytoskeleton caused by signals received through the T-cell receptor or B-cell receptor. We will describe their actions in more detail in Section 7-19.

Small GTPases exist in two states, depending on whether they are bound to GTP or to GDP. The GDP-bound form is inactive but is converted into the active form by exchange of the GDP for GTP. This reaction is mediated by proteins known as **guanine nucleotide exchange factors, or GEFs**, which cause the GTPase to release GDP and to bind the more abundant GTP (Fig. 7.5). One



In the resting state, small G proteins are bound to GDP and are inactive
GTP
GEF
GDP:Ras
Signaling activates guanine nucleotide exchange factors (GEFs) such as Sos, which increase the rate of exchange of GDP for GTP
The GTP-bound small G protein is the active effector molecule
Ras (active)
GTP:Ras
Over time, the small G protein hydrolyzes the GTP to GDP and becomes inactive, a process that is accelerated by GAPs
GDP:Ras

Fig. 7.5 Small G proteins are switched from inactive to active states by guanine nucleotide exchange factors (GEFs) and the binding of GTP. Ras is a small GTP-binding protein with intrinsic GTPase activity. In its resting state, Ras is bound to GDP. Receptor signaling activates GEFs, such as Sos, which can bind to small G proteins such as Ras and increase the rate of exchange of GDP for GTP (center panels). The GTP-bound form of Ras can then bind to a large number of effectors, recruiting them to the membrane. Over time, the intrinsic GTPase activity of Ras will result in the hydrolysis of GTP to GDP. GTPase-activating proteins (GAPs) can accelerate the hydrolysis of GTP to GDP, thus shutting off the signal more rapidly.

of the GEFs for Ras, Sos, is recruited to signaling pathways by the adaptor Grb2. The binding of GTP induces a conformational change in the small GTPase that enables it to bind to and induce effector activity in a variety of target proteins. Thus, GTP binding functions as an on/off switch for small GTPases.

This GTP-bound form does not remain permanently active but is eventually converted into the inactive GDP-bound form by the intrinsic GTPase activity in the G protein, which removes a phosphate group from the bound GTP. Regulatory cofactors known as **GTPase-activating proteins (GAPs)** accelerate the conversion of GTP to GDP, thus rapidly down-regulating the activity of the small GTPase. Because of GAP activity, small GTPases are usually present in the inactive GDP-bound state and are activated only transiently in response to a signal from an activated receptor. *RAS* is frequently mutated in cancer cells, and the mutated Ras protein is thought to be a significant contributor to the cancerous state. The importance of GAPs in signaling regulation is indicated by the fact that some mutations in Ras found in cancer act by preventing GAP from enhancing the intrinsic GTPase activity of Ras, thus prolonging the duration for which Ras exists in the active GTP-bound state.

GEFs are the key to G-protein activation and are recruited to the site of receptor activation at the cell membrane by binding to adaptor proteins or to lipid metabolites produced by receptor activation. Once recruited, they are able to activate Ras or other small G proteins, which are localized to the inner surface of the plasma membrane via fatty acid or polybasic motifs that bind acidic lipids. Thus, G proteins act as molecular switches, becoming switched on when a cell-surface receptor is activated and then being switched off. Each G protein has its own specific GEFs and GAPs, which help to confer specificity on the pathway.

7-4 Signaling proteins are recruited to the membrane by a variety of mechanisms.

We have seen how receptors can recruit intracellular signaling proteins to the plasma membrane through tyrosine phosphorylation of the receptor itself or of an associated adaptor, followed by recruitment of SH2 domain–containing signaling proteins and additional adaptors, such as Grb2 (Fig. 7.6). A second mechanism for membrane recruitment of signaling proteins is via binding to small GTPases, such as Ras, after their activation. As described in Section 7-3, small GTPases are constitutively bound to the cytoplasmic surface of the plasma membrane because of their fatty acid modifications. Once activated by exchange of GDP for GTP, the activated GTPases bind to signaling proteins such as Raf, relocalizing the bound proteins to the plasma membrane (see Fig. 7.6).

Another way in which receptors can recruit signaling molecules to the plasma membrane is by the local production of modified membrane lipids. These lipids are produced by phosphorylation of the membrane phospholipid

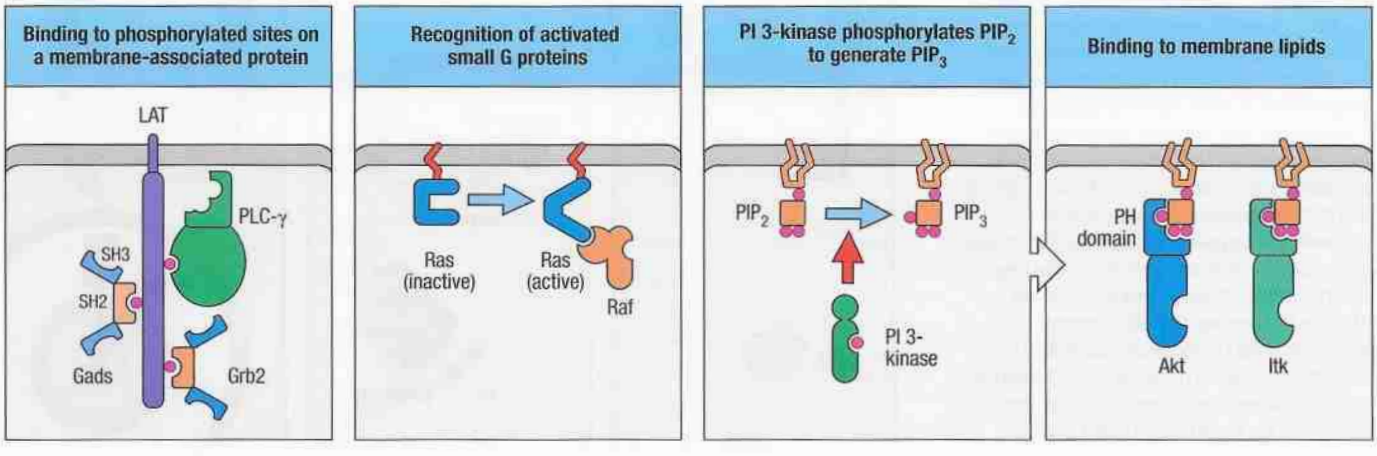


Fig. 7.6 Signaling proteins can be recruited to the membrane in a variety of ways. Recruitment of signaling proteins to the plasma membrane is important in signal propagation because this is where receptors are usually located. Left panel: Tyrosine phosphorylation of membrane-associated proteins, such as the adaptor LAT, recruits phosphotyrosine-binding proteins. This can also protect the adaptor from dephosphorylation by tyrosine phosphatases, which inhibit signaling. Second panel: Small G proteins such as Ras can associate with the membrane by having lipid modifications (shown in red). When activated, they can bind a variety of signaling proteins. Right two panels: Modifications to the membrane itself that result from receptor activation can recruit signaling proteins. In this example the membrane lipid PIP_3 has been produced in the inner leaflet of the plasma membrane by the phosphorylation of PIP_2 by PI 3-kinase. PIP_3 is recognized by the pleckstrin homology (PH) domains of signaling proteins such as the protein kinases Akt and Itk.

phosphatidylinositol by enzymes known as **phosphatidylinositol kinases**, which are activated as a result of receptor signaling. The inositol headgroup of phosphatidylinositol is a carbohydrate ring that can be phosphorylated at one or more positions to generate a wide variety of derivatives. The ones that we will focus on in this chapter are phosphatidylinositol 4,5-bisphosphate ($\mathbf{PIP_2}$) and phosphatidylinositol 3,4,5-trisphosphate ($\mathbf{PIP_3}$), the latter of which is generated from PIP_2 by the enzyme **phosphatidylinositol 3-kinase (PI 3-kinase)** (see Fig. 7.6). PI 3-kinase is often recruited by binding of the SH2 domain of its regulatory subunit to phosphotyrosines in a receptor tail or an adaptor protein, bringing its catalytic subunit into proximity with inositol phospholipid substrates in the membrane. In this way, membrane phosphoinositides such as PIP_3 are rapidly produced after receptor activation. This, combined with their short life span, makes them ideal signaling molecules. PIP_3 is recognized specifically by proteins containing a pleckstrin homology (PH) domain or, less commonly, a PX domain (see Fig. 7.3), and one of its functions is to recruit such proteins to the membrane and in some cases contribute to enzyme activation.

7-5 Post-translational modifications of proteins can both activate and inhibit signaling responses.

Protein phosphorylation is a common mechanism for transducing signals from cellular receptors to downstream pathways. These signals are terminated by the action of protein phosphatases, which dephosphorylate signaling intermediates (Fig. 7.7). The importance of protein phosphatases in terminating signaling is underscored by the existence of diseases, such as autoimmunity and cancer, which may result from absent or deficient protein phosphatase activity. However, protein dephosphorylation can also function as a mechanism of activation. Dephosphorylation can regulate protein–protein interactions, protein subcellular localization, or nucleic acid binding, thereby promoting downstream signaling events.

Another general mechanism of protein regulation by post-translational modification is the covalent attachment of one or more molecules of the small protein **ubiquitin**. Ubiquitination is a potent means of signal termination, as it often leads to protein degradation. Ubiquitin is attached by its carboxyl-terminal glycine to lysine residues of target proteins in a multistep process. First, an E1 ubiquitin-activating enzyme promotes attachment of ubiquitin to an E2 ubiquitin-conjugating enzyme. The ubiquitin is then transferred to the protein substrate by an enzyme known as an E3 **ubiquitin ligase**. Ubiquitin ligases can continue to add ubiquitin molecules to form polyubiquitin chains.

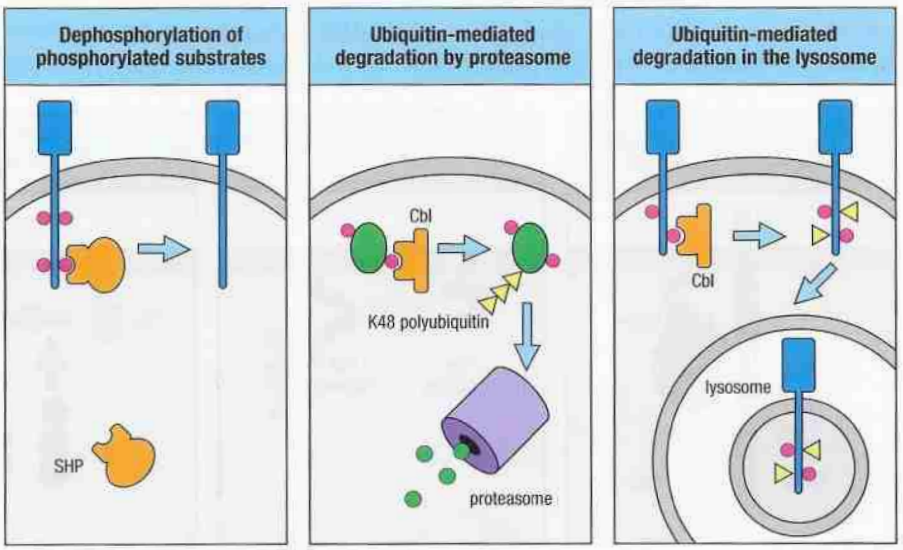

Fig. 7.7 Signaling must be turned off as well as turned on. The inability to terminate a signaling pathway can result in serious diseases such as autoimmunity or cancer. Because a significant proportion of signaling events depend on protein phosphorylation, protein phosphatases, such as SHP, have an important part in shutting down signaling pathways (left panel). Another common mechanism for terminating signaling is regulated protein degradation (center and right panels). Phosphorylated proteins recruit ubiquitin ligases, such as Cbl, that add the small protein ubiquitin to proteins, thus targeting them for degradation. Cytoplasmic proteins are targeted for destruction in the proteasome by the addition of polyubiquitin chains, linked through lysine 48 (K48) of ubiquitin (center panel). Membrane receptors that become ubiquitinated by individual ubiquitin molecules or di-ubiquitin are internalized and transported to the lysosome for destruction (right panel).

Importantly, different ubiquitin ligases add the carboxyl terminus of one ubiquitin molecule to different lysine residues of the conjugated ubiquitin, typically either lysine 48 (K48) or lysine 63 (K63). These different forms of polyubiquitination produce divergent outcomes for signaling pathways.

When polyubiquitin chains are formed using K48 linkages, the outcome is to target the protein to the proteasome, a large protein complex responsible for degradation of cellular proteins (see Fig. 7.7). An important ubiquitin ligase of this kind in lymphocytes is Cbl, which selects its targets via its SH2 domain. Cbl can thus bind to specific tyrosine-phosphorylated targets, causing them to become ubiquitinated via K48 linkages, resulting in target protein degradation. Membrane proteins such as receptors can be tagged by single ubiquitin molecules or by di-ubiquitin. These are not recognized by the proteasome but instead are recognized by specific ubiquitin-binding proteins that target proteins for degradation in lysosomes or for release from cells in small membrane vesicles known as exosomes (see Fig. 7.7). Thus, ubiquitination of proteins can inhibit signaling. Unlike inhibition by phosphatases, which is reversible, inhibition by ubiquitin-mediated protein degradation is a longer-lasting means of terminating signaling.

Ubiquitination can also activate signaling pathways. We have already discussed this mechanism in Section 3-7 in connection with the NFκB signaling pathway from TLRs. There, the ubiquitin ligase TRAF6 produces K63-linked polyubiquitin chains on TRAF6 and NEMO. In lymphocytes, K63-linked polyubiquitination is a key step in signaling through tumor necrosis factor (TNF) receptor family members, as will be discussed in Section 7-24 (and Fig. 7.33). This form of polyubiquitination is recognized by specific domains in signaling proteins that recruit additional signaling molecules to the pathway (see Fig. 3.14). Thus, like tyrosine phosphorylation, K63-linked ubiquitination functions as a protein–protein interaction motif to promote the formation of multiprotein signaling complexes (see Fig. 7.3).

7-6 The activation of many receptors generates small-molecule second messengers.

In many cases, intracellular signaling involves the activation of enzymes that produce small-molecule biochemical mediators known as **second messengers** (Fig. 7.8). These mediators can diffuse throughout the cell, enabling the signal to activate a variety of target proteins. The enzymatic production of second messengers also serves the dual purpose of achieving concentrations of them sufficient to activate the next stage of the pathway and of amplifying the signaling cascade. The second messengers generated by receptors

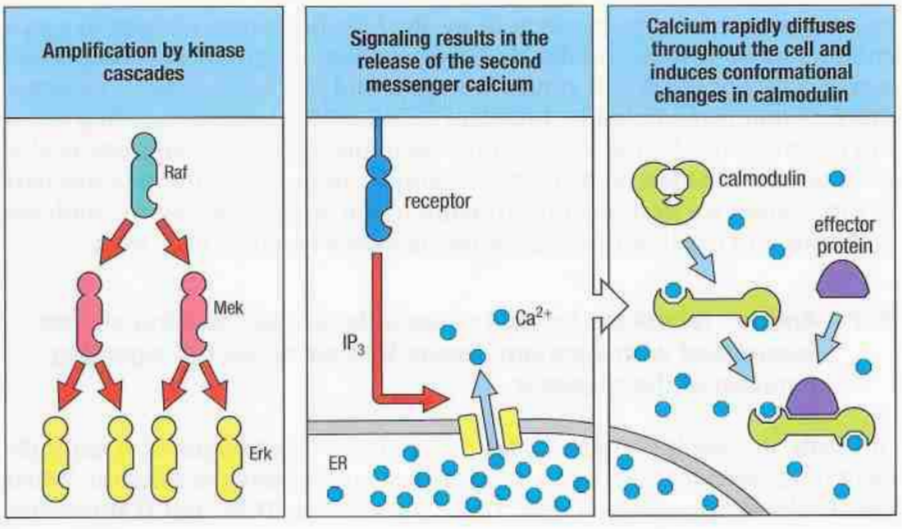

Fig. 7.8 Signaling pathways amplify the initial signal. Amplification of the initial signal is an important element of most signal transduction pathways. One means of amplification is a kinase cascade (left panel), in which protein kinases successively phosphorylate and activate each other. In this example, taken from a common kinase cascade (see Fig. 7.20), activation of the kinase Raf results in the phosphorylation and activation of a second kinase, Mek, that phosphorylates yet another kinase, Erk. Because each kinase can phosphorylate many different substrate molecules, the signal is amplified at each step, resulting in a huge amplification of the initial signal. Another method of signal amplification is the generation of second messengers (center and right panels). In this example, signaling results in the release of the second messenger calcium (Ca^{2+}) from intracellular stores into the cytosol or its influx from the extracellular environment. Ca^{2+} release from the endoplasmic reticulum (ER) is shown here. The sharp increase in free Ca^{2+} in the cytoplasm can potentially activate many downstream signaling molecules, such as the calcium-binding protein calmodulin. Calcium binding induces a conformational change in calmodulin, which allows it to bind to and regulate a variety of effector proteins.

that signal via tyrosine kinases include calcium ions (Ca^{2+}) and a variety of membrane lipids and their soluble derivatives. Although some of these lipid messengers are confined to membranes, they can move within them. A second messenger binding to its target protein typically induces a conformational change that allows the protein to be activated, and can also participate in recruitment of proteins to cellular locations where they function.

Summary.

Cell-surface receptors serve as the front line of a cell's interaction with its environment; they sense extracellular events and convert them into biochemical signals for the cell. Because most receptors sit in the plasma membrane, a critical step in the transduction of extracellular signals to the interior of the cell is recruitment of intracellular proteins to the membrane and changes in the composition of the membrane surrounding the receptor. Many immune receptors operate by activating tyrosine kinases to transmit their signals onward, often using adaptors to form large multiprotein signaling complexes. Both the qualitative and quantitative changes that take place in the composition of these signaling complexes determine the character of the response and biological outcomes. Formation of signaling complexes is mediated by a wide variety of protein-interaction domains, or modules, including the SH2, SH3, and PH domains found in proteins. In many cases, the increase in enzymatically produced small-molecule signaling intermediates called second messengers regulates and amplifies the signaling cascade. Termination of signaling involves protein dephosphorylation as well as ubiquitin-mediated protein degradation.

Antigen receptor signaling and lymphocyte activation.

The ability of T cells and B cells to recognize and respond to their specific antigen is central to adaptive immunity. As described in Chapters 4 and 5, the B-cell antigen receptor (BCR) and the T-cell antigen receptor (TCR) are made up of antigen-binding chains—the heavy and light immunoglobulin chains in the B-cell receptor, and the TCRα and TCRβ chains in the T-cell receptor on conventional T cells. These variable chains have exquisite specificity for antigen, allowing each lymphocyte to detect the presence of one type of pathogen. However, binding of antigen to the antigen receptor is not sufficient for a lymphocyte to respond—the information that antigen receptor engagement has occurred also needs to be transduced into the intracellular compartment of the lymphocyte. Thus, the fully functional antigen receptor complex must include proteins that can transduce a signal across the plasma membrane. For the B-cell antigen receptor and the T-cell antigen receptor, this function is mediated by invariant proteins that initiate signaling when the receptors bind antigen. Assembly with these signaling subunits is also essential for transport of the receptor complex to the cell surface. In this part of the chapter we describe the structure of the antigen receptor complexes on T cells and B cells and the signaling pathways that lead from them.

7-7 Antigen receptors consist of variable antigen-binding chains associated with invariant chains that carry out the signaling function of the receptor.

In T cells, the highly variable TCRαβ heterodimer (see Chapter 5) is not sufficient on its own to make up a complete cell-surface antigen receptor. When non-T cells were transfected with cDNAs encoding the TCRα and TCRβ chains,

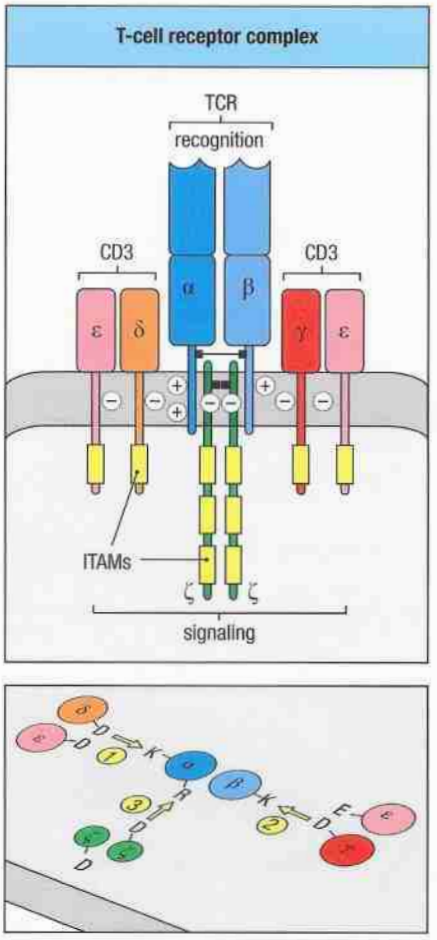

Fig. 7.9 The T-cell receptor complex is made up of variable antigen-recognition proteins and invariant signaling proteins. Upper panel: The functional T-cell receptor (TCR) complex is composed of the antigen-binding TCRαβ heterodimer associated with six signaling chains: two ε, one δ, and one γ, collectively called CD3, plus a homodimer of ζ. Cell-surface expression of the antigen-binding chains requires assembly of TCRαβ with the signaling subunits. Each CD3 chain has one immunoreceptor tyrosine-based activation motif (ITAM), shown as a yellow segment, whereas each ζ chain has three. The transmembrane regions of each chain have unusual acidic (–) or basic (+) residues as shown. Lower panel: The transmembrane regions of the various TCR subunits are represented in cross section. It is thought that one of the positive charges, from a lysine (K) of the α chain, interacts with the two negative charges of aspartic acid (D) of the CD3δε dimer (1), while the other positive charge, of arginine (R), interacts with aspartic acids of the ζ homodimer (3). The positive lysine (K) charge of the β chain interacts with the negative charges of aspartic acid and glutamic acid (E) in the CD3γε dimer (2).

the heterodimers formed were degraded and did not appear on the cell surface. This implied that other molecules are required for the T-cell receptor to be expressed on the cell surface. In the T-cell receptor, the other required molecules are the CD3γ, CD3δ, and CD3ε chains, which together form the **CD3 complex**, and the **ζ chain**, which is present as a disulfide-linked homodimer (Fig. 7.9). The CD3 proteins have an extracellular immunoglobulin-like domain, whereas the ζ chain contains only a short extracellular domain. Throughout the remainder of the chapter, we will use the term 'T-cell receptor' to refer to the entire T-cell receptor complex, including antigen-binding proteins and the signaling subunits.

The stoichiometry of the complete T-cell receptor is shown in Fig. 7.9. The T-cell receptor consists of one receptor α chain that interacts with one CD3δ:CD3ε dimer and with one ζ dimer, and one receptor β chain that interacts with one CD3γ:CD3ε dimer. These interactions are mediated by reciprocal charge interactions between basic and acidic intramembrane amino acids of the receptor subunits. There are two positive charges in the TCRα transmembrane region and one in the TCRβ transmembrane domain. Negative charges in the CD3 and ζ transmembrane domains interact with the positive charges in α and β. Assembly of CD3 and a ζ dimer with the αβ heterodimer stabilizes the α and β dimer during its production in the endoplasmic reticulum and allows the complex to be transported to the plasma membrane. These associations ensure that all T-cell receptors present on the plasma membrane are properly assembled.

Signaling from the T-cell receptor is initiated by tyrosine phosphorylation within cytoplasmic regions called **immunoreceptor tyrosine-based activation motifs (ITAMs)** in the CD3ε, CD3γ, CD3δ, and ζ chains. CD3γ, CD3δ, and CD3ε each contain one ITAM, and each ζ chain contains three, giving the T-cell receptor a total of 10 ITAMs. This motif is also present in the signaling chains of the B-cell receptor and in the NK-cell receptors described in Chapter 3, as well as in the receptors for the immunoglobulin constant region (Fc receptors) that are present on mast cells, macrophages, monocytes, neutrophils, and NK cells (see Section 7-11).

Each ITAM contains two tyrosine residues that become phosphorylated by specific protein tyrosine kinases when the receptor binds its ligand, providing sites for the recruitment of the SH2 domains of signaling proteins as described earlier in the chapter. Two YXXL/I motifs are separated by about six to nine amino acids within each ITAM, so the canonical ITAM sequence is . . . YXX[L/I]X_{6-9}YXX[L/I]. . ., where Y is tyrosine, L is leucine, I is isoleucine, and X represents any amino acid. The two tyrosines of the ITAM make it particularly efficient in recruiting signaling proteins that contain tandem SH2 domains (Fig. 7.10). When both tyrosines of the ITAM are phosphorylated, tandem SH2 domain–containing proteins Syk or ZAP-70 are recruited. This leads to the phosphorylation of Syk or ZAP-70, an essential step in the activation of these kinases, as will be discussed further later (see Section 7-10).

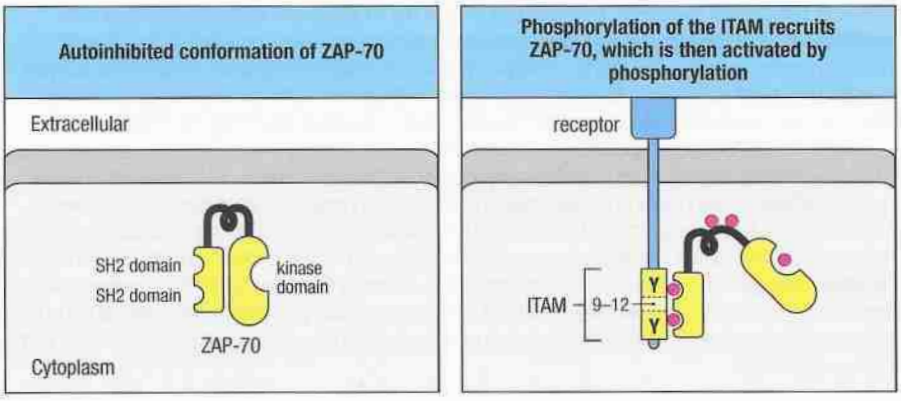

Fig. 7.10 ITAMs recruit signaling proteins that have tandem SH2 domains. The ITAMs of the T-cell receptor (TCR) and B-cell receptor (BCR) contain tyrosine residues within the motif. . . YXX[L/I]X_{6-9}YXX[L/I]. . . . The spacing between the tyrosines is important in binding to tandem SH2-containing proteins such as Syk and ZAP-70. Left panel: Prior to TCR or BCR stimulation, these kinases are in an inactive conformation, known as the autoinhibited conformation. The autoinhibited conformation is stabilized by interactions between the tandem SH2 domain–kinase domain linker region and the kinase domain that hold the enzyme in a catalytically inactive state. Right panel: After phosphorylation of both tyrosines within one ITAM (here depicted as two tyrosines separated by 9–12 amino acids), the tandem SH2 domains of Syk or ZAP-70 can dock cooperatively to both phosphotyrosines, as shown here for ZAP-70. By being recruited into the active signaling complex, ZAP-70 can itself be phosphorylated, so that it becomes an active kinase that can then phosphorylate its substrates. This final step of ZAP-70 activation requires phosphorylation on two tyrosines in the ZAP-70 linker region between the tandem SH2 domains and the kinase domain, together with phosphorylation of a tyrosine in the catalytic site of the ZAP-70 kinase domain.

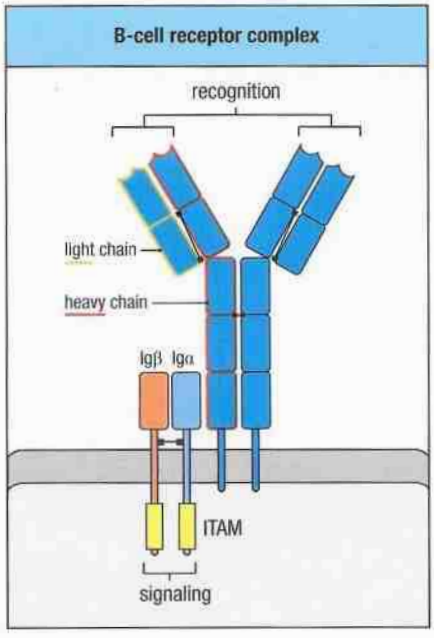
The antigen-binding immunoglobulin on the B-cell surface is also associated with invariant protein chains that mediate signaling. These two polypeptides, called **Igα** and **Igβ**, are required for transport of the receptor to the surface and for B-cell receptor signaling (Fig. 7.11). Igα and Igβ are each composed of an extracellular immunoglobulin-like domain connected by a transmembrane domain to a cytoplasmic tail. They form a disulfide-linked heterodimer that becomes associated with immunoglobulin heavy chains and enables their transport to the cell surface. The Igα:Igβ dimer associates with the B-cell receptor through hydrophilic rather than charge interactions between their transmembrane regions. The complete B-cell receptor is thought to be a complex of six chains—two identical light chains, two identical heavy chains, and one associated heterodimer of Igα and Igβ. Like CD3 and the ζ chains of the T-cell receptor, Igα and Igβ have ITAMs, but just one each, and these are essential for the ability of the B-cell receptor to signal.



7-8 Antigen recognition by the T-cell receptor and its co-receptors transduces a signal across the plasma membrane to initiate signaling.

To make an effective immune response, T cells and B cells must be able to respond to their specific antigen even when it is present at extremely low levels. This is especially important for T cells, as an antigen-presenting cell will display on its surface many different peptides from both self and foreign

Fig. 7.11 The B-cell receptor complex is made up of cell-surface immunoglobulin with one each of the invariant signaling proteins Igα and Igβ. The immunoglobulin recognizes and binds antigen but cannot itself generate a signal. It is associated with antigen-nonspecific signaling molecules—Igα and Igβ. These each have a single ITAM (yellow segment) in their cytosolic tails that enables them to signal when the B-cell receptor is ligated with antigen. Igα and Igβ form a disulfide-linked heterodimer that is noncovalently associated with the heavy chains.

proteins, and the number of peptide:MHC complexes specific for a particular T-cell receptor is likely to be very low. Some estimates suggest that naive T cells can become activated by one or a few antigenic peptide:MHC complexes displayed by an antigen-presenting cell. B cells become activated when about 20 B-cell receptors are engaged. These estimates are based on *in vitro* studies and may not be precise for cells *in vivo*, but it is clear that the antigen receptors on T cells and B cells confer remarkable sensitivity to antigen.

For a peptide:MHC complex to activate T cells, it must bind directly to the T-cell receptor (Fig. 7.12, upper panel, and see Fig. 4.27). Although it remains unclear precisely how this extracellular recognition event is transmitted across the T-cell membrane to initiate signaling, several components of this process have now been established.

Biophysical experiments indicate that mechanical force changes contribute to the initiation of T-cell receptor signaling. When T-cell receptors on the surface of T cells bind to peptide:MHC complexes present on an opposing surface, the application of a force pulling the T cell away from the interaction activates T-cell receptor signaling. This physical force applied to the T-cell receptor is thought to elicit conformational changes in the associated signaling subunits, exposing the ITAM sequences of their cytoplasmic domains to phosphorylation by tyrosine kinases. When T cells encounter peptide:MHC complexes on antigen-presenting cells in a lymph node, the movement of the T cell over the antigen-presenting cell surface as it scans the peptide:MHC complexes on that cell is the most likely source of this mechanical force.

Another component promoting T-cell receptor signal initiation is the formation of higher-order receptor oligomers or clusters on the T cell surface. The contribution of receptor clustering to signaling has long been appreciated, as early studies showed that antibodies that bind to and cross-link T-cell receptors can activate T cells. Because antigenic peptides are vastly outnumbered by other peptides displayed on the surface of the antigen-presenting cell, it is unlikely that physiologic amounts of antigen induce conventional oligomerization as observed with antibodies. However, assemblies of small numbers of T-cell receptors called **microclusters** have been observed in the zone of contact between the T cell and the antigen-presenting cell. These microclusters form rapidly after TCR stimulation and quickly merge with microclusters containing downstream signaling components, such as adaptors. Current evidence indicates that signaling is initiated in these microclusters, which may include T-cell receptor interactions with self-peptide:MHC complexes. Although T-cell receptor binding to self-peptide:MHC is likely to be very low affinity, these interactions may contribute to T-cell receptor clustering and hence to T-cell signaling. This contribution of weak T-cell receptor binding to self-peptide:MHC complexes may explain the ability of T cells to be activated by antigen-presenting cells carrying one or a few antigenic peptide:MHC complexes. Another aspect of the T-cell receptor microclusters that form rapidly after T-cell receptor stimulation is their exclusion of inhibitory signaling proteins. Prior to TCR signaling, activating and inhibitory enzymes are in a balanced equilibrium; the initiation of signaling occurs when this equilibrium is perturbed in favor of the activating modifications.

In addition to studies dissecting the mechanism of T-cell receptor signal transduction across the membrane, substantial effort has been focused on determining the biochemical and biophysical parameters that determine when a T-cell receptor interaction with peptide:MHC will result in T-cell activation. Precise measurements of T-cell receptor:peptide:MHC binding affinities and kinetics and correlation of these measurements with T-cell activation responses have yielded a working model that postulates a parameter known as T-cell receptor dwell time or T-cell receptor occupancy. In this model, the individual binding affinity of the T-cell receptor for peptide:MHC as well as the density or abundance of specific peptide:MHC complexes on the

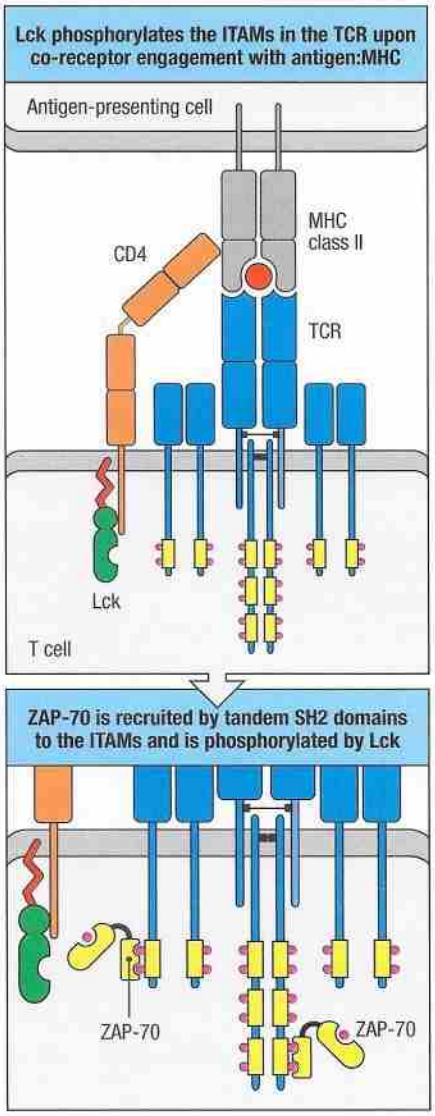


Fig. 7.12 Engagement of co-receptors with the T-cell receptor enhances phosphorylation of the ITAMs. Upper panel: For simplicity, we show the CD4 co-receptor engaging the same MHC molecule as the T-cell receptor (TCR), although signaling within receptor microclusters may differ from this arrangement. When T-cell receptors and co-receptors are brought together by binding to peptide:MHC complexes on the surface of an antigen-presenting cell, recruitment of the co-receptor–associated kinase Lck leads to phosphorylation of ITAMs in CD3γ, CD3δ, and CD3ε, and in the ζ chains. Lower panel: The tyrosine kinase ZAP-70 binds to phosphorylated ITAMs through its SH2 domains, enabling ZAP-70 to be phosphorylated and activated by Lck. ZAP-70 then phosphorylates other intracellular signaling molecules.

antigen-presenting cell surface both contribute to the average time, usually measured in seconds, that T-cell receptors in a cluster remain engaged with peptide:MHC complexes. When comparisons of many different T-cell receptors are made, the estimated T-cell receptor dwell time provides the best predictor of successful T-cell activation.

The concept of T-cell receptor dwell time as a key determinant of T-cell activation fits well with a popular model called the **kinetic proofreading model**. In this model, T-cell receptor interactions with peptide:MHC that persist for a sufficient time induce T-cell activation, whereas dissociation of T-cell receptor: peptide:MHC interactions before that time elapses produce transient, easily reversible signaling events. Successful T-cell activation depends on the signaling pathway progressing to a step that is no longer reversible. For instance, tyrosine phosphorylation of ITAM motifs or of adaptor proteins may be readily reversed by the action of protein phosphatases as soon as the T-cell receptor dissociates from peptide:MHC. In contrast, the production of second messengers, a later event in T-cell receptor signaling, may represent an irreversible step of the pathway. Once produced, these second messengers will exert their activity regardless of whether the T-cell receptor remains engaged with peptide:MHC. In this way, the T cell can 'measure' the T-cell receptor dwell time and use this measurement to determine whether T-cell activation should proceed or not.

7-9 Antigen recognition by the T-cell receptor and its co-receptors leads to phosphorylation of ITAMs by Src family kinases, generating the first intracellular signal in a signaling cascade.

Early biochemical studies performed in T-cell tumor lines indicated that the first intracellular signal generated after the T cell has detected its specific antigen, or, in some cases, a self-peptide:MHC complex, is the phosphorylation of both tyrosines in the ITAMs of the T-cell receptor. Using these cultured T-cell lines, the basic steps of the T-cell receptor signaling pathway were elucidated, leading to the following general model. In response to T-cell receptor engagement, ITAM phosphorylation is initiated with the help of the CD4 and CD8 co-receptors, which bind to MHC class II molecules and class I molecules, respectively, via their extracellular domains (see Section 4-21), and associate with **nonreceptor kinases** via their intracellular domains. The Src family kinase **Lck** is constitutively associated with the cytoplasmic domains of CD4 and CD8 and is thought to be the kinase primarily responsible for phosphorylation of the ITAMs of the T-cell receptor (see Fig. 7.12).

Evidence suggests that binding of the co-receptor to the peptide:MHC complex that binds the T-cell receptor enhances the recruitment of Lck to the engaged T-cell receptor, leading to more efficient phosphorylation of the T-cell receptor ITAMs. The importance of this event is demonstrated by the loss of T-cell receptor signaling in T-cell tumor lines lacking Lck and by the profound reduction in T-cell development in Lck-deficient mice. This indicates the essential role of Lck in T-cell receptor signaling during the selection of developing T cells in the thymus (discussed in Chapter 8). Lck is important for T-cell receptor signaling in naive T cells and effector T cells but is less important for the activation or maintenance of memory CD8 T cells by their specific antigen. A related tyrosine kinase, **Fyn**, is weakly associated with the ITAMs of the T-cell receptor and may have some role in signaling. Whereas mice lacking Fyn develop normal CD4 and CD8 T cells that respond in essentially normal fashion to antigen, mice lacking both Lck and Fyn show a more complete loss of T-cell development than mice lacking Lck alone. Overall, the activity of a Src family kinase is required, as all T-cell receptor signaling is abolished when T cells are treated with an inhibitor that blocks both Lck and Fyn.

The Lck bound to the cytoplasmic tails of CD4 or CD8 is brought near its substrate ITAMs in the T-cell receptor when the co-receptor binds the

Fig. 7.13 Lck activity is regulated by tyrosine phosphorylation and dephosphorylation. Src kinases such as Lck contain SH3 (blue) and SH2 (orange) domains preceding the kinase domain (green). Lck also contains a unique amino-terminal motif (yellow) with two cysteine residues that bind a Zn ion that is also bound to a similar motif in the cytoplasmic domain of CD4 or CD8. Upper panel: In inactive Lck, the two lobes of the kinase domain are constrained by interactions with both the SH2 and SH3 domains. The SH2 domain interacts with a phosphorylated tyrosine (red) at the carboxyl-terminal end of the kinase domain. The SH3 domain interacts with a proline-rich sequence in the linker between the SH2 domain and the kinase domain. Middle panel: Dephosphorylation of the carboxyl-terminal tyrosine by the phosphatase CD45 (not shown) releases the SH2 domain. Binding of other ligands to the SH3 region can facilitate release of the linker region (not shown). Lower panel: Full activation of Lck catalytic activity requires autophosphorylation on the activation loop in the kinase domain. Active Lck can then phosphorylate ITAMs in the signaling chains of the nearby T-cell receptor. Rephosphorylation of the carboxyl-terminal tyrosine by the C-terminal Src kinase (Csk) or loss of the SH3 ligand returns Lck to the inactive state.

receptor:peptide:MHC complex (see Fig. 7.12). CD4 or CD8 binding to MHC adds another level of fidelity to the signaling process by ensuring the coincident binding of the T-cell receptor and co-receptor to the same ligand and avoiding T-cell receptor signaling initiation to non-MHC ligands. Lck's kinase activity is also regulated confirmationally by phosphorylation of a tyrosine in its carboxyl terminus by the **C-terminal Src kinase (Csk)**. The resulting phosphotyrosine interacts with Lck's SH2 domain and helps maintain Lck in a closed conformation, resulting in a catalytically inactive state (Fig. 7.13). The absence of Csk during T-cell development causes T cells to mature autonomously in the thymus without needing to bind peptide:MHC, presumably as a result of abnormal activation of TCR signaling by hyperactive Lck in Csk-deficient thymocytes. Full activation of catalytic activity also requires Lck autophosphorylation of a tyrosine in its kinase domain. In nonstimulated lymphocytes, phosphorylation of Lck is counteracted by a **tyrosine phosphatase, CD45**, which can dephosphorylate both of the Lck tyrosine phosphorylation sites.

7-10 Phosphorylated ITAMs recruit and activate the tyrosine kinase ZAP-70.

The precise spacing of the two YXXL/I motifs in an ITAM suggests that the ITAM is a binding site for a signaling protein with two SH2 domains. In the case of the T-cell receptor, this protein is the tyrosine kinase ZAP-70 (ζ chain–associated protein), which carries the activation signal onward. ZAP-70 has tandem SH2 domains that can be simultaneously engaged by the two phosphorylated tyrosines in an ITAM (see Fig. 7.10). The affinity of the phosphorylated YXXL sequence for a single SH2 domain is low; furthermore, one of the ZAP-70 SH2 domains is incomplete and requires the second SH2 domain to complete its phosphotyrosine binding pocket. This ensures ZAP-70 specificity for fully phosphorylated ITAM sequences. Unlike the low levels of ITAM phosphorylation in unstimulated tumor T cell lines, T cells isolated directly from mice have substantial levels of constitutive ITAM phosphorylation and have constitutive ZAP-70 binding; however, the ZAP-70 protein bound to the ITAMs in nonstimulated T cells is not enzymatically active.

Once bound, ZAP-70 is activated by phosphorylation by Lck. This phosphorylation occurs at three tyrosine residues, two in the linker region between the tandem SH2 domains and the kinase domain, and a third residue in the catalytic domain. Together these phosphorylations activate ZAP-70 by disrupting the autoinhibited form of inactive ZAP-70, allowing the ZAP-70 kinase domain to adopt the active conformation (Fig. 7.14). In addition, the Lck SH2 domain binds to one of phosphorylated tyrosines in the ZAP-70 linker region (pY319), thereby stabilizing active Lck at the T-cell receptor complex.

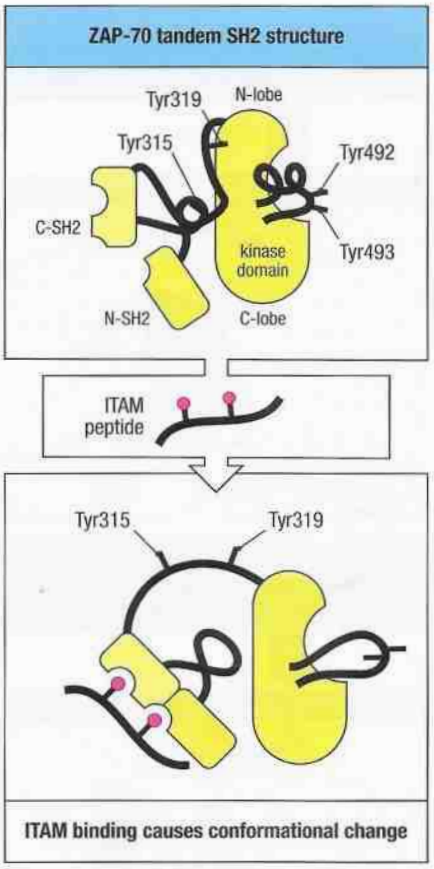

Fig. 7.14 ITAM binding induces a conformational change in ZAP-70. Prior to binding to a phosphorylated ITAM in the T-cell receptor complex, the ZAP-70 kinase is in the inactive conformation through interactions between the tandem SH2 domain–kinase domain linker region (shown in orange) and the kinase domain. These interactions stabilize ZAP-70 in a catalytically inactive state, referred to as the autoinhibited form of ZAP-70, by locking the kinase domain in an inactive conformation. After ITAM binding, the linker region is released and can be phosphorylated by Lck on two tyrosine residues, Y315 and Y319. Lck also phosphorylates two tyrosine residues in the catalytic (kinase) domain. When Y315 and Y319 and the kinase domain are phosphorylated, ZAP-70 is stabilized in the active conformation.

7-11 ITAMs are also found in other receptors on leukocytes that signal for cell activation.

The signaling subunits of the T-cell receptor and the B-cell receptor each contain ITAMs, which are essential for T-cell receptor and B-cell receptor signaling. Phosphorylation of both tyrosines in the ITAM functions to recruit a tyrosine kinase with tandem SH2 domains—ZAP-70 in the case of T cells, and a closely related kinase, Syk, in B cells. Other immune-system receptors also use ITAM-containing accessory chains to transduce activating signals (Fig. 7.15). One example is **FcγRIII** (CD16), a receptor for IgG that triggers antibody-dependent cell-mediated cytotoxicity (ADCC) by NK cells, which we consider in Chapter 11. CD16 is also found on macrophages and neutrophils, where it facilitates the uptake and destruction of antibody-bound pathogens. To signal, FcγRIII must associate either with the ζ chain found also in the T-cell receptor or with another member of the same protein family known as the Fcγ chain. The Fcγ chain is also the signaling component of another Fc receptor—the Fcε receptor I (FcεRI) on mast cells. As we discuss in Chapter 14, this receptor binds IgE antibodies, and on cross-linking by allergens, it triggers the degranulation of mast cells. Last, many activating receptors on NK cells are associated with DAP12, another ITAM-containing protein (see Section 3-26). Each of these additional ITAM-containing signaling chains becomes tyrosine phosphorylated after stimulation of its associated receptor, leading to the recruitment of a tyrosine kinase, either Syk or ZAP-70. With the exception of T cells, Syk is broadly expressed in all leukocyte subsets; in contrast, in healthy individuals, ZAP-70 has been found only in T cells, NK cells, and innate lymphoid cells (ILCs).

ANIMATION 7.1

Several viral pathogens seem to have acquired ITAM-containing receptors from their hosts. These include the Epstein–Barr virus (EBV), whose LMP2A gene encodes a membrane protein with a cytoplasmic tail containing an ITAM. This enables EBV to trigger B-cell survival by the signaling pathways discussed in Section 7-20, an important step in the development of EBV-induced malignancies. Another virus that expresses an ITAM-containing protein is the Kaposi's sarcoma herpesvirus (KSHV or HHV8), which causes malignant transformation and proliferation of the cells it infects.

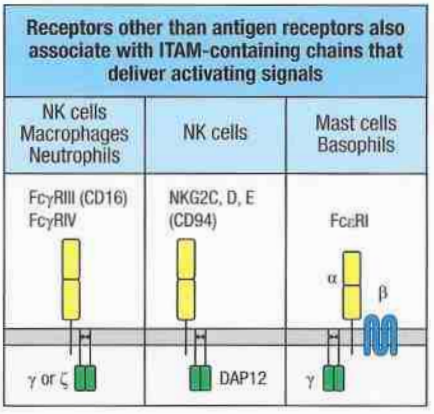

Fig. 7.15 Other receptors that pair with ITAM-containing chains can deliver activating signals. Cells other than B and T cells have receptors that pair with accessory chains containing ITAMs, which are phosphorylated when the receptor is cross-linked. These receptors deliver activating signals. The Fcγ receptor III (FcγRIII, or CD16) is found on NK cells, macrophages, and neutrophils. Binding of IgG to this receptor activates the killing function of the NK cell, leading to the process known as antibody-dependent cell-mediated cytotoxicity (ADCC). Activating receptors on NK cells, such as NKG2C, NKG2D, and NKG2E, also associate with ITAM-containing signaling chains. The Fcε receptor (FcεRI) is found on mast cells and basophils. The α subunit binds to IgE antibodies with very high affinity. The β subunit is a four-spanning transmembrane protein. When antigen subsequently binds to the IgE, the mast cell is triggered to release granules containing inflammatory mediators. The γ chain associated with the Fc receptors, and the DAP12 chain that associates with the NK killer-activating receptors, also contain one ITAM per chain and are present as homodimers. Some Fc receptors, such as CD16, can associate with the T-cell receptor ζ homodimer rather than with γ.

7-12 Activated ZAP-70 phosphorylates adaptor proteins and promotes PI 3-kinase activation.

As described in Section 7-10, phosphorylation of the tyrosines in the T-cell receptor ITAMs leads to the recruitment and activation of ZAP-70. This provides ZAP-70 proximity to the cell membrane, where it phosphorylates the adaptor protein **LAT (linker for activation of T cells)**, a transmembrane protein with a large cytoplasmic domain (Fig. 7.16). ZAP-70 also phosphorylates another adaptor protein, **SLP-76**. LAT and SLP-76 can be linked by the adaptor protein Gads; this three-protein complex, referred to as the LAT:Gads:SLP-76 complex, plays a central role in T-cell activation. This is illustrated by the profound TCR signaling and T-cell development defects seen in mice lacking any one of these components and in humans lacking ZAP-70. A second essential event that occurs rapidly after ZAP-70 activation is the recruitment and activation of the enzyme PI 3-kinase (see Section 7-4); currently, the detailed mechanism linking PI 3-kinase activation to T-cell receptor stimulation is not understood.

After formation of the LAT:Gads:SLP-76 complex and the activation of PI 3-kinase, the T-cell receptor signaling pathway branches into several downstream modules, each of which induces cellular changes that contribute to optimal T-cell activation (see Fig. 7.16). Together, these signals lead to profound changes in the T cell. A small resting naive T cell that has little cytoplasm expands in size and content and prepares for the rapid rounds of cell division that will begin approximately 30–36 hours after activation. Each

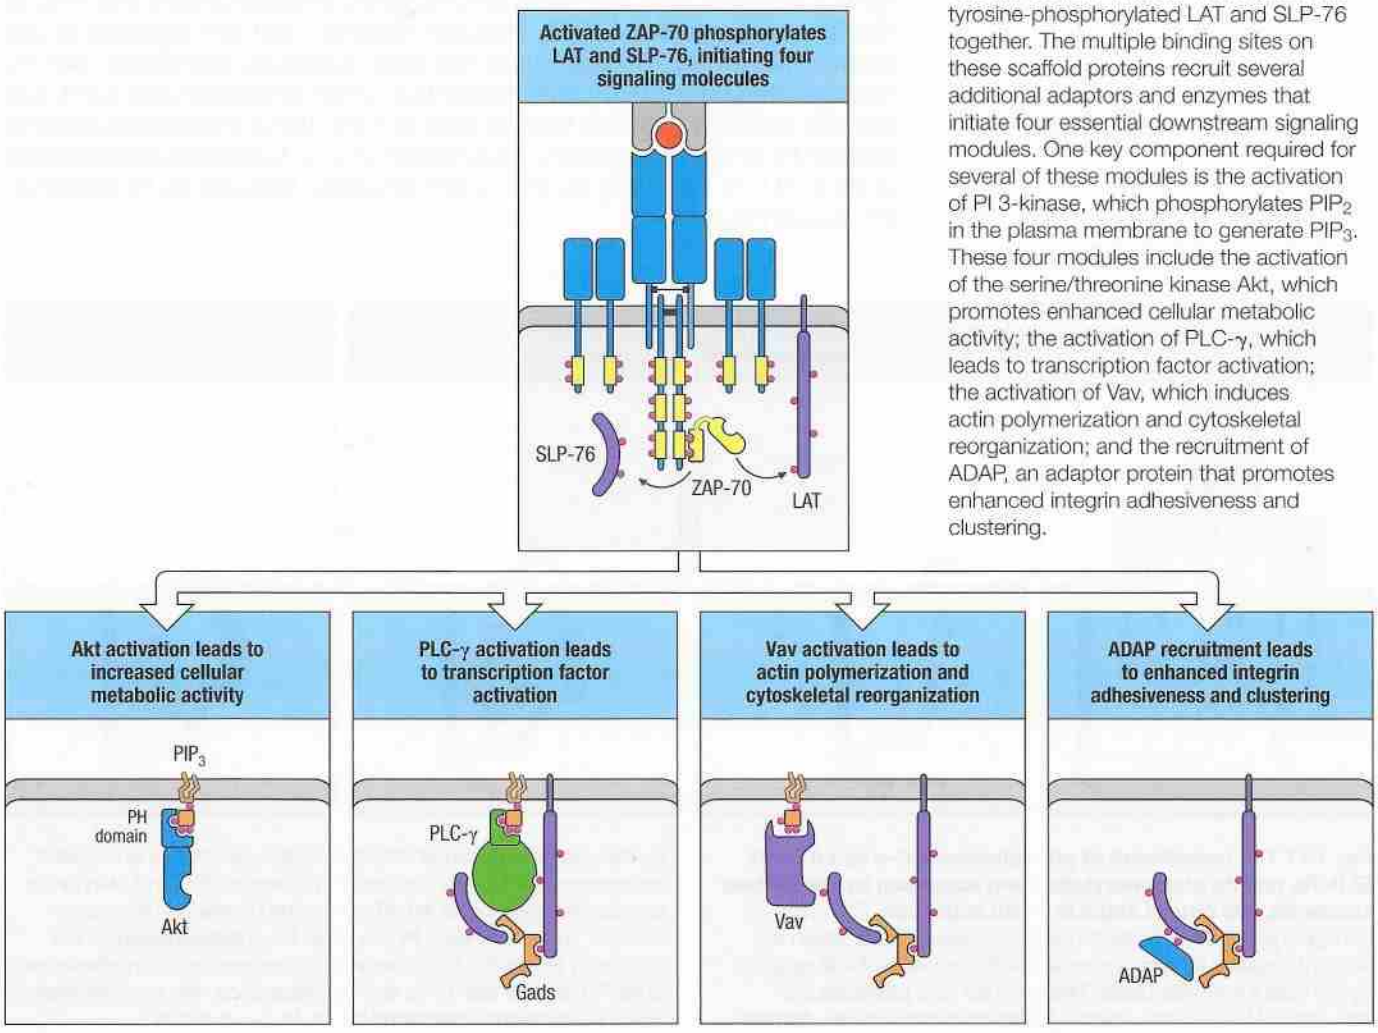

Fig. 7.16 ZAP-70 phosphorylates LAT and SLP-76, initiating four downstream signaling modules. Activated ZAP-70 phosphorylates the adaptor proteins LAT and SLP-76 and recruits them to the activated T-cell receptor (TCR) complex. Another adaptor protein, Gads, holds the tyrosine-phosphorylated LAT and SLP-76 together. The multiple binding sites on these scaffold proteins recruit several additional adaptors and enzymes that initiate four essential downstream signaling modules. One key component required for several of these modules is the activation of PI 3-kinase, which phosphorylates PIP_2 in the plasma membrane to generate PIP_3. These four modules include the activation of the serine/threonine kinase Akt, which promotes enhanced cellular metabolic activity; the activation of PLC-γ, which leads to transcription factor activation; the activation of Vav, which induces actin polymerization and cytoskeletal reorganization; and the recruitment of ADAP, an adaptor protein that promotes enhanced integrin adhesiveness and clustering.

T-Cell Signaling Defects

module is initiated by the recruitment of a key intermediate to the active signaling complexes, either via binding to the LAT:Gads:SLP-76 complex, to the PIP_3 generated by PI 3-kinase, or to both. In brief, these modules lead to the activation of phospholipase C-γ (PLC-γ), which affects transcription; the activation of the serine/threonine kinase Akt, which affects metabolism, among other things; the recruitment of the adaptor protein ADAP, which up-regulates cell adhesion; and the activation of the protein Vav, which initiates actin polymerization. Each of these four modules will be described in detail in the sections that follow.

7-13 Activated PLC-γ generates the second messengers diacylglycerol and inositol trisphosphate that lead to transcription factor activation.

One important module of T-cell receptor signaling is the activation of the enzyme **phospholipase C-γ (PLC-γ)**. First, PLC-γ is brought to the inner face of the plasma membrane by the binding of its PH domain to the PIP_3 that has been formed by the phosphorylation of PIP_2 by PI 3-kinase. It then binds to phosphorylated LAT and SLP-76. The actions of PLC-γ produce two second messengers that activate three distinct terminal branches of the T-cell receptor pathway leading to transcription factor activation.

Because of this crucial role in T-cell activation, PLC-γ activation is controlled at several different levels. Recruitment to the membrane, while necessary, is not sufficient to activate PLC-γ. PLC-γ activation requires phosphorylation by Itk, a member of the Tec family of cytoplasmic tyrosine kinases. Like PLC-γ, Tec kinases contain PH, SH2, and SH3 domains and are recruited to the plasma membrane by interactions via these domains; specifically, the PH domain interacts with PIP_3 on the inner face of the membrane (Fig. 7.17), and the SH2 and SH3 domains interact with SLP-76. These interactions serve to localize Itk in close proximity to its substrate, PLC-γ, leading to direct binding of Itk to PLC-γ, via one of the PLC-γ SH2 domains, followed by Itk phosphorylation of PLC-γ.

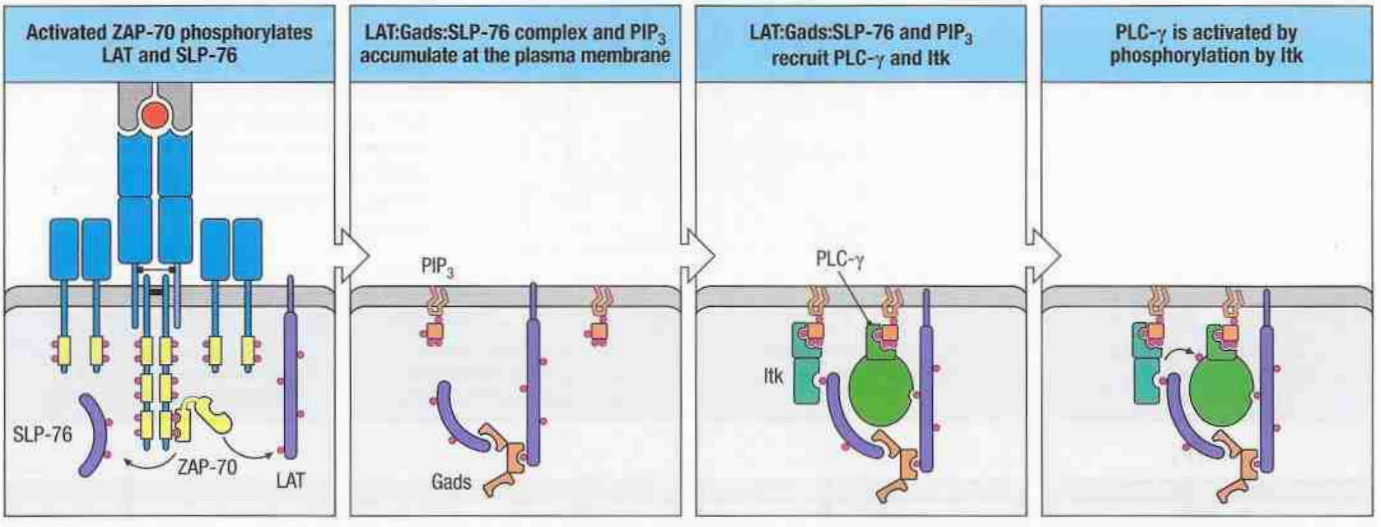

Fig. 7.17 The recruitment of phospholipase C-γ by LAT and SLP-76, and its phosphorylation and activation by the protein kinase Itk, are crucial steps in T-cell activation. ZAP-70 phosphorylates the adaptor proteins LAT and SLP-76, which are brought together to form a complex at the activated T-cell receptor by the adaptor protein Gads. This complex also promotes the activation of PI 3-kinase, leading to the production of PIP_3 (formed by the phosphorylation of PIP_2 by PI 3-kinase). PLC-γ is recruited to the membrane by its PH domain binding to PIP_3 and then binds to phosphorylated sites in LAT and to the proline-rich domain of SLP-76. To be activated, PLC-γ must be phosphorylated by the Tec-family kinase Itk. Itk is recruited to the membrane by interaction of its PH domain with PIP_3, and by interactions with phosphorylated SLP-76. Once phosphorylated by Itk, PLC-γ is active.

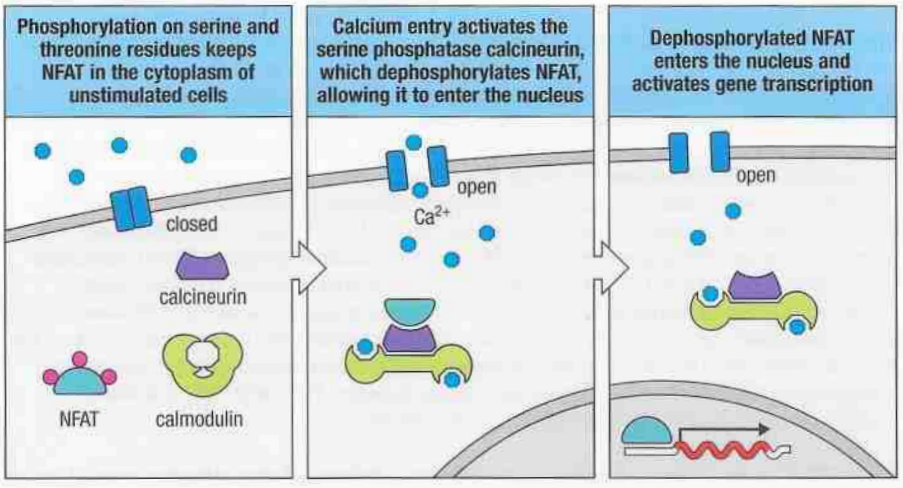
Fig. 7.18 Phospholipase C-γ cleaves inositol phospholipids to generate two important signaling molecules. Top panel: Phosphatidylinositol 4,5-bisphosphate (PIP_2) is a component of the inner leaflet of the plasma membrane. When PLC-γ is activated by phosphorylation, it cleaves PIP_2 into two parts: inositol 1,4,5-trisphosphate (IP_3), which diffuses away from the membrane into the cytosol, and diacylglycerol (DAG), which stays in the membrane. Both of these molecules are important in signaling. Middle panel: There are two phases of calcium release. IP_3 binds to a receptor in the endoplasmic reticulum (ER) membrane, opening calcium channels (yellow) and allowing the early phase of calcium ions (Ca^{2+}) to enter the cytosol from the ER. The depletion of Ca^{2+} stores in the ER causes the aggregation of an ER calcium sensor, STIM1. Bottom panel: Aggregated STIM1 stimulates the second phase of calcium entry by binding to and opening calcium channels called ORAI1 in the plasma membrane. This further increases cytosolic calcium and restores ER Ca^{2+} stores. DAG binds and recruits signaling proteins to the membrane, most important the Ras GEF called RasGRP and a serine/threonine kinase called protein kinase C-θ (PKC-θ). Recruitment of RasGRP to the plasma membrane activates Ras, and PKC-θ activation results in the activation of the transcription factor NFκB.

Once PLC-γ has been recruited to the inner face of the plasma membrane and has been activated, it can catalyze the breakdown of the membrane lipid PIP_2 (see Section 7-4 and Fig. 7.6) to generate two products, the membrane lipid **diacylglycerol (DAG)** and the diffusible second messenger **inositol 1,4,5-trisphosphate (IP_3)** (not to be confused with the membrane lipid PIP_3) (Fig. 7.18). DAG is confined to the membrane but diffuses in the plane of the membrane and serves as a molecular target that recruits other signaling molecules to the membrane. IP_3 signaling relies on the very low concentrations of calcium ions (Ca^{2+}) normally found in the cytoplasm of resting cells. After release from the membrane lipid, IP_3 diffuses into the cytosol and binds to IP_3 receptors on the endoplasmic reticulum (ER) membrane. These receptors are Ca^{2+} channels, which open and release calcium stored in the ER into the cytosol. The loss of calcium from the ER then causes a conformational change in the transmembrane protein **STIM1**, promoting its clustering within the ER membrane. The STIM1 oligomers bind to the plasma membrane, where they interact directly with ORAI1, the plasma membrane calcium channel (also known as the **CRAC channel**: calcium release-activated calcium channel). Binding of STIM1 to ORAI1 triggers calcium channel opening, allowing extracellular calcium to flow into the cell to activate further signaling pathways and to replenish ER calcium stores.

The activation of PLC-γ marks an important step in T-cell activation, because after this point the PLC-γ signaling module splits into three distinct branches—the stimulation of Ca^{2+} entry, the activation of Ras, and the activation of **protein kinase C-θ (PKC-θ)**—each of which ends in the activation of a different transcription factor. These signaling pathways are utilized by many cell types, in addition to lymphocytes. Their importance in T-cell activation is shown by the observation that treatment of T cells with phorbol myristate acetate (an analog of DAG) and ionomycin (a pore-forming drug that allows extracellular calcium to flow into the cell) can reconstitute many of the effects of T-cell receptor stimulation. Additionally, deficiencies in several of these signaling components, including Lck, ZAP-70, Itk, CD45, CARMA1, and ORAI1, have been found to be the cause of severe combined immune deficiency (SCID).

7-14 Ca^{2+} entry activates the transcription factor NFAT.

One of the three signaling pathways leading from PLC-γ results in an influx of calcium ions into the cytosol. An important outcome of the increased cytosolic Ca^{2+} resulting from T-cell receptor signaling via PLC-γ is the activation of a family of transcription factors called **NFAT (nuclear factor of activated T cells)**. NFAT is something of a misnomer, because the five members of this family are expressed in many different tissues. In the absence of activating signals, NFAT is kept in the cytosol of resting T cells by phosphorylation on serine/threonine residues. This phosphorylation is mediated by serine/threonine kinases,



Phosphorylation on serine and threonine residues keeps NFAT in the cytoplasm of unstimulated cells
Calcium entry activates the serine phosphatase calcineurin, which dephosphorylates NFAT, allowing it to enter the nucleus

Fig. 7.19 The transcription factor NFAT is regulated by calcium signaling. Left panel: NFAT is maintained in the cytoplasm by phosphorylation on serine and threonine residues. Center panel: After antigen receptor stimulation, calcium enters the cytosol, first from the endoplasmic reticulum (not shown; see Fig. 7.18) and later from the extracellular space (shown). After entering the cytosol, calcium binds to calmodulin, and the Ca^{2+}:calmodulin complex binds to the serine/threonine phosphatase calcineurin, activating it to dephosphorylate NFAT. Right panel: Once dephosphorylated, NFAT moves into the nucleus, where it binds to promoter elements and activates the transcription of various genes.

including glycogen synthase kinase 3 (GSK3) and casein kinase 2 (CK2). When phosphorylated, the nuclear localization sequence of NFAT is not recognized by nuclear transporters, and NFAT is unable to enter into the nucleus (Fig. 7.19).

The cytoplasmic Ca^{2+} resulting from T-cell receptor signaling binds to and induces a conformational change in a protein called **calmodulin**, which is then able to bind to and activate a wide range of different target enzymes. In T cells, an important target of calmodulin is **calcineurin**, a protein phosphatase that acts on NFAT. Dephosphorylation of NFAT by calcineurin allows the nuclear localization sequence to be recognized by nuclear transporters, and NFAT enters the nucleus (see Fig. 7.19). There it participates in turning on many of the genes crucial for T-cell activation, such as the gene for the cytokine interleukin-2 (IL-2).

The importance of NFAT in T-cell activation is illustrated by the effects of selective inhibitors of calcineurin called **cyclosporin A (CsA)** and **tacrolimus** (also known as **FK506**). CsA forms a complex with the protein cyclophilin A, and this complex binds to and inhibits calcineurin. Tacrolimus binds a different protein, FK-binding protein (FKBP), making a complex that similarly inhibits calcineurin. By inhibiting calcineurin, these drugs prevent the formation of active NFAT after T-cell receptor stimulation. T cells express low levels of calcineurin, so they are more sensitive to inhibition of this pathway than are many other cell types. NFAT is an important regulator of numerous genes in T cells, including those for cytokines, cytokine receptors, adhesion molecules, and transcription factors. As a consequence of this broad function for NFAT, both cyclosporin A and tacrolimus act as effective immunosuppressants and are widely used to prevent the rejection of organ transplants (see Section 16-2).

7-15 Ras activation stimulates the mitogen-activated protein kinase (MAPK) relay and induces expression of the transcription factor AP-1.

ANIMATION 7.2

A second branch of the PLC-γ signaling module is the activation of the small GTPase Ras. This can occur by various means. The most efficient mechanism for Ras activation in T cells is via the DAG generated by PLC-γ, which diffuses in the plasma membrane and activates a variety of proteins. One of these is the protein RasGRP, which is a guanine nucleotide exchange factor (GEF) that specifically activates Ras. RasGRP contains a protein-interaction module called a C1 domain that binds to DAG. This interaction recruits RasGRP to the membrane near active signaling complexes (Fig. 7.20), where it activates Ras by promoting the exchange of GDP for GTP. Ras is also activated in the T-cell

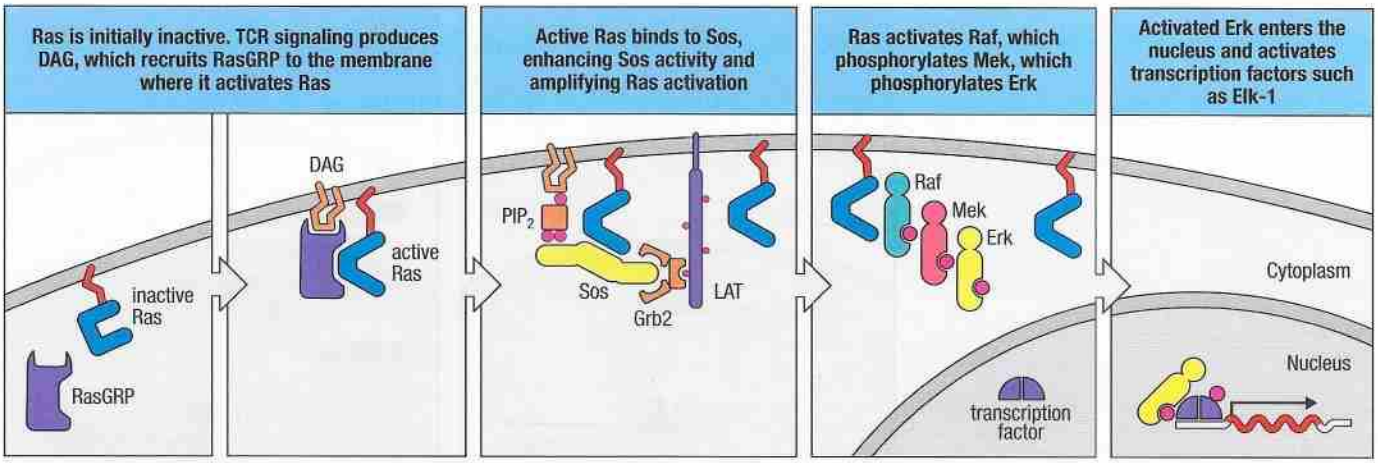

Fig. 7.20 DAG activates MAPK cascades, leading to transcription factor activation. All MAPK cascades are initiated by the activation of small G proteins, such as Ras in this example. Ras is switched from an inactive state (first panel) to an active state (second panel) by a guanine nucleotide exchange factor (GEF), RasGRP, which is recruited to the membrane by DAG. Active Ras binds to an allosteric pocket in a second Ras GEF called Sos, which is recruited by its PH domain binding PIP_3 and its proline-rich region binding to Grb2 on LAT. Once Sos is bound to a molecule of active Ras, Sos activity is enhanced by 75-fold, leading to the production of many molecules of active Ras. Ras activates the first enzyme of the cascade, a protein kinase called Raf, a MAP3K (third panel). Raf phosphorylates Mek, a MAP2K, which in turn phosphorylates and activates Erk, a MAPK. Phosphorylation and activation of Erk releases it from the complex so that it can diffuse within the cell and enter the nucleus (fourth panel). Phosphorylation of transcription factors by Erk results in new gene transcription.

receptor signaling pathway by the GEF Sos, which is recruited by the adaptor protein Grb2 (see Sections 7-2 and 7-3), which has itself been recruited by binding to phosphorylated LAT and SLP-76. An efficient positive feedback loop contributes to robust Ras activation after T-cell receptor signaling. Once a small amount of GTP-bound Ras is generated by RasGRP, this activated Ras binds to a regulatory pocket on a second Ras GEF called Sos. Sos is recruited to the site of T-cell receptor signaling when its PH domain binds to PIP_3 and a proline-rich region in Sos binds to the LAT:Grb2 complex (see Fig 7.20). When the Sos protein binds a molecule of active Ras (Ras GTP), this enhances the activity of Sos by 75-fold. This dramatic enhancement of Sos activity after binding Ras GTP generates an all-or-nothing pattern of Ras activation, such that low levels of antigen receptor signaling can induce maximal Ras activation.

Activated Ras triggers a three-kinase relay that ends in the activation of a serine/threonine kinase known as a **mitogen-activated protein kinase** or **MAP kinase (MAPK)** (see Fig. 7.20). In the case of antigen receptor signaling, the first member of the relay is a MAPK kinase kinase (MAP3K) called **Raf**. Raf is a serine/threonine kinase that phosphorylates the next member of the series, a MAPK kinase (MAP2K) called **Mek1**. Mek1 is a dual-specificity protein kinase that phosphorylates a tyrosine and a threonine residue on the last member of the relay, a MAPK which in T cells and B cells is **Erk (extracellular signal-related kinase)**.

As predicted by the positive feedback loop regulating Ras activation, measurements of Erk activation in T cells demonstrate a bimodal (all-or-nothing) pattern of response (Fig 7.21).

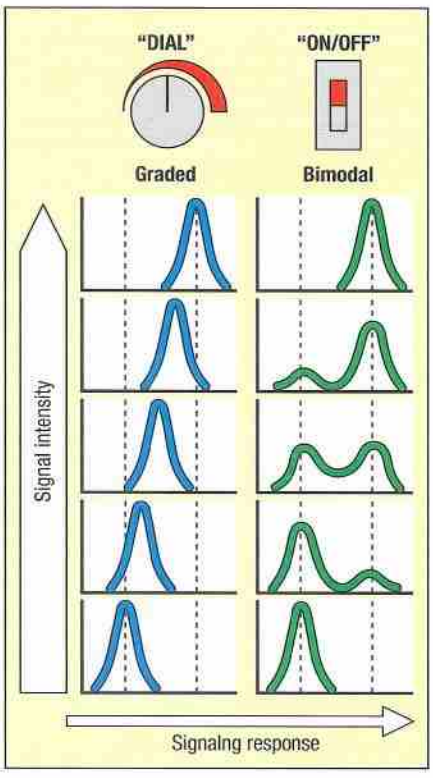

Fig 7.21. Signaling responses can be graded or all-or-nothing. T cells stimulated by differing intensities of T-cell receptor signaling can produce distinct patterns of responses. These patterns can be visualized by flow cytometry experiments that individually measure the response in each cell and then display a histogram of the entire cell population. For these histograms, the *x*-axis indicates the magnitude of the response, and the *y*-axis indicates the number of cells displaying a response of that magnitude. Graded responses act like dials, in which the entire population of cells show a response that is proportional to the T-cell receptor signal intensity. Bimodal responses act like on/off switches, in which the signal intensity determines the relative proportion of cells in the population that respond; for these responses, increasing the signal intensity increases the proportion of responding cells, but the magnitude of the response does not vary. Because of the positive feedback loop for Ras activation in response to T-cell receptor stimulation, activation of the Erk MAPK displays on/off switchlike behavior.

Fig. 7.22 The transcription factor AP-1 is formed as a result of the Ras–MAPK signaling pathway. Left panel: Phosphorylation of the MAPK Erk activated as a result of the Ras–MAPK cascade allows Erk to enter the nucleus, where it phosphorylates the transcription factor Elk-1. Elk-1, along with serum response factor (SRF), binds to the serum response element (SRE) in the promoter of the gene (*FOS*) for the transcription factor c-Fos, stimulating its transcription. Right panel: The protein kinase PKC-θ can induce the phosphorylation of another MAPK called Jun kinase (JNK). This enables JNK to enter the nucleus and phosphorylate the transcription factor c-Jun, which forms a dimer with c-Fos. The phosphorylated c-Jun:Fos dimer is an active AP-1 transcription factor that binds to AP-1 sites and promotes transcription of many target genes.

An important function of MAPKs is to phosphorylate and activate transcription factors that can then induce new gene expression. Erk acts indirectly to generate the transcription factor **AP-1**, which is a heterodimer composed of one monomer each from the Fos and Jun families of transcription factors (Fig. 7.22). Active Erk phosphorylates the transcription factor Elk-1, which cooperates with a transcription factor called serum response factor (SRF) to initiate transcription of the *FOS* gene. Fos protein then associates with Jun to form the AP-1 heterodimer, but this remains transcriptionally inactive until another MAPK called **Jun N-terminal kinase (JNK)** phosphorylates Jun. Similar to NFAT, AP-1 participates in turning on transcription of many genes important for T-cell activation, including the genes encoding the cytokine IL-2 and the cell-cycle protein cyclin D1.

7-16 Protein kinase C activates the transcription factors NFκB and AP-1.

The third signaling pathway leading from PLC-γ results in the activation of PKC-θ, an isoform of protein kinase C that is restricted to T cells and muscle. Mice lacking PKC-θ develop T cells in the thymus, but their mature T cells have a defect in the activation of two crucial transcription factors, NFκB and AP-1, in response to signaling by the T-cell receptor and CD28. These transcription factors also participate in turning on genes required for T-cell activation. For example, transcription of the gene for IL-2 requires NFκB in addition to NFAT and AP-1, making PKC-θ activation an important component of T-cell activation.

PKC-θ has a C1 domain and is recruited to the membrane when DAG is generated by activated PLC-γ (see Fig. 7.18). In this location, the kinase activity of PKC-θ initiates a series of steps that results in the activation of NFκB (Fig. 7.23). PKC-θ phosphorylates the large membrane-localized adaptor protein CARMA1, causing it to oligomerize and form a multi-subunit complex with other proteins. This complex recruits and activates TRAF6, the same

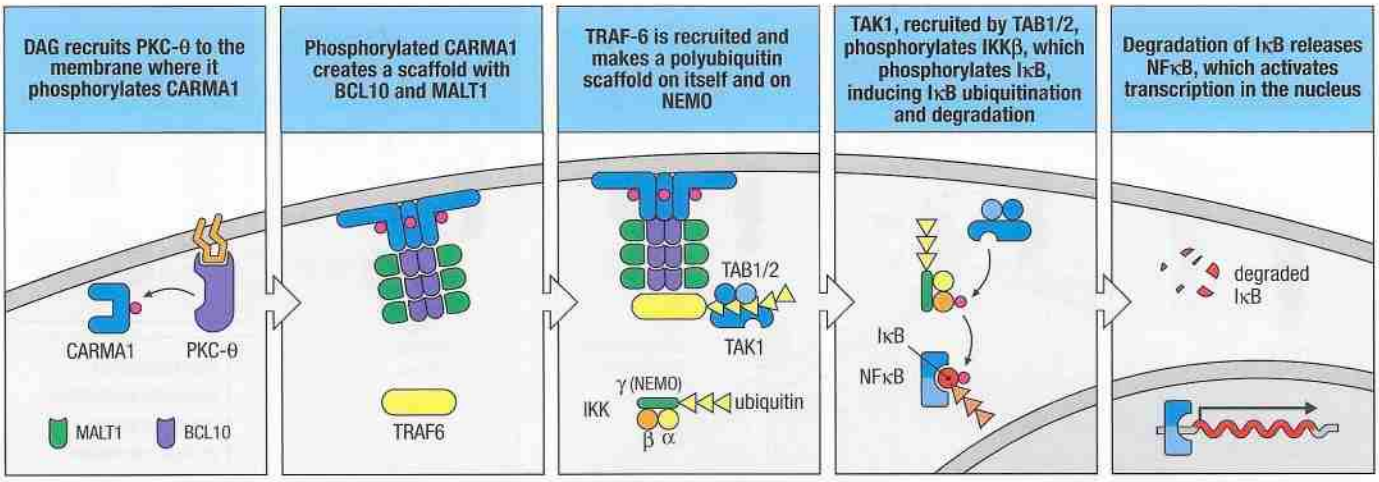

Fig. 7.23 Activation of the transcription factor NFκB by antigen receptors is mediated by protein kinase C. Diacylglycerol (DAG), produced as a result of T-cell receptor signaling activating PLC-γ, recruits a protein kinase C (PKC-θ) to the membrane, where it phosphorylates an adaptor protein called CARMA1. This forms a complex with BCL10 and MALT1 that recruits the E3 ubiquitin ligase TRAF6. As described in Fig. 3.14, the kinase TAK1 is recruited by the polyubiquitin scaffold produced by TRAF6 and phosphorylates the IκB kinase (IKK) complex [IKKα:IKKb:IKKγ (NEMO)]. IKK phosphorylates IκB, stimulating its ubiquitination, which targets IκB for degradation by the proteasome. This releases NFκB to enter the nucleus and stimulate transcription of its target genes. A defect in IKKγ (NEMO) that prevents NFκB activation causes immunodeficiency that results in susceptibility to extracellular bacterial infections, along with a skin disease known as ectodermal dysplasia.

protein that we encountered in Chapter 3 in its role in activating NFκB in the TLR signaling pathway (see Fig. 3.14).

NFκB is the general name for a member of a family of homodimeric and heterodimeric transcription factors made up of the Rel family of proteins. The most common NFκB activated in lymphocytes is a heterodimer of p50:p65Rel. The dimer is held in an inactive state in the cytoplasm by binding to an inhibitory protein called inhibitor of κB (IκB). As described for TLR signaling (see Fig. 3.14), TRAF6 stimulates the degradation of IκB by first activating the kinase TAK1, which activates a complex of serine kinases—IκB kinase (IKK). IKK phosphorylates IκB, causing its ubiquitination and subsequent degradation, and the consequent release and entry into the nucleus of active NFκB. Inherited deficiency of the IKKγ subunit (also called **NEMO**) leads to a syndrome known as **X-linked hypohidrotic ectodermal dysplasia and immunodeficiency**, which is characterized by developmental defects in ectodermal structures such as skin and teeth, as well as immunodeficiency.

PKC-θ can also activate JNK and might be able to activate the transcription factor AP-1 by this route. However, T cells lacking PKC-θ have a defect in AP-1 activation in addition to their defect in NFκB activation, but no defect in JNK activation, indicating that our understanding of this pathway is still incomplete.

7-17 PI 3-kinase activation up-regulates cellular metabolic pathways via the serine/threonine kinase Akt.

While the activation of transcription factors is an important outcome of antigen receptor signaling, a productive T-cell response also requires substantial changes in cellular metabolism, which are needed to accommodate the energetic and macromolecular demands of rapidly dividing cells. The PI 3-kinase pathway plays a central role in this response via the recruitment and activation of the second important T-cell receptor signaling module, initiated by the serine/threonine kinase Akt (also known as protein kinase B). Akt, via its PH domain, binds to PIP_3 in the membrane, which is generated by PI 3-kinase (Fig. 7.24; see also Fig. 7.6). In that location, Akt is phosphorylated by PDK1 and, once activated, phosphorylates a variety of downstream proteins. One of its effects is to promote cell survival by inhibiting cell death via multiple mechanisms. A major mechanism is the phosphorylation of the pro-apoptotic protein Bad. When phosphorylated, Bad can no longer bind to and inhibit the anti-apoptotic (pro-survival) protein Bcl-2 (see Fig. 7.24).

Another effect of activated Akt is to regulate the expression of homing and adhesion receptors that orchestrate the migratory properties of activated T cells. Briefly, activated T cells down-regulate surface receptors that promote

Fig. 7.24 The serine/threonine kinase Akt is activated by TCR signaling and promotes cell survival and enhanced metabolic activity via mTOR. First panel: T-cell receptor (TCR) signaling activates PI 3-kinase (not shown), generating PIP_3 in the plasma membrane; PIP_3 recruits and activates the kinase PDK1. Akt, a second serine/threonine kinase, binds to PIP_3 via its PH domain and is phosphorylated and activated by PDK1. Second panel: Active Akt phosphorylates the pro-apoptotic protein Bad, which is binding to and inhibiting the anti-apoptotic protein Bcl-2 at the mitochondrial membrane. Third panel: Phosphorylated Bad binds to 14-3-3, releasing Bcl-2 to promote cell survival. Fourth panel: A second function of active Akt is to phosphorylate the TSC1/2 complex, a GAP for the small GTPase Rheb. Fifth panel: When TSC1/2 is phosphorylated, it releases the inactive Rheb protein, leading to Rheb activation. Active Rheb binds to and activates mTOR (mammalian target of rapamycin). Once activated, mTOR acts on multiple pathways that lead to increased lipid production, ribosome biosynthesis, mRNA synthesis, and protein translation.

T-cell entry into lymph nodes and up-regulate chemokine receptors and integrins that direct T-cell migration from the blood into the tissues, particularly at sites of inflammation or infection (discussed in detail in Chapters 9 and 11). In this context, Akt functions to inactivate the transcription factors expressed in naive T cells, factors that maintain expression of receptors required for lymph node homing and T cell recirculation in the blood.

Activated Akt also functions to stimulate the cell's metabolism by increasing the utilization of glucose; this is mediated by increasing the activity of glycolytic enzymes and by inducing the up-regulation of nutrient transporters, such as the glucose transporter Glut 1, on the T-cell membrane. While resting T cells depend primarily on oxidative metabolism to generate energy, activated T cells switch their metabolism to favor aerobic glycolysis, a less efficient pathway for ATP production, but one that provides an abundant source of carbon for the biosynthesis of amino acids and nucleic acids used for protein and DNA/RNA synthesis, respectively. This switch to glycolytic metabolism is essential to support the rapid rate of cell division of activated T cells, which must duplicate their cellular contents once every 4–8 hours.

Yet another important function of activated Akt is to stimulate the **mTOR (mammalian target of rapamycin)** pathway, a key regulator of macromolecular biosynthesis (see Fig. 7.24). In this case, Akt phosphorylates and inactivates the TSC1/2 complex, a GAP for the small GTPase Rheb. As no GEF for Rheb has yet been identified, it is presumed that inactivation of TSC is sufficient for Rheb activation. Rheb activation, in turn, leads to the activation of mTOR. The mTOR pathway has multiple effects on cellular metabolism; these changes include up-regulating the activities and/or expression of molecules that promote protein synthesis, nucleotide synthesis, mitochondrial biogenesis, lipid biosynthesis, and glucose uptake and glycolysis. At the same time, mTOR also represses protein degradation, in part through the inhibition of the ubiquitin–proteasome system. Collectively, these changes are essential to provide the raw materials needed to carry out the increased gene expression, protein production, DNA/RNA synthesis, and lipid synthesis required for the rapid cell divisions that accompany T-cell activation.

7-18 T-cell receptor signaling leads to enhanced integrin-mediated cell adhesion.

The third signaling module induced by T-cell receptor stimulation leads to enhanced integrin adhesion. Together with cytoskeletal changes (discussed in the next section), this process promotes stability of the T cell–antigen-presenting cell (APC) interaction and localizes active signaling complexes into a structure known as the 'immune synapse' described in Section 7-19 (and see Fig. 7.27). The **immune synapse**, the region of the T-cell membrane that is in direct and stable contact with the APC or target cell, is formed within minutes of T-cell receptor recognition of peptide:MHC ligands. One important component of this is increased adhesiveness of the T-cell integrin LFA-1. On nonstimulated T cells, LFA-1 resides in a low-affinity state and is well dispersed on the T-cell membrane, resulting in weak binding to its ligand, ICAM-1. After T-cell receptor stimulation, LFA-1 molecules aggregate at the synapse and also undergo a conformational change that converts each LFA-1 molecule into a high-affinity binding partner for ICAM-1. Together, these changes lead to enhanced adhesion between the T cell and the APC and to stabilization of this cell–cell interaction. These effects on LFA-1 are induced by the recruitment of the adaptor protein ADAP to the LAT:Gads:SLP-76 complex (Fig. 7.25). In turn, ADAP recruits two additional proteins, SKAP and RIAM. The ADAP:SKAP:RIAM complex binds to the small GTPase Rap1, and, together with the Rap1 guanine nucleotide exchange factor (GEF) C3G and the adaptor protein CrkL, activates Rap1 at the site of T-cell receptor signaling. An additional Rap1 GEF known as CALDAG-GEF1 may also contribute to Rap1 activation. GTP-bound Rap1 then promotes LFA-1 aggregation and the conformational change that converts LFA-1 into a high-affinity binding partner for ICAM-1. The observation that ADAP-deficient T cells show impaired proliferation and cytokine production after T-cell receptor stimulation demonstrates the importance of this pathway in providing a positive feedback loop to promote T-cell activation.

7-19 T-cell receptor signaling induces cytoskeletal reorganization by activating the small GTPase Cdc42.

The fourth T-cell receptor signaling module, also involved in the formation of a stable immune synapse, leads to reorganization of the actin cytoskeleton. Without this process, integrin aggregation would not occur, interactions between the T cell and the APC would not stabilize, and, in fact, T-cell activation would completely fail. A major component of this T-cell receptor signal is transduced by Vav, a GEF that activates Rho family GTPases, including Cdc42. Like PLC-γ and Itk, Vav is recruited to the site of receptor activation by

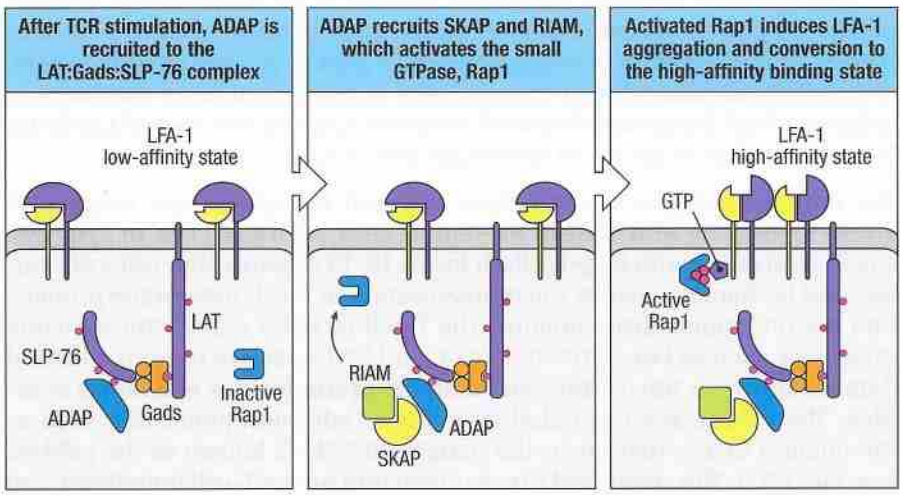

Fig. 7.25 Recruitment of ADAP to the LAT:Gads:SLP-76 complex activates integrin adhesion and aggregation. Left panel: Prior to T-cell receptor (TCR) signaling, the integrin LFA-1 is present on the T-cell membrane in a low-affinity conformation that binds weakly to ICAM-1 on antigen-presenting-cells. Middle panel: After TCR signaling, the adaptor protein ADAP is recruited to the LAT:Gads:SLP-76 complex by an interaction between tyrosine-phosphorylated ADAP and the SH2 domain of SLP-76. ADAP then recruits a complex of SKAP and RIAM (Rap1-GTP-interacting adaptor molecule), activating the small GTPase Rap1. Right panel: Active Rap1 induces aggregation of LFA-1 and a conformational change in LFA-1 that leads to high-affinity binding to ICAM-1.

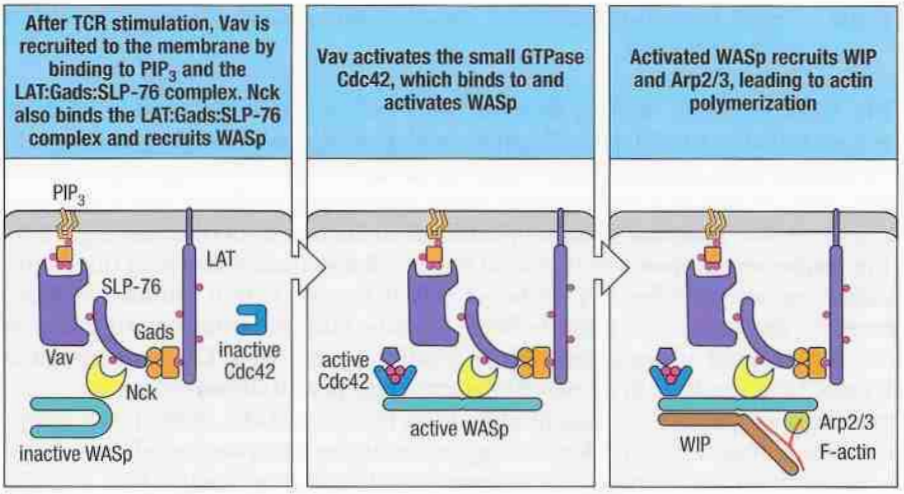

After TCR stimulation, Vav is recruited to the membrane by binding to PIP3 and the LAT:Gads:SLP-76 complex. Nck also binds the LAT:Gads:SLP-76 complex and recruits WASp

Fig. 7.26 Recruitment of Vav to the LAT:Gads:SLP-76 complex induces activation of Cdc42, leading to actin polymerization. Left panel: Vav, a guanine nucleotide exchange factor (GEF) for the small GTPase Cdc42, is recruited to the activated T-cell receptor (TCR) complex by binding via its PH domain to PIP_3 in the membrane and by binding to phosphorylated SLP-76. The small adaptor protein Nck binds to an adjacent phosphorylated tyrosine on SLP-76 and recruits the inactive form of the protein WASp. Middle panel: Vav activates Cdc42, which binds to and activates WASp. Right panel: Active WASp binds to WIP, recruiting Arp2/3 and inducing actin polymerization. The importance of this pathway is illustrated by the discovery of WASp as the protein encoded by the gene responsible for the human immunodeficiency disease Wiskott–Aldrich syndrome.

Wiskott–Aldrich Syndrome

interactions of the Vav PH domain with PIP_3 and of the Vav SH2 domain with the LAT:Gads:SLP-76 scaffold complex (Fig. 7.26). When Cdc42 is activated by Vav, the GTP-bound Cdc42 induces a conformational change in the protein **WASp** (**Wiskott–Aldrich syndrome protein**), which is also recruited to the LAT:Gads:SLP-76 scaffold complex by binding to the small adaptor protein Nck. This active form of WASp binds to WIP, named for its ability to interact with WASp (WASp-interacting protein). Together, WASp and WIP recruit Arp2/3, leading to actin polymerization. The importance of this pathway is underscored by the fact that defects in WASp are the basis for the immunodeficiency disease Wiskott–Aldrich syndrome. Because of expression of WASp in all lineages of hematopoietic cells, individuals suffering from this disease have impairments in multiple immune cell types, all of which depend on WASp-dependent actin polymerization for their functions. One major defect in this disease is a significant reduction in platelet numbers in the blood, called thrombocytopenia, leading to impaired blood clotting at sites of injury. Additionally, individuals with Wiskott–Aldrich syndrome have defects in T cell–dependent antibody responses because of the requirement for actin polymerization to ensure effective interactions between CD4 T cells and B cells. Thus, the failure of WASp-deficient T cells to provide adequate 'help' to B cells most likely results from a defect in the formation of the immune synapse, which is normally required to ensure directed secretion of cytokines from the T cell onto the B-cell membrane (Fig. 7.27).

The immune synapse is a structure observed by microscopic imaging of T cells interacting with antigen-presenting cells, such as B cells, or cytotoxic T cells interacting with target cells. It forms 10–15 minutes after cell–cell contact and is characterized by the reorganization of T-cell membrane proteins into discrete topological domains. The T-cell receptor along with signaling molecules such as Lck, ZAP-70, PKC-θ, and LAT coalesce to form a central domain known as the cSMAC, for central **supramolecular activation complex**. The cSMAC is surrounded by a ring of adhesion molecules, such as the integrin LFA-1, that forms the peripheral SMAC, known as the pSMAC (see Fig. 7.27). This organized site of interaction on the T-cell membrane can

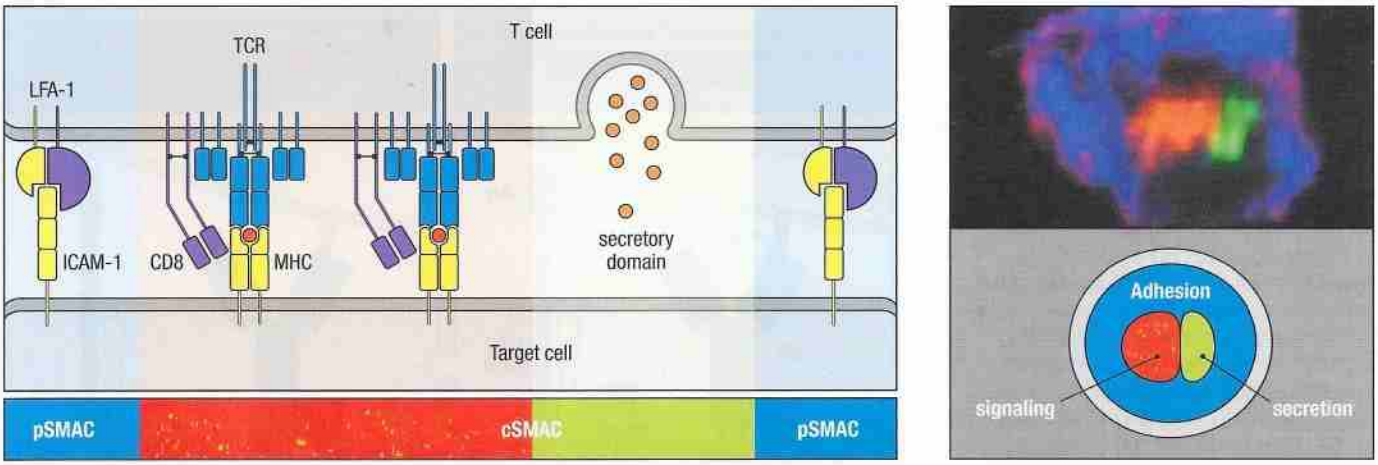

Fig. 7.27 The immune synapse provides a structure for directed secretion of T-cell cytokines. When the T-cell receptors (TCRs) on a T cell recognize peptide:MHC on an antigen-presenting cell, a process of receptor reorganization takes place on the plasma membranes of the two interacting cells. Left panel: When a CD8 T cell recognizes its peptide:MHC ligand on a target cell, the immune synapse functions to direct T cell–secreted cytokines and cytotoxic molecules onto the target-cell surface at the site of closest contact between the plasma membranes of the two cells. The right top panel shows a confocal microscopy image of the TCR signaling complex (Lck, shown in red), granzyme to mark secretory vesicles (shown in green), and actin (shown in blue) to identify the zone of cell adhesion molecules; the right bottom panel provides an illustration of this organizational structure. The central accumulation of the TCR signaling complexes and the secretory vesicles is known as the central supramolecular activation complex (cSMAC), and the ring of adhesion molecules is known as the peripheral supramolecular activation complex (pSMAC).

persist for hours after initial contact and signal initiation and is thought to aid in promoting ongoing T-cell receptor signaling. When the immune synapse is visualized during cytotoxic T cell killing of target cells, the organization of the cSMAC is not symmetric. Instead, the signaling molecules in the cSMAC are segregated to one area of this central domain, while cytotoxic granules are secreted by the cytotoxic T cell from an adjacent area of the cSMAC. This topological organization is thought to allow ongoing T-cell receptor signaling in a cytotoxic T cell that is simultaneously releasing granules to kill a target cell (see Fig 7.27).

7-20 The logic of B-cell receptor signaling is similar to that of T-cell receptor signaling, but some of the signaling components are specific to B cells.

There are many similarities between signaling from T-cell receptors and signaling from B-cell receptors. As with the T-cell receptor, the B-cell receptor is composed of antigen-specific chains associated with ITAM-containing signaling chains, in this case Igα and Igβ (see Fig. 7.11). In B cells, three protein tyrosine kinases of the Src family—Fyn, Blk, and Lyn—are thought to be responsible for phosphorylation of the ITAMs (Fig. 7.28). These kinases associate with resting receptors via a low-affinity interaction with unphosphorylated ITAMs in Igα and Igβ. After the receptors have bound antigen, the receptor-associated kinases are activated and phosphorylate the tyrosine residues in the ITAMs. Signal

Fig. 7.28 Src family kinases are associated with B-cell receptors and phosphorylate the tyrosines in ITAMs to create binding sites for Syk and Syk activation via transphosphorylation. The membrane-bound Src family kinases Fyn, Blk, and Lyn associate with the B-cell antigen receptor by binding to ITAMs, either (as shown in the figure) through their amino-terminal domains or by binding a single phosphorylated tyrosine through their SH2 domains. After ligand binding and receptor clustering, the associated kinases phosphorylate tyrosines in the ITAMs on the cytoplasmic tails of Igα and Igβ. Subsequently, Syk binds to the phosphorylated ITAMs of the Igβ chain. Because there are at least two receptor complexes in each cluster, Syk molecules become bound in close proximity and can activate each other by transphosphorylation, thus initiating further signaling.

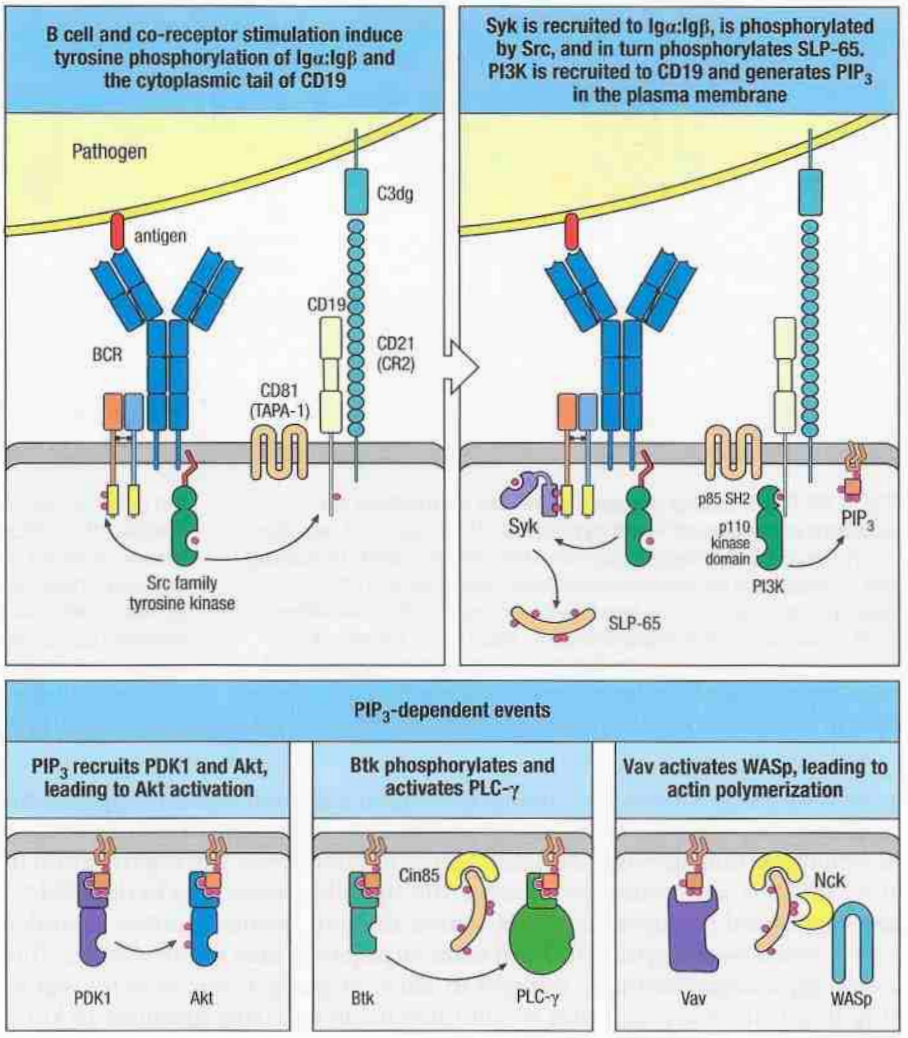

Fig. 7.29 B-cell antigen receptor plus co-receptor engagement activate downstream signaling modules leading to activation of Akt, PLC-γ, and WASp. B-cell receptor (BCR) signaling is greatly enhanced when the antigen is tagged by complement fragments, engaging the B-cell co-receptor together with the B-cell antigen receptor. Cleavage of the antigen-bound complement component C3 to C3dg (see Fig. 2.30) allows the C3dg tag of the pathogen to bind to the cell-surface protein CD21 (complement receptor 2; CR2), a component of the B-cell co-receptor complex, which also includes CD19 and CD81 (TAPA-1). Cross-linking and clustering of the co-receptor with the antigen receptor result in the phosphorylation of tyrosine residues in the ITAM sequences of the cytoplasmic domains of the BCR signaling subunits, Igα and Igβ. The Src family kinase also phosphorylates tyrosine residues in the cytoplasmic domain of CD19. The phosphorylated ITAMs in Igα and Igβ recruit and activate the tyrosine kinase Syk, which functions similarly to ZAP-70 in T cells. The phosphorylated tail of CD19 recruits PI 3-kinase (PI3K), leading to PIP_3 generation in the plasma membrane. Activated Syk phosphorylates the membrane-associated scaffold protein SLP-65, which associates with the plasma membrane by binding Cin85. PIP_3 recruits PDK1 and Akt, leading to Akt activation. Phosphorylated SLP-65 and PIP_3 recruit the Tec family tyrosine kinase Btk and PLC-γ, leading to Btk phosphorylation and activation of PLC-γ. Phosphorylated SLP-65 and PIP_3 also recruit Vav, Nck, and inactive WASp. Vav activates small GTPases that activate WASp, leading to actin polymerization; the activated GTPases also induce integrin aggregation and conversion of LFA-1 to the high-affinity binding state.

initiation at the B-cell receptor is induced by multiple receptors binding to a multivalent antigen, a process that leads to receptor clustering. Alternatively, when the antigen is membrane associated, B-cell receptor signaling can be initiated by monovalent antigen binding (see Fig. 7.28). B cells do not express ZAP-70; instead, a closely related tyrosine kinase, **Syk**, containing tandem SH2 domains organized as in ZAP-70, is recruited to the phosphorylated ITAM. In contrast to ZAP-70, which requires additional phosphorylation for activation, Syk can be activated simply by its binding to the phosphorylated site.

For B cells, accessory receptor functions are combined into one complex of cell-surface proteins—**CD19**, **CD21**, and **CD81**—often referred to as the **B-cell co-receptor** (Fig. 7.29). As with T cells, antigen-dependent signaling from the B-cell receptor is enhanced if this complex is simultaneously bound by its ligand and clusters with the antigen receptor. CD21 (also known as complement receptor 2; CR2) is a receptor for the C3dg fragment of complement. The role of the CD81 (TAPA-1) component of the B-cell receptor complex is as yet unknown. The presence of CD21 in this receptor complex means that antigens, such as bacterial pathogens, on which C3dg is bound (see Fig. 7.29) can cross-link the B-cell receptor with the CD21:CD19:CD81 complex. This induces phosphorylation of the cytoplasmic tail of CD19 by B-cell receptor–associated tyrosine kinases, which in turn leads to the binding of additional Src family kinases, the augmentation of signaling through the B-cell receptor itself, and the recruitment of PI 3-kinase (see Section 7-4). Some molecules of CD19 are present on the B-cell membrane as monomers, rather than in a complex with

CD21 and CD81. This allows CD19 to associate with activated B-cell receptors and amplify signaling even in the absence of complement deposition on the antigen. Overall, this receptor activates PI 3-kinase, thereby enhancing the signaling pathways leading from the B-cell receptor (see Fig. 7.29).

Once activated, Syk phosphorylates the adaptor protein **SLP-65** (also known as **BLNK**), In B cells, SLP-65 combines the functions of LAT and SLP-76 in T cells. SLP-65 provides multiple sites for tyrosine phosphorylation and the recruitment of a variety of SH2-containing proteins, including enzymes and additional adaptor proteins. Several distinct multiprotein signaling complexes can form on individual SLP-65 molecules, and these different complexes act in concert to promote signaling. As in T cells, a key signaling protein is the phospholipase PLC-γ, which is activated with the aid of the B cell–specific Tec kinase **Bruton's tyrosine kinase (Btk)** and hydrolyzes PIP_2 to form DAG and IP_3 (see Fig. 7.29). As discussed for the T-cell receptor, signaling by calcium and DAG leads to the activation of downstream transcription factors. A deficiency in Btk (which is encoded by a gene on the X chromosome) prevents the development and functioning of B cells, resulting in the disease **X-linked agammaglobulinemia**, which is characterized by a lack of antibodies. Besides Btk, mutations in other signaling molecules in B cells, including receptor chains and SLP-65, have been linked to B-cell immunodeficiencies (see Chapter 8).

X-linked Agammaglobulinemia

Several other downstream pathways described for TCR signaling are also shared with BCR signaling and are dependent on the adaptor protein SLP-65. These include the Vav-dependent induction of actin polymerization by Cdc42 and WASp, and the recruitment and activation of small GTPases that promote integrin adhesion (see Fig. 7.27). In the case of B-cell recognition of membrane-bound antigen, B-cell receptor signaling also produces an immune synapse that localizes signaling complexes to the cell–cell interface. One key function of the immune synapse in B cells is to promote antigen uptake by the B cell, a prerequisite to presenting that antigen in the form of peptide:MHC complexes to CD4 T cells.

B-cell receptor signaling also induces metabolic changes in activated B cells. As is the case for T cells, this response is dependent on the action of PI 3-kinase, whose activation leads to formation of the membrane phosphoinositide PIP_3 at the site of the activated B-cell receptor. This response is augmented by combined signaling through the B-cell receptor plus the B-cell co-receptor component CD19. PIP_3 recruits Akt, which is then phosphorylated and activated, leading to downstream activation of mTOR, as well as additional Akt-dependent pathways promoting cell survival and proliferation (see Fig. 7.29).

7-21 Antigen receptor signaling is a dynamic process that evolves over time.

Early biochemical experiments defined the protein–protein interactions and key signaling modules activated by B-cell and T-cell receptor stimulation. These studies provided 'snapshots' of the multiprotein complexes induced by receptor stimulation and identified many of the enzyme–substrate relationships in the pathway, such as the tyrosine phosphorylation of ITAMs by the Src family kinases and the tyrosine phosphorylation of adaptors by the Syk family kinases. However, we now appreciate that these signaling pathways are not static, but involve large-scale changes in protein localization and the assembly and disassembly of protein complexes that vary over time.

High-resolution imaging studies first revealed many of the dynamic movements of membrane proteins after antigen receptor stimulation, as described earlier for the formation of the immune synapse. More recent experiments utilizing affinity purification followed by mass spectrometry have yielded quantitative profiling of signaling complexes from primary lymphocytes at

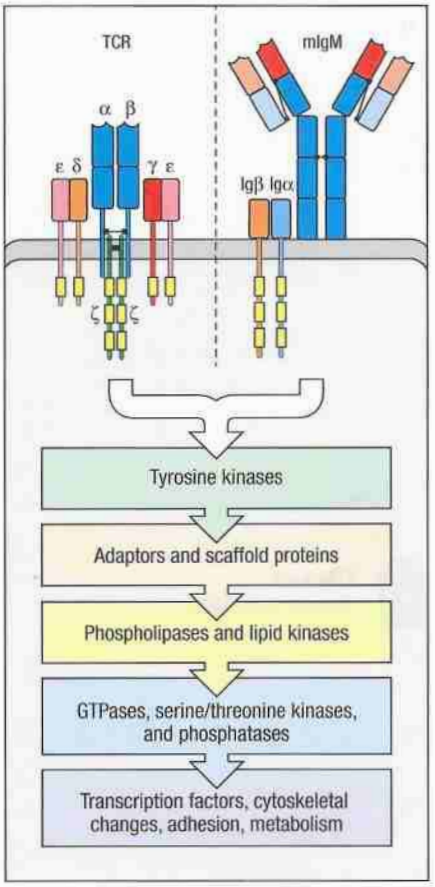

Fig. 7.30 Summary of antigen receptor signaling pathways. As outlined in this part of the chapter, the signal transduction pathways downstream of the T-cell and B-cell receptors occur in an orchestrated series of stages involving many categories of proteins that produce widespread changes in the cells. The first detectable events after antigen receptor stimulation are the activation of tyrosine kinases. Following this, adaptor proteins are modified, recruiting phospholipases and lipid kinases to the activated receptor complexes. The next level of signaling amplifies these earlier stages by activating multiple small GTPases, serine/threonine kinases, and protein phosphatases. Together, these lead to transcription factor activation, cytoskeletal changes, and increases in cellular adhesion and metabolism, all of which contribute to T- and B-cell activation.

multiple time points after activation and from cells at multiple developmental stages. These proteomic data are then combined with known physical protein–protein interaction data extracted from the research literature to develop a more comprehensive picture of the composition and dynamics of large multiprotein signaling modules.

Summary.

The antigen receptors on the surface of lymphocytes are multiprotein complexes in which the antigen-binding chains interact with additional proteins that are responsible for signaling from the receptor. These protein chains carry tyrosine-containing signaling motifs known as ITAMs. Signaling chains containing ITAMs are widely used by activating receptors in many immune cell types in addition to lymphocytes. In lymphocytes, activation of the receptors by antigen results in a series of biochemical events that are broadly outlined in Fig. 7.30. This signaling cascade is initiated by the phosphorylation of the ITAMs by Src family kinases. The phosphorylated ITAM then recruits another tyrosine kinase, ZAP-70 in T cells and Syk in B cells. Activation of ZAP-70 or Syk results in the phosphorylation of adaptors called LAT and SLP-76 in T cells and SLP-65 in B cells, and in the activation of PI 3-kinase. Multiple signaling proteins are recruited and activated by these phosphorylated scaffolds, including phospholipase C-γ, ADAP, and Vav, whereas Akt is recruited and activated by the action of PI 3-kinase generating PIP_3 at the plasma membrane. PLC-γ generates inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 has an important role in inducing changes in intracellular calcium concentrations, and DAG is involved in activating protein kinase C-θ and the small G protein Ras. In T cells, these pathways ultimately result in the activation of three transcription factors, namely, AP-1, NFAT, and NFκB; together, these transcription factors induce transcription of the cytokine IL-2, which is essential for the proliferation and further differentiation of the activated lymphocyte. In addition to transcription factor activation, antigen receptor signaling in both T cells and B cells leads to enhanced cell survival, metabolic activity, adhesiveness, and cytoskeletal reorganization. Signaling by antigen receptors is facilitated by co-receptors that become engaged as a result of receptor–antigen binding. These co-receptors are the MHC-binding CD4 and CD8 transmembrane proteins in T cells and the complement-binding B-cell co-receptor complex containing CD19 in B cells.

Co-stimulatory and inhibitory receptors modulate antigen receptor signaling in T and B lymphocytes.

Signals initiated by the T-cell and B-cell antigen receptors are essential for lymphocyte activation and determine the specificity of the adaptive immune response that is initiated. However, signaling from the antigen receptor is not

on its own sufficient to activate a naive T cell or B cell. These naive lymphocytes require additional signals to achieve full activation. Receptors on T cells and B cells that can provide this necessary second signal are called **co-stimulatory receptors** and are members of either the CD28 family of proteins or of the TNF receptor superfamily. While naive T cells primarily utilize CD28 as the co-stimulatory receptor, naive B cells use the TNF receptor family member CD40. The overall function of signaling through these co-stimulatory receptors is to enhance the antigen receptor signals that induce transcription factor activation and PI 3-kinase activation, thereby ensuring activation of the T cell or B cell. In contrast to these activating co-stimulatory receptor signals, other cell-surface receptors on T cells and B cells function to down-regulate activation signals. These inhibitory receptors are important in preventing excessive immune responses that can lead to destructive inflammatory or autoimmune conditions, particularly in the case of chronic infections that are inefficiently controlled by the immune system.

7-22 The cell-surface protein CD28 is a required co-stimulatory signaling receptor for naive T-cell activation.

The signaling through the T-cell receptor complex described in the second part of the chapter is not by itself sufficient to activate a naive T cell. As noted in Chapter 1, antigen-presenting cells that can activate naive T cells bear cell-surface proteins known as co-stimulatory molecules or co-stimulatory ligands. These interact with cell-surface receptors, known as co-stimulatory receptors, on the naive T cell to transmit a signal that is required, along with antigen stimulation, for T-cell activation—this signal is sometimes called 'signal 2.' We discuss the immunological consequences of this requirement for co-stimulation in detail in Chapter 9.

The best understood of these co-stimulatory receptors is the cell-surface protein **CD28**. CD28 is present on the surface of all naive T cells and binds the co-stimulatory ligands **B7.1 (CD80) and B7.2 (CD86)**, which are expressed mainly on specialized antigen-presenting cells such as dendritic cells, once the antigen-presenting cells have had stimulation via their pattern recognition receptors. To become activated, the naive lymphocyte must engage both antigen and a co-stimulatory ligand on the same antigen-presenting cell. CD28 signaling aids antigen-dependent T-cell activation mainly by promoting T-cell proliferation, cytokine production, and cell survival. All these effects are mediated by signaling motifs present in the cytoplasmic domain of CD28.

After engagement by B7 molecules, CD28 becomes tyrosine phosphorylated by Lck in its cytoplasmic domain on tyrosine residues in a YXN motif that can recruit the adaptor protein Grb2 and in a non-ITAM motif YMNM, which binds to the regulatory subunit of PI 3-kinase. The cytoplasmic tail of CD28 also carries two proline-rich motifs (PXXP) that bind the SH3 domains of Lck and Itk. This association of CD28 with tyrosine kinases, Lck in particular, serves to amplify the activation of T-cell receptor signaling, as all downstream pathways are dependent on the initial recruitment and activity of Lck. Another effect of CD28 phosphorylation is to activate PI 3-kinase to generate PIP_3 (Fig. 7.31). By this mechanism, the co-stimulatory signal induced by CD28 cooperates with the T-cell receptor signal to ensure maximal activation of three of the four T-cell receptor signaling modules described in the second part of the chapter. Specifically, a high concentration of PIP_3 recruits Itk to the membrane, where Lck can phosphorylate it, thereby enhancing PLC-γ activation. PIP_3 also functions to recruit and activate Akt, which promotes cell survival and increased cellular metabolism (see Section 7.17). Finally, PIP_3 recruits Vav, leading to cytoskeletal reorganization (see Section 7.19). Thus, co-stimulatory signaling through CD28 functions to amplify most of the downstream responses to T-cell receptor stimulation (see Fig. 7.31).

ANIMATION 7.3

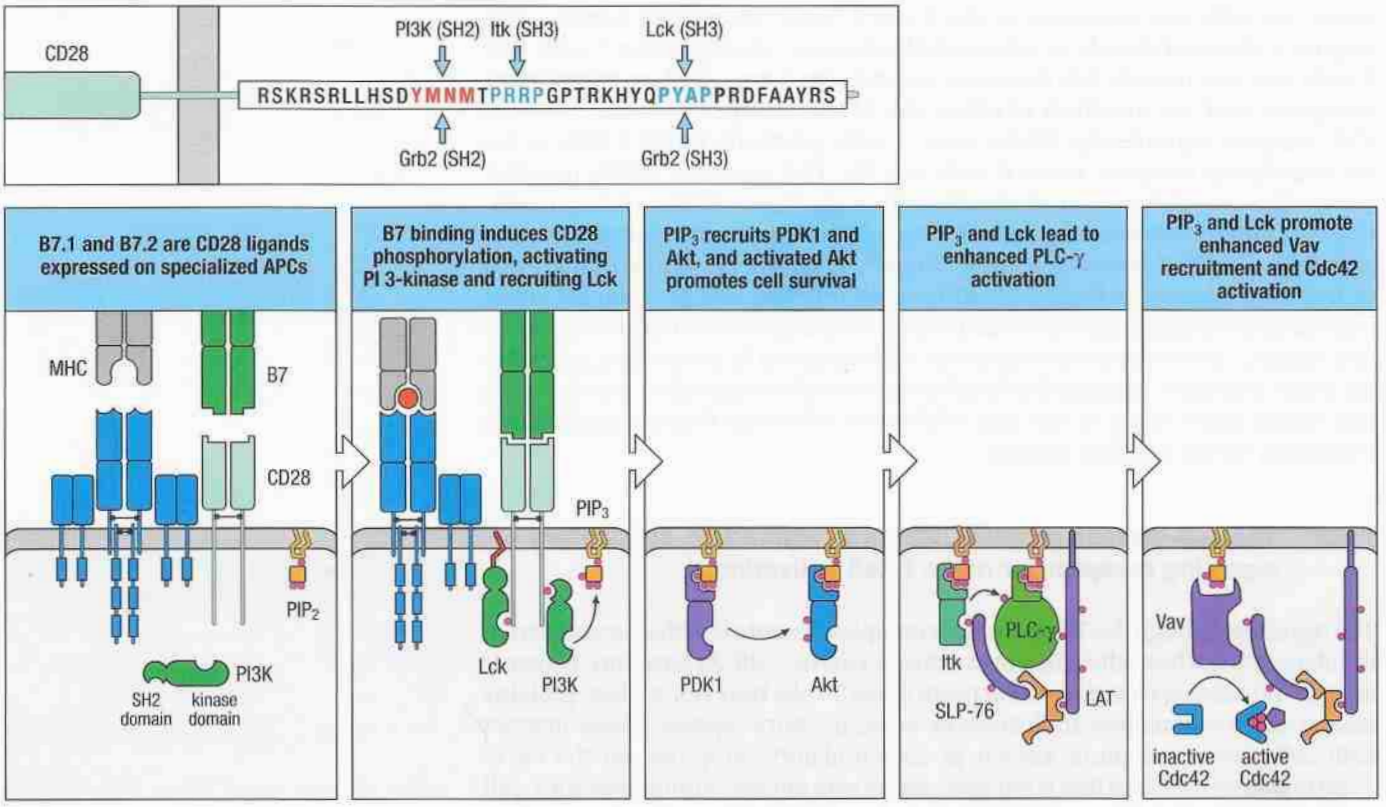

Fig. 7.31 The T-cell co-stimulatory protein CD28 transduces signals that enhance antigen receptor signaling pathways. Upper panel: The amino acid sequence of the CD28 cytoplasmic tail is illustrated, along with the binding sites of several signaling proteins. Red text indicates an SH2 domain binding motif and blue text indicates SH3 domain binding motifs. Proteins known to bind to those motifs are indicated by arrows. Lower panel: The ligands for CD28, namely B7.1 and B7.2, are expressed only on specialized antigen-presenting cells (APCs), such as dendritic cells. Engagement of CD28 together with TCR binding to peptide:MHC leads to CD28 recruitment to the immune synapse, where it functions to enhance TCR signaling by binding to Lck, Grb2, and Itk. CD28 also becomes tyrosine phosphorylated, leading to the binding and activation of PI 3-kinase (PI3K), with subsequent production of PIP_3, which recruits several enzymes via their PH domains, thus bringing them together with their substrates in the membrane. The protein kinase Akt, which becomes phosphorylated by phosphoinositide-dependent protein kinase-1 (PDK1), is activated and enhances cell survival and up-regulates cell metabolism (see Fig. 7.24). Recruitment of the kinase Itk to the membrane is critical for the full activation of PLC-γ (see Fig. 7.17). PIP_3 also recruits Vav, leading to Cdc42 activation and inducing actin polymerization (see Fig. 7.26). All of these pathways are enhanced by CD28 binding to Lck.

7-23 Maximal activation of PLC-γ, which is important for transcription factor activation, requires a co-stimulatory signal induced by CD28.

One important function of co-stimulatory signaling through CD28 is to promote the maximal activation of PLC-γ via the local production of PIP_3. This recruits Itk by its PH domain, enhancing Itk phosphorylation by Lck. Activated Itk is then recruited to the phosphorylated LAT:Gads:SLP-76 complex by its SH2 and SH3 domains binding to SLP-76, where it phosphorylates and activates PLC-γ (see Fig. 7.17). PLC-γ also binds to PIP_3 generated at the membrane, further amplifying its local activation. Activated PLC-γ cleaves PIP_2 to produce the two second messengers DAG and IP_3, ultimately leading to the activation of transcription factors NFAT, AP-1, and NFκB. Thus, the full activation of PLC-γ leading to transcription factor activation requires signals emanating from both the T-cell receptor and CD28.

In T cells, one of the major functions of NFAT, AP-1, and NFκB is to act together to stimulate expression of the gene for the cytokine IL-2, which is essential for promoting T-cell proliferation, survival, and differentiation into effector cells. The promoter for the IL-2 gene contains multiple regulatory elements that must be bound by transcription factors to initiate *IL2* expression. Some control sites are already bound by transcription factors, such as Oct1, that are produced constitutively in lymphocytes, but this is not sufficient to switch on *IL2*. Only when AP-1, NFAT, and NFκB are all activated and are bound to their control sites in the *IL2* promoter is the gene expressed. NFAT and AP-1 bind to the promoter cooperatively and with higher affinity by forming a heterotrimer of NFAT, Jun, and Fos. In addition, CD28 co-stimulation further enhances transcription of *IL2* by increasing NFκB activation. Thus, the *IL2* promoter integrates signals from both the T-cell receptor and CD28 signaling pathways to ensure that IL-2 is produced only in appropriate circumstances (Fig. 7.32). CD28 co-stimulation also induces the phosphorylation of NF-90, an mRNA-binding protein that stabilizes the IL-2 mRNA. Together, the CD28-induced increase in

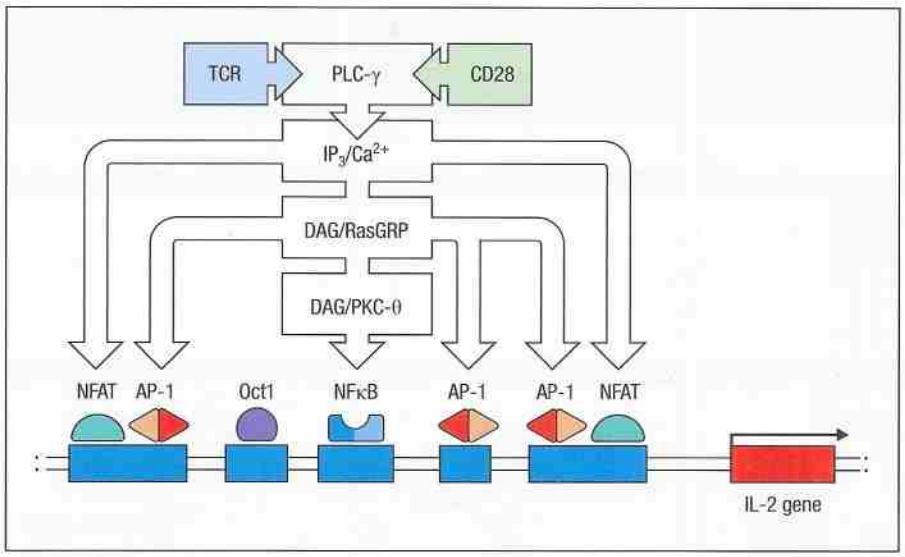

Fig. 7.32 Simplified scheme depicting multiple signaling pathways that converge on the *IL2* promoter. AP-1, NFAT, and NFκB binding to the promoter of the IL-2 gene integrate multiple signaling pathways emanating from the T-cell receptor (TCR) and CD28 into a single output, the production of the cytokine IL-2. The MAPK pathway activates AP-1; calcium activates NFAT; and protein kinase C activates NFκB. All three pathways are required to stimulate transcription of *IL2*. Activation of the gene requires both the binding of NFAT and AP-1 to a specific promoter element, and the additional binding of AP-1 on its own to another site. Oct1 is a transcription factor that is required for transcription of *IL2*. Unlike the other transcription factors, it is constitutively bound to the promoter and is therefore not regulated by T-cell receptor or CD28 signaling.

IL-2 gene transcription plus the increase in IL-2 mRNA stability lead to substantially increased production of IL-2 by activated T cells, in addition to the general amplification of T-cell receptor signals by CD28 co-stimulation.

7-24 TNF receptor superfamily members augment T-cell and B-cell activation.

While naive T- and B-cell activation requires signaling through the antigen receptors on these cells, T-cell receptor and B-cell receptor signaling is not sufficient to activate the cells. For naive T cells, an additional co-stimulatory signal is required and, as discussed earlier (see Sections 7-22 and 7-23), is frequently provided by the CD28 receptor. For naive B cells, the additional activation signal can be contributed by direct interactions between the pathogen and an innate pattern-recognition receptor (PRR), such as a TLR, on the B cell. An alternative second signal for B-cell activation can be provided by interactions between the B cell and a CD4 T follicular helper cell. These two forms of second signals for B-cell activation do not produce equivalent outcomes, however. More effective B-cell activation, leading to the production of all classes of antibodies and to the formation of memory B cells, requires B-cell activation signals that are contributed by CD4 T cells. One component of this mechanism is the production of T-cell cytokines, which bind to and stimulate their receptors on the B-cell surface (see Chapter 10). The second and more essential component provided by the CD4 T cells is the stimulation of CD40 on the B cell by the CD40 ligand expressed on the T cell. The importance of the CD40–CD40-ligand interaction for B-cell responses to protein antigens is highlighted by the discovery that a severe immunodeficiency disease resulting from impaired antibody responses is caused by the absence of CD40 ligand expression on an individual's CD4 T cells. Because of the presence of the CD40L gene on the X chromosome, this disease is generally observed in boys.

CD40 Ligand Deficiency

CD40 is a member of the large TNF receptor superfamily, which consists of more than 20 members. While some members of this family, such as Fas (see Chapter 11), are specialized to induce cell death, the majority of TNF receptor superfamily members, including CD40, primarily activate the NFκB pathway after receptor stimulation, leading to enhanced cell survival (Fig. 7.33). TNF receptor superfamily members signal by a mechanism distinct from that of antigen receptors, as it does not involve the activation of tyrosine kinases. Instead, stimulation of TNF receptors recruits adaptor proteins known as TRAFs (TNF receptor-associated factors). In addition to serving as simple

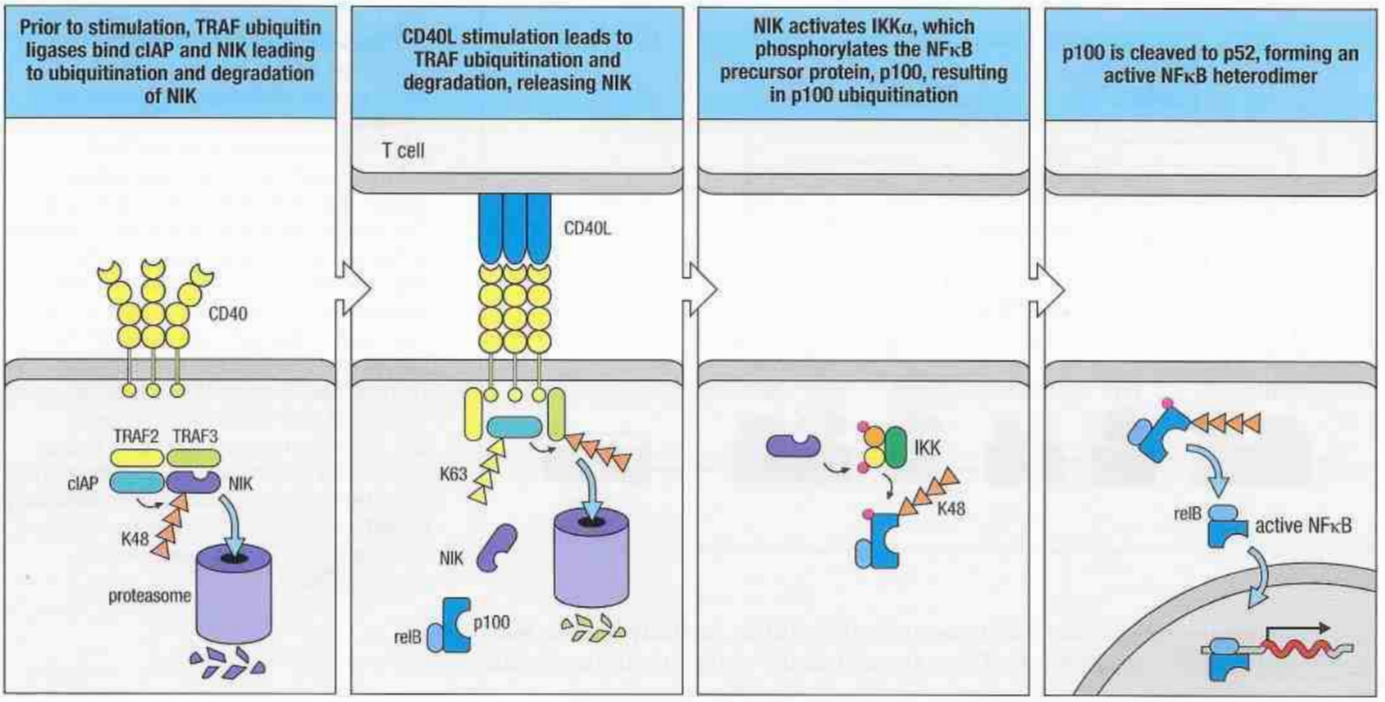

Fig. 7.33 The TNF receptor superfamily member CD40 is an important co-stimulatory molecule on B cells. Several members of the TNF receptor superfamily are expressed on T cells and B cells. A key function of these receptors is the activation of NFκB, which occurs by a pathway distinct from the one initiated by antigen receptor stimulation and is often referred to as the non-canonical NFκB pathway. TNF receptor superfamily members also activate PI 3-kinase signaling pathways (not shown). One important TNF receptor superfamily member on B cells is CD40. Prior to stimulation, TRAF molecules, which are ubiquitin ligases, are associated in a complex with cIAP (another ubiquitin ligase) and the NFκB-inducing kinase (NIK). Under these steady-state conditions, TRAF binding promotes ubiquitination and degradation of NIK. When CD40 is stimulated by binding to CD40L, the aforementioned complex is recruited to the intracellular domain of CD40. TRAF2 catalyzes K63-linked ubiquitination of cIAP, leading to cIAP-mediated K48-linked ubiquitination of TRAF3. This leads to TRAF3 degradation, releasing NIK, and allowing NIK to phosphorylate and activate IκB kinase α (IKKα). IKKα phosphorylates the NFκB precursor protein p100, inducing its cleavage to form the active p52 subunit, which remains bound to relB to form the active NFκB transcription factor.

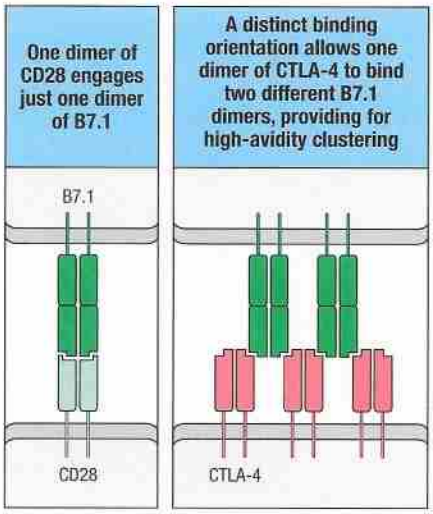
adaptors that promote the assembly of multiprotein complexes, five of the six known TRAFs also function as E3 ubiquitin ligases. This activity contributes to the ability of most TNF receptor superfamily members to activate the NFκB pathway, using a pathway distinct from the one initiated by antigen receptor stimulation and often referred to as the **non-canonical NFκB pathway** (see Fig. 7.33).

CD40 is constitutively expressed on B cells and functions during B-cell activation in response to antigen recognition by the B-cell receptor. Additional TNF receptor superfamily members are also expressed on B cells, and each of them is important in B-cell survival at a particular stage of B-cell maturation, including B cells that have differentiated into antibody-secreting cells or memory cells. Similarly, TNF receptor superfamily members are expressed on T cells, many of which are up-regulated after T-cell activation. These molecules, such as OX40, 4-1BB, CD30, and CD27, contribute important survival signals and function to enhance cellular metabolism at later stages of the T-cell response to infection (see Chapter 11).

7-25 Inhibitory receptors on lymphocytes down-regulate immune responses by interfering with co-stimulatory signaling pathways.

CD28 belongs to a family of structurally related receptors that are expressed by lymphocytes and bind B7 family ligands. Some, such as the receptor ICOS, which is discussed in Chapter 9, act as activating receptors, but others inhibit signaling by the antigen receptors, can stimulate apoptosis, and are important in regulating the immune response. Inhibitory receptors related to CD28 and expressed by T cells include **CTLA-4** (CD152) and **PD-1 (programmed death-1)**, while the **B and T lymphocyte attenuator (BTLA)** is expressed by both T cells and B cells. Of these, CTLA-4 seems to be the most important: mice lacking CTLA-4 die at a young age from an uncontrolled proliferation of T cells in multiple organs, whereas loss of PD-1 or BTLA causes less marked changes that alter the magnitude of responses after lymphocyte activation, rather than causing widespread spontaneous lymphoproliferation. Both CTLA-4 and PD-1 have been targeted for the development of protein-based therapeutics



One dimer of CD28 engages just one dimer of B7.1
A distinct binding orientation allows one dimer of CTLA-4 to bind two different B7.1 dimers, providing for high-avidity clustering
B7.1
CD28
CTLA-4

Fig. 7.34 CTLA-4 has a higher affinity for B7 than does CD28 and engages it in a multivalent orientation. CD28 and CTLA-4 are both expressed as dimers on the cell surface and both bind to two ligands of B7.1, which is a dimer, and B7.2, which is not. However, the orientations of the B7 binding of CD28 and of CTLA-4 differ in a way that contributes to the inhibitory action of CTLA-4. One dimer of CD28 engages just one dimer of B7.1. But one dimer of CTLA-4 binds in such a way that two different dimers of B7.1 are engaged at once, allowing these molecules to cluster into complexes of high avidity. This, together with the higher affinity of CTLA-4 for B7 molecules, may give CTLA-4 an advantage in competing for available B7 molecules on an antigen-presenting cell, providing one mechanism by which it could block the co-stimulation of T cells.

that block the activities of these receptors. The goal of these therapeutics is to enhance T-cell responses by inhibiting these inhibitory receptors, a therapeutic strategy referred to as **checkpoint blockade** (see Chapter 16). Recent clinical data demonstrate that both CTLA-4 and PD-1 blockade have efficacy in the treatment of some cancers by enhancing the patient's own antitumor T-cell responses.

CTLA-4 is induced on activated T cells and binds to the same co-stimulatory ligands (B7.1 and B7.2) as CD28, but CTLA-4 engagement inhibits T-cell activation rather than enhancing it (Fig. 7.34). The function of CTLA-4 is controlled largely by regulation of its surface expression. Initially, CTLA-4 resides on intracellular membranes but moves to the cell surface after T-cell receptor signaling. The surface expression of CTLA-4 is controlled by phosphorylation of the tyrosine-based motif GVYYVKM in its cytoplasmic tail. When this motif is not phosphorylated, it is able to bind to the clathrin adaptor molecule AP-2, which removes CTLA-4 from the surface. When it is phosphorylated, this motif cannot bind AP-2, and CTLA-4 remains in the membrane, where it can bind B7 molecules on antigen-presenting cells.

CTLA-4 has a higher affinity for its B7 ligands than does CD28, and, apparently of importance for its inhibitory function, it engages B7 molecules in a different orientation. CD28, CTLA-4, and B7.1 are all expressed as homodimers. A CD28 dimer engages one B7.1 dimer in a direct one-to-one correspondence, but a CTLA-4 dimer engages two different B7.1 dimers in a configuration that allows for extended cross-linkages that confer high avidity to the interaction (see Fig. 7.34). The precise mechanism of CTLA-4–mediated inhibition of T cells is still unclear. Initial evidence favored a role for inhibitory phosphatases recruited to the CTLA-4 cytoplasmic tail, a mechanism used by other inhibitory receptors described in the next section. Additional evidence also indicates that inhibition mediated by CTLA-4 may, in part, result from blocking the binding of CD28 to B7 or, in some cases, by stripping B7 molecules from the antigen-presenting cell membrane, thereby reducing CD28-dependent co-stimulation.

7-26 Inhibitory receptors on lymphocytes down-regulate immune responses by recruiting protein or lipid phosphatases.

Some other receptors that can inhibit lymphocyte activation possess motifs in their cytoplasmic regions that are known as the **immunoreceptor tyrosine-based inhibition motif (ITIM**; consensus sequence [I/V]XYXX[L/I], where X is any amino acid) (Fig. 7.35) or the related **immunoreceptor tyrosine-based switch motif (ITSM**; consensus sequence TXYXX[V/I]). When the tyrosine in an ITIM or ITSM is phosphorylated, it can recruit inhibitory phosphatases, **SHP (SH2-containing phosphatase)** and **SHIP (SH2-containing**

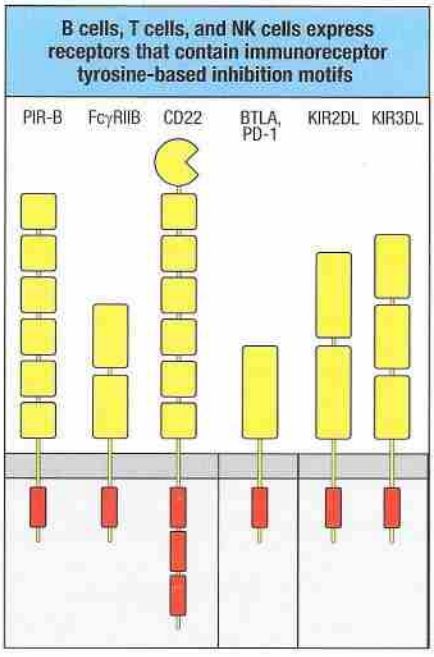


Fig. 7.35 Some lymphocyte cell-surface receptors contain motifs involved in down-regulating activation. Several receptors that transduce signals inhibiting lymphocyte or NK-cell activation contain one or more ITIMs (immunoreceptor tyrosine-based inhibition motifs) in their cytoplasmic tails (red rectangles). ITIMs bind to various phosphatases that, when activated, inhibit signals derived from ITAM-containing receptors.

inositol phosphatase), via their SH2 domains. SHP is a protein tyrosine phosphatase that removes phosphate groups added by tyrosine kinases to a variety of proteins. SHIP is an inositol phosphatase that removes the phosphate from PIP_3 to generate PIP_2, thus reversing the recruitment of proteins such as Tec kinases, PLC-γ, and Akt to the cell membrane and inhibiting signaling.

One ITIM-containing receptor is PD-1 (see Fig. 7.35), which is induced transiently on activated T cells, B cells, and myeloid cells. It can bind to the B7 family ligands **PD-L1 (programmed death ligand-1; B7-H1)** and **PD-L2 (programmed death ligand-2; B7-DC)**. Despite their names, we now understand that these proteins function as ligands for the inhibitory receptor PD-1, rather than acting directly in cell death. PD-L1 is constitutively expressed by a wide variety of cells, whereas PD-L2 expression is induced on antigen-presenting cells during inflammation. Because PD-L1 is expressed constitutively, regulation of PD-1 expression could have a critical role in controlling T-cell responses. For example, signaling by pro-inflammatory cytokines can repress PD-1, a mechanism that might contribute to enhancing the T-cell response. Mice lacking PD-1 gradually develop autoimmunity, presumably because of an inability to regulate T-cell activation. In chronic infections, the widespread expression of PD-1 reduces the effector activity of T cells; this helps to limit potential damage to bystander cells, but at the expense of pathogen clearance. Protein-based therapeutics that inhibit PD-1 binding to its ligands have also provided clinical benefit in checkpoint blockade strategies used for treating some cancers (see Section 16-17). Although it is not known whether PD-1 blockade is acting to directly enhance T-cell recognition of infected cells and tumor cells in all disease models, recent evidence indicates that antiviral or antitumor T cells that respond in individuals treated with PD-1 blockade require CD28. A potential function of PD-1 on T cells in inhibiting CD28 co-stimulatory signaling is also supported by direct biochemical evidence that PD-1 recruits the tyrosine phosphatase SHP2 and that this phosphatase acts to efficiently dephosphorylate the cytoplasmic tail of CD28, thereby curtailing the overall activation signal.

BTLA contains an ITIM and an ITSM and is expressed on activated T cells and B cells, as well as on some cells of the innate immune system. Unlike other CD28 family members, however, BTLA does not interact with B7 ligands but binds a member of the TNF receptor family called the **herpes virus entry molecule (HVEM)**; this receptor is highly expressed on resting T cells and immature dendritic cells. When BTLA and HVEM are coexpressed on the same cell, BTLA utilizes a second mechanism that further inhibits lymphocyte activation. In this configuration, BLTA binds to HVEM and prevents HVEM from binding to alternative partners that would stimulate NFκB-dependent pro-survival signaling pathways downstream of HVEM. Alternatively, when BTLA and HVEM are expressed on different cells, the interaction of these two receptors functions to stimulate the positive pro-survival signal in the HVEM-expressing cell.

Other receptors on B cells and T cells also contain ITIMs and can inhibit cell activation when ligated along with the antigen receptors. One example is the receptor **FcγRIIB** on B cells, which binds the Fc region of IgG antibodies and is the only Fc receptor expressed on B cells. As a result, antigens present as immune complexes containing IgG antibodies are poor at activating naive B cells because of the co-engagement of the B-cell receptor with this inhibitory Fc receptor. This mechanism provides B cells with a means of monitoring the levels of antigen-specific antibodies in their environment. The inhibitory signal transduced by FcγRIIB results from phosphorylation of the ITIM in the receptor cytoplasmic tail, leading to recruitment of SHIP into a complex with the B-cell receptor to block the actions of PI 3-kinase (Fig. 7.36). The importance of this pathway is illustrated by the fact that FcγRIIB deficiencies are associated with B-cell hyperreactivity in humans with and mouse models of autoimmunity, such as systemic lupus erythematosus. Another inhibitory receptor on

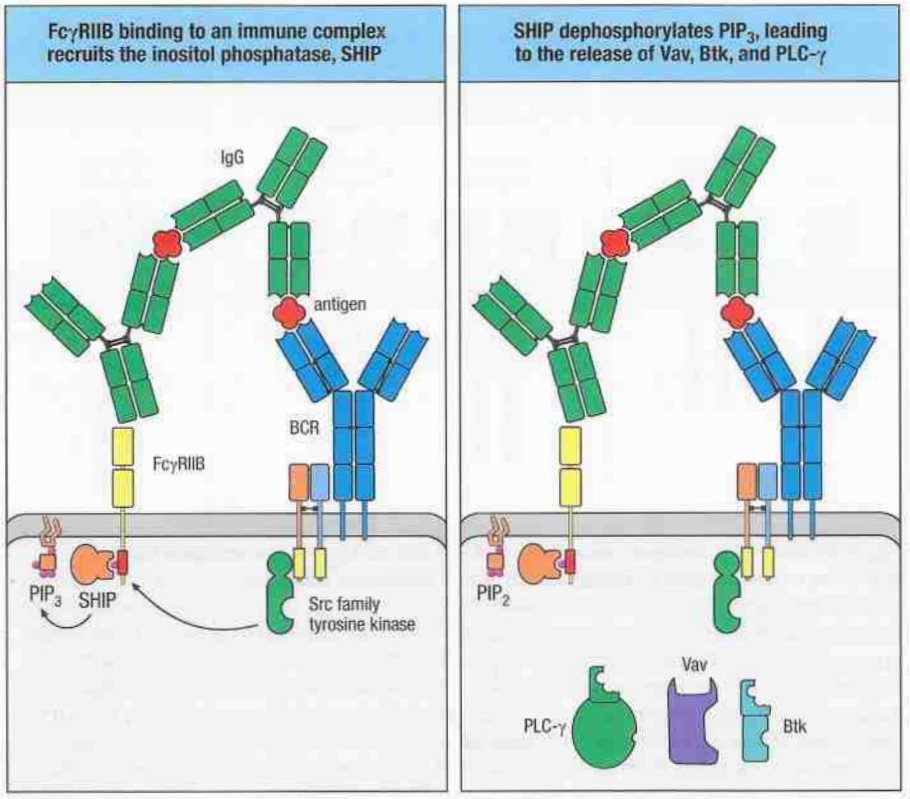

Fig. 7.36 The ITIM-containing Fc receptor inhibits B-cell receptor signaling by recruiting the inositol phosphatase SHIP. When the B-cell receptor binds an antigen that is already present in immune complexes with IgG, the ITIM-containing Fc receptor FcγRIIB is engaged at the same time as the B-cell receptor. The Src family kinase present at the B-cell receptor (BCR) phosphorylates the ITIM motif of FcγRIIB, which then recruits the SH2-containing inositol phosphatase, SHIP. SHIP dephosphorylates PIP_3 in the plasma membrane, generating PIP_2. PH domain–containing enzymes, such as Vav, Btk, and PLC-γ, depend on their PH domain binding to PIP_3 for their stable recruitment to the activated B-cell receptor complex. The loss of PIP_3 terminates the recruitment of these enzymes and inhibits B-cell receptor signaling.

B cells is **CD22**, a transmembrane protein that recognizes sialic acid–modified glycoproteins commonly found on mammalian cells but rarely on microbial pathogen surfaces. CD22 contains an ITIM that interacts with SHP, a phosphatase that can dephosphorylate adaptors such as SLP-65 that associate with CD22, thereby inhibiting signaling from the B-cell receptor.

The ITIM motif is also an important motif in signaling by receptors on NK cells that inhibit the killer activity of these cells (see Section 3-26). These inhibitory receptors recognize MHC class I molecules and inhibit the release of the NK cell's cytotoxic granules when the NK cell recognizes a healthy uninfected cell. In NK cells, ITIM-containing receptors play an important role in setting the threshold for NK-cell activation by balancing positive signals from ITAM-containing receptors.

7-27 Knowledge of lymphocyte receptor signaling pathways can be exploited to engineer chimeric antigen receptors.

In 1991, a seminal paper reported that a chimeric receptor formed by fusing the extracellular and transmembrane portions of the CD8 protein with the cytoplasmic tail of the T-cell receptor ζ chain was sufficient to transduce activation signals that mimicked those of the intact T-cell receptor complex (Fig. 7.37). More than 20 years later, in 2014, the US Food and Drug Administration licensed the first use of this concept, now called chimeric antigen receptor (CAR) T-cell therapy (CAR-T therapy), for the treatment of patients with B-cell lymphomas. This treatment is implemented by isolating and expanding the patient's T cells in culture and transducing them with a gene encoding the chimeric receptor, as discussed further in Chapter 16. For patients with B-cell lymphoma, the chimeric antigen receptor is composed of an antibody fragment that binds to CD19, a surface receptor expressed on the lymphoma tumor cells. This anti-CD19 antibody domain forms the extracellular portion of the chimeric receptor, and it is fused to a transmembrane domain and cytoplasmic tail containing multiple signaling domains. The patient's

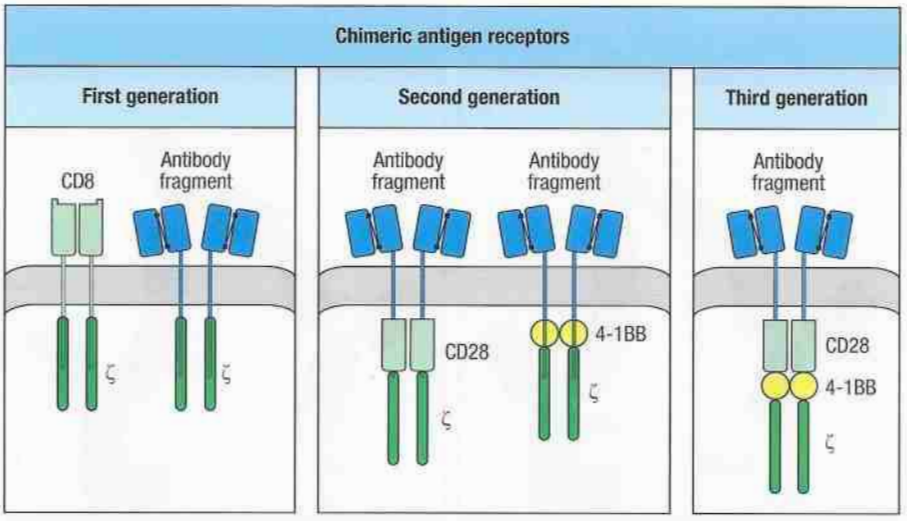

Fig. 7.37 Chimeric antigen receptors (CARs) link extracellular antigen-binding domains of antibodies to intracellular T-cell signaling domains. Initial studies from A. Weiss demonstrated that a simple chimeric antigen receptor, composed of the extracellular domain of CD8 and the intracellular domain of TCRζ, was sufficient to activate T cells when aggregated into multimers by anti-CD8 antibodies. This study led to the development of a chimeric receptor in which the extracellular CD8 domain was replaced by an antibody fragment. These chimeric receptors are often referred to as first-generation CAR. The next phase of this approach (second-generation CAR) included signaling domains from a co-stimulatory receptor, such as CD28 or 4-1BB. Third-generation CAR includes all three signaling domains: one from TCRζ, one from a CD28 family member, and one from a TNF receptor family member.

T cells, now expressing the chimeric antigen receptor, are then infused back into the patient. The CD19 antibody domain directs the CAR-T cells to bind to the tumor cells, and this interaction triggers signaling via the attached signaling domains. When expressed in cytotoxic T cells, CD19 recognition by the chimeric receptor leads to killing of the tumor cells. For other tumor types, the extracellular domain consists of an antibody fragment that recognizes a surface antigen on the relevant tumor cells.

Several generations of chimeric antigen receptors have been developed and tested in patients. Initial versions included sequences from the T-cell receptor ζ chain as the sole intracellular signaling domain. CAR-T cells expressing this chimeric receptor showed little clinical benefit, predominantly because of the failure of the infused CAR-T cells to expand and persist in patients. Improved efficacy was observed with second-generation chimeric receptors that included two signaling domains in the intracellular tail, one derived from the T-cell receptor ζ chain and a second derived from a co-stimulatory receptor, such as CD28 or the TNF receptor family member 4-1BB. These second-generation approaches provided substantial clinical benefit in a subset of patients. Third-generation chimeric receptors provide even better clinical effects. These receptors include three signaling domains, one derived from the T-cell receptor ζ chain, one from a CD28 family receptor (CD28 or ICOS), and one from a TNF receptor family member, most commonly 4-1BB (see Fig. 7.37). These recent advances in cancer therapy, using patients' T cells and modifying them to target tumor cells for killing, highlight the importance of studies aimed at understanding lymphocyte receptor signaling pathways.

Summary.

Signaling through the antigen receptors on T cells and B cells is essential for the activation of these cells. However, for naive T and B cells, the signal through the T-cell receptor or B-cell receptor is not sufficient to initiate a

response. In addition to the antigen receptor signals, these cells require signals through accessory receptors that serve to monitor the environment of the cell to ensure the presence of an infection. An important secondary signaling system in naive T cells is provided by the CD28 family of co-stimulatory proteins, which bind members of the B7 family of proteins. Activating members of the CD28 family provide co-stimulatory signals that amplify the signal from the T-cell receptor and are important in ensuring the activation of naive T cells by the appropriate target cell. In B cells, these secondary signals are provided by members of the TNF receptor superfamily, such as CD40. Inhibitory members of the CD28 and other receptor families function to attenuate or completely block signaling by activating receptors. The regulated expression of activating and inhibitory receptors and their ligands generates a sophisticated level of control of immune responses that is an ongoing area of active investigation.

Summary to Chapter 7.

Signaling by cell-surface receptors of many different sorts is crucial to the ability of the immune system to respond appropriately to foreign pathogens. The importance of these signaling pathways is demonstrated by the many diseases that are due to aberrant signaling, including both immunodeficiency diseases and autoimmune diseases. Common features of many signaling pathways are the generation of second messengers such as calcium and phosphoinositides and the activation of both serine/threonine and tyrosine kinases. An important concept in the initiation of signaling pathways by receptor proteins is the recruitment of signaling proteins to the plasma membrane and the assembly of multiprotein signaling complexes. In many cases, signal transduction leads to the activation of transcription factors that lead directly or indirectly to the proliferation, differentiation, and effector function of activated lymphocytes. Signal transduction also serves to mediate changes in the cytoskeleton that are important for cell functions such as migration and shape changes. These steps of the T-cell and B-cell receptor signaling pathways are summarized in Fig. 7.30.

While we are beginning to understand the basic circuitry of signal transduction pathways, it is important to keep in mind that we do not yet understand why these pathways are so complex. One reason might be that the signaling pathways have roles in properties such as amplification, robustness, diversity, and efficiency of signaling responses. An important goal for the future will be to understand how the design of each signaling pathway contributes to the particular quality and sensitivity needed for specific signaling responses. The application of this knowledge to designing immune-based therapies for diseases such as cancer highlights the importance of these investigations.

Discussion Questions

7.1 Explain the function of adaptor proteins in signaling pathways, and name two protein domains often found in adaptor proteins.

7.2 Describe two mechanisms by which protein phosphorylation can alter the function of an enzyme important in a signaling pathway.

7.3 Because antigen receptors are present at the lymphocyte plasma membrane, a key step in antigen receptor signaling is the recruitment of signaling proteins to the membrane. List three mechanisms by which signaling proteins can be recruited to the plasma membrane.

7.4 There are two major mechanisms for terminating signaling pathways. Describe these two mechanisms, and indicate the most important difference between these two mechanisms.

7.5 Studies have shown that the ITAM sequences in the T-cell receptor signaling chains (for example, the T-cell receptor ζ chain) are constitutively phosphorylated and have ZAP-70 bound in nonstimulated T cells. Yet this does not lead to the constitutive activation of downstream signaling pathways. Explain why constitutive ITAM phosphorylation and ZAP-70 binding does not result in constitutive T-cell receptor signaling activation.

7.6 T-cell activation can be initiated by treatment of T cells with two pharmacological agents: phorbol myristate acetate (PMA) and ionomycin. Which natural products generated by T-cell receptor signaling are these pharmacological agents mimicking? Name three T-cell proteins that would be dispensable for T-cell activation when cells are treated with PMA and ionomycin.

7.7 Many T-cell receptor–stimulated signaling events involve the phosphorylation of enzymes, adaptor proteins, or transcription factors in T cells. Name an example of a protein that is activated by protein dephosphorylation. Also, name an example of a protein for which T-cell receptor stimulation induces phosphorylation of that protein, leading to inactivation of the protein.

7.8 The PI 3-kinase pathway activates enzymes that control many metabolic and biosynthetic pathways in activated lymphocytes. A number of these PI 3-kinase–dependent responses can be inhibited by the immunosuppressive drug rapamycin. List three fundamental features of cells (for example, total nuclear DNA content, total RNA content, number of mitochondria) that would be altered by treating activated T or B cells with rapamycin.

7.9 The immune synapse is an organized site of interaction between T cells and antigen-presenting cells or target cells. The formation of the immune synapse requires T-cell receptor signaling. Would inhibitors of RNA synthesis block the formation of the immune synapse after T-cell receptor stimulation? Would inhibitors of protein tyrosine kinases block this process? How does the activation of a Rho family GTPase contribute to the formation of the immune synapse?

7.10 How is B-cell activation mediated by B-cell receptor signaling enhanced by the innate immune response; for example, when the antigen recognized by the B-cell receptor is on the surface of a bacterium?

7.11 CD28 is known as a co-stimulatory receptor. When engaged by CD80 or CD86, CD28 functions to amplify most of the downstream responses to T-cell receptor stimulation. Yet, stimulation of CD28 in the absence of T-cell receptor stimulation is unable to activate a T cell. Which key step(s) in T-cell receptor signaling is CD28 unable to mediate on its own?

7.12 CD40 is an important receptor on B cells and contributes signals that are essential for B-cell activation leading to the production of all classes of antibodies and to the formation of memory B cells. Unlike many signaling receptors on B cells and T cells, CD40 signaling does not require the activation of protein tyrosine kinases. How does CD40 signaling lead to the activation of the transcription factor NFκB?

7.13 In addition to co-stimulatory receptors, lymphocytes express a variety of inhibitory receptors. Why might the immune system have evolved to include inhibitory receptors, and what might occur if these receptors did not exist?

The Development of B and T Lymphocytes

8

IN THIS CHAPTER

Development of B lymphocytes.

Development of T lymphocytes.

Positive and negative selection of T cells.

After birth, the production of new lymphocytes, or **lymphopoiesis**, takes place in specialized lymphoid tissues—the **central (or primary) lymphoid tissues**—which are the bone marrow for most B cells and the thymus for most T cells. Precursors for both populations originate in the bone marrow, but whereas B cells complete most of their development there, the precursors of most T cells migrate to the thymus, where they develop into mature T cells. A major goal of lymphopoiesis is to generate a diverse repertoire of B-cell receptors and T-cell receptors on circulating B and T cells, respectively, thereby enabling an individual to make adaptive immune responses against the wide range of pathogens encountered during a lifetime. In the fetus and the juvenile, the central lymphoid tissues are the sources of large numbers of new lymphocytes, which migrate to populate the **peripheral (or secondary) lymphoid tissues** such as lymph nodes, spleen, and mucosal lymphoid tissue, a process that generally slows with age. This chapter will focus on the development of T cells and B cells from their uncommitted progenitors, with an emphasis on the major populations of $CD4^+$ and $CD8^+$ T cells and B cells. The development of additional subsets of T cells and B cells, such as invariant NKT (iNKT) cells, T_{reg} cells, $\gamma\delta$ TCR^+ T cells, B-1 B cells, and marginal zone B cells, will be briefly discussed.

The structure of the antigen receptor genes expressed by B cells and T cells, and the mechanisms by which a complete antigen receptor is assembled, were described in Chapters 4 and 5. Once an antigen receptor has been formed, rigorous testing is required to select lymphocytes that carry useful antigen receptors; that is, antigen receptors that can recognize a wide spectrum of pathogens and yet will not react against an individual's own cells. Given the incredible diversity of receptors the rearrangement process can generate, it is important that those lymphocytes that mature are likely to be useful in recognizing and responding to foreign antigens, especially as an individual can express only a small fraction of the total possible receptor repertoire in his or her lifetime. We describe how the specificity and affinity of the receptor for self ligands are tested to determine whether the immature lymphocyte will either survive and join the mature repertoire or die. In general, it seems that developing lymphocytes whose receptors interact weakly with self antigens or that bind self antigens in a particular way receive a signal that enables them to survive. This process, known as **positive selection**, is particularly critical in the development of $\alpha\beta$ T cells (which recognize composite antigens consisting of peptides bound to MHC molecules) because it ensures that an individual's T cells will be able to respond to peptides bound to one's own MHC molecules.

In contrast, lymphocytes with strongly self-reactive receptors must be eliminated to prevent autoimmune reactions; this process of **negative selection** is one of the ways in which the immune system is made self-tolerant. The default fate of developing lymphocytes, in the absence of any signal being received from the receptor, is death by apoptosis, and as we will see, the vast majority of developing lymphocytes die before emerging from the central lymphoid organs or before completing maturation in the peripheral lymphoid organs.

In this chapter we describe the different stages of the development of B cells and T cells in mice and humans from the uncommitted stem cell in the bone marrow up to the mature, functionally specialized lymphocyte with a unique antigen receptor ready to respond to a foreign antigen. The final stages in the life history of a mature lymphocyte, in which an encounter with its antigen activates it to become an effector or memory lymphocyte, are discussed in Chapters 9–11. We now know that the B-and T-cell development that predominates during late fetal life and after birth is distinct from waves of lymphocyte development that take place earlier in fetal ontogeny. These earlier waves originate from stem cells found in the fetal liver and in even more primitive hematopoietic tissues in the developing embryo. Unlike the lymphocytes that develop from bone marrow stem cells, B and T cells that develop from these early fetal progenitors generally populate mucosal and epithelial tissues and function in innate immune responses. In the adult, these subsets of lymphocytes are minority populations in peripheral lymphoid tissues.

This chapter will focus on B and T cells that develop from bone marrow stem cells and that compose the cells of the adaptive immune response (see Figs 1.7 and 1.20). These lymphocyte subsets, along with innate lymphoid cells (ILCs), are derived from lymphoid progenitor cells, which themselves derive from the multipotent **hematopoietic stem cells (HSCs)** that give rise to all blood cells (see Fig. 1.3). Development from precursors into cells that are committed to becoming B cells or T cells occurs over several stages of differentiation, as cells gradually acquire lineage-specific properties and lose properties of immature cells. In the case of lymphocyte development, cells become committed first to the lymphoid lineage, as opposed to the myeloid, and then to either the B-cell or the T-cell lineage (Fig. 8.1).

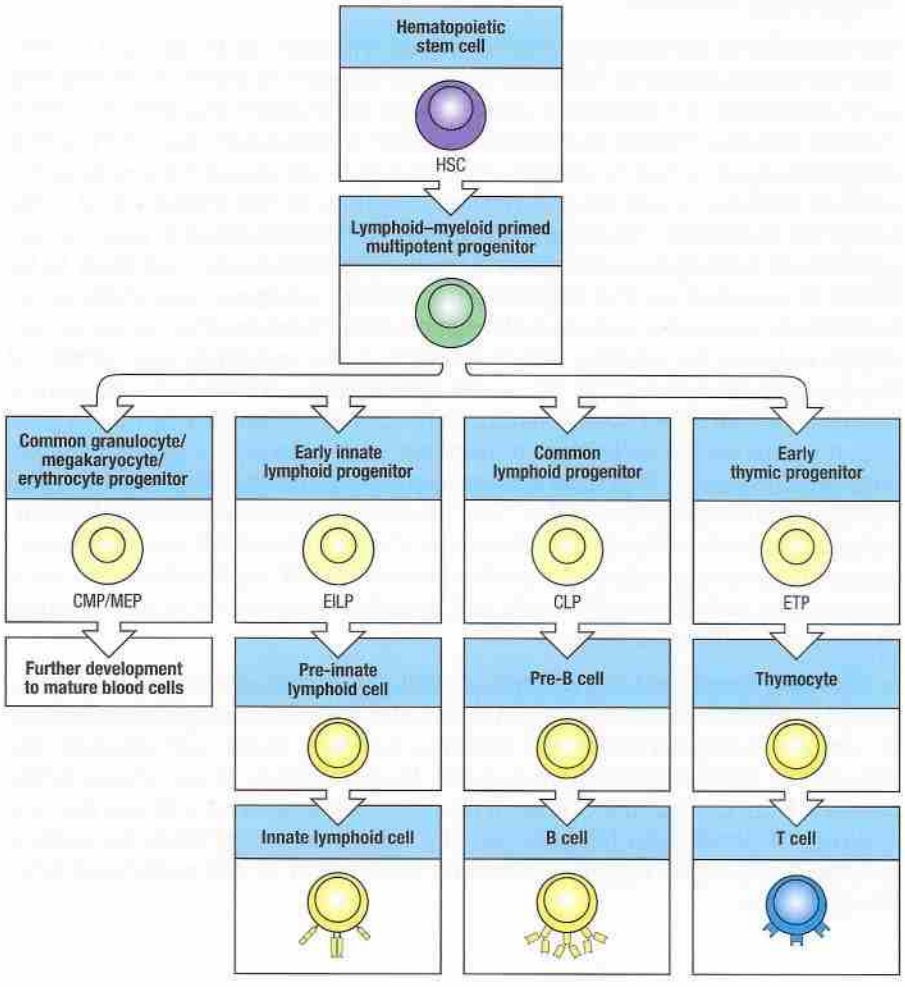

Fig. 8.1 A multipotent hematopoietic stem cell generates all the cells of the immune system. In the bone marrow or other hematopoietic sites, the multipotent stem cell gives rise to cells with progressively more limited potential. A simplified progression is shown here. The lymphoid–myeloid primed multipotent progenitor (LMPP), for example, has lost its stem-cell properties. The first differentiated branch leads to cells with myeloid and erythroid potential (common myeloid progenitors, CMPs; and megakaryocyte–erythroid progenitors, MEPs), and the other differentiated branches lead to several lymphoid progenitors, including early innate lymphoid progenitors (EILPs), common lymphoid progenitors (CLPs), and early thymic progenitors (ETPs). The myeloid–erythroid branch gives rise to all nonlymphoid cellular blood elements, including circulating monocytes and granulocytes, as well as the macrophages and dendritic cells that reside in tissues and peripheral lymphoid organs (not shown). The branches of lymphoid progenitors are heterogeneous, and each progenitor is biased to give rise to different subsets of lymphoid cells after successive stages of differentiation in either the bone marrow or thymus. EILPs generally produce innate lymphoid cells, including NK cells, innate lymphoid cells (groups 1–3 ILCs), and lymphoid tissue inducer (LTi) cells. CLPs are biased toward producing B cells, and ETPs migrate to the thymus and preferentially produce T cells. There is considerable plasticity in these pathways, in that in certain circumstances progenitor cells may switch their commitment.

Development of B lymphocytes.

The main phases of a B lymphocyte's life history are shown in Fig. 8.2. The stages of both B-cell and T-cell development are defined mainly by the successive steps in the assembly and expression of functional antigen-receptor genes. At each step of lymphocyte development, the progress of gene rearrangement is monitored; the major recurring theme is that successful gene rearrangement leads to the production of a protein chain that serves as a signal for the cell to progress to the next stage. We will see that a developing B cell is presented with opportunities for multiple rearrangements that increase the likelihood of expressing a functional antigen receptor, but there are also checkpoints that reinforce the requirement that each B cell express just one receptor specificity. We will start by looking at how the earliest recognizable cells of the B-cell lineage develop from the multipotent hematopoietic stem cells in the bone marrow, and at what point the B-cell and T-cell lineages diverge.

8-1 Lymphocytes derive from hematopoietic stem cells in the bone marrow.

The specialized microenvironment of the bone marrow provides signals both for the development of lymphocyte progenitors from hematopoietic stem cells and for the subsequent differentiation of B cells. Such signals act on the developing lymphocytes to switch-on key genes that direct the developmental program and are produced by the network of specialized nonlymphoid connective tissue **stromal cells** that are in intimate contact with the developing lymphocytes (Fig. 8.3). The contribution of the stromal cells is twofold. First, they form specific adhesive contacts with the developing lymphocytes by interactions between cell-adhesion molecules and their ligands. Second, they provide soluble and membrane-bound cytokines and chemokines that control lymphocyte differentiation and proliferation.

memory cell
Antibody secretion and memory cells in bone marrow and lymphoid tissue

Fig. 8.2 B cells develop in the bone marrow and migrate to peripheral lymphoid organs, where they can be activated by antigens. In the first phase of development, progenitor B cells in the bone marrow rearrange their immunoglobulin genes. This phase is independent of antigen but is dependent on interactions with bone marrow stromal cells (first panels). It ends in an immature B cell that carries an antigen receptor in the form of cell-surface IgM (second panels), and in the second phase the immature B cell can now interact with antigens in its environment. Immature B cells that are strongly stimulated by antigen at this stage are removed from the repertoire by receptor editing or by apoptosis, thus removing many self-reactive B cells from the repertoire. In the third phase of development, the surviving immature B cells emerge into the periphery and mature to express IgD as well as IgM. They can now be activated by encounter with their specific foreign antigen in a peripheral lymphoid organ (third panels). Activated B cells proliferate and differentiate into antibody-secreting plasma cells and long-lived memory cells (fourth panels).

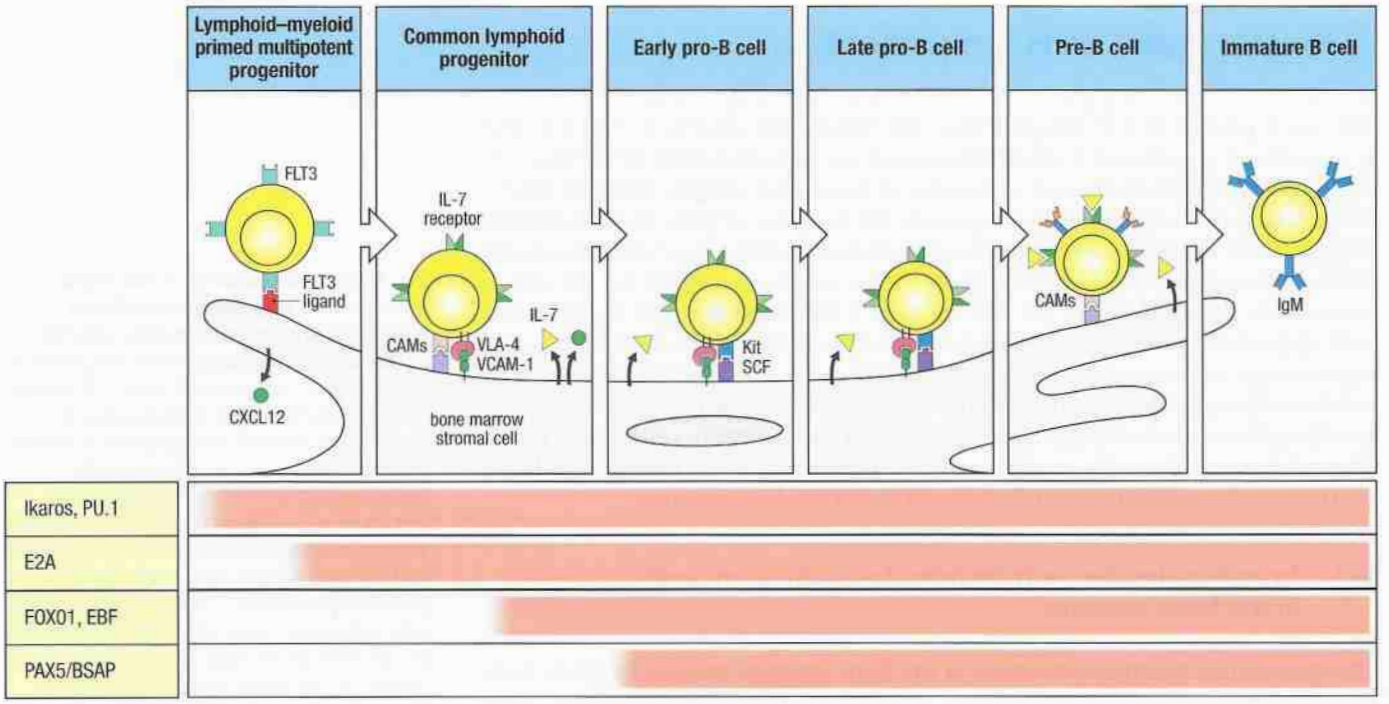

Fig. 8.3 The early stages of B-cell development are dependent on bone marrow stromal cells. Interaction of B-cell progenitors with bone marrow stromal cells is required for development to the immature B-cell stage. The designations pro-B cell and pre-B cell refer to defined phases of B-cell development, as described in Fig. 8.4. Lymphoid–myeloid primed multipotent progenitor cells express the receptor tyrosine kinase FLT3, which binds to its ligand on stromal cells. Signaling through FLT3 is required for differentiation to the next stage, the common lymphoid progenitor. The chemokine CXCL12 (SDF-1) acts to retain stem cells and lymphoid progenitors at appropriate stromal cells in the bone marrow. The receptor for interleukin-7 (IL-7) is present at this stage, and IL-7 produced by stromal cells is required for the development of B-lineage cells. Progenitor cells bind to the adhesion molecule VCAM-1 on stromal cells through the integrin VLA-4 and also interact through other cell-adhesion molecules (CAMs). The adhesive interactions promote the binding of the receptor tyrosine kinase Kit (CD117) on the surface of the pro-B cell to stem-cell factor (SCF) on the stromal cell, which activates the kinase and induces the proliferation of B-cell progenitors. The actions of the listed transcription factors in B-cell development are discussed in the text. The pink horizontal bands denote the expression of particular proteins at the indicated stages of development.

The hematopoietic stem cells first differentiate into **lymphoid–myeloid primed multipotent progenitors (LMPPs)**, which can produce both lymphoid and myeloid cells but are no longer self-renewing stem cells. LMPPs express a cell-surface receptor tyrosine kinase known as FLT3, which binds the membrane-bound FLT3 ligand on stromal cells. Additionally, LMPPs express transcription factors and receptors that are required for the development of multiple hematopoietic lineages, such as the transcription factors PU.1 and Ikaros, and the receptor tyrosine kinase Kit. In the next stage, LMPPs produce three major subsets of progenitor cells that give rise to all the lymphocyte lineages (see Fig. 8.1). One progenitor cell, known as the **early innate lymphoid progenitor (EILP)**, produces the ILC subsets, ILC1 (including NK cells), ILC2, and ILC3 cells. A second progenitor cell is known as the **common lymphoid progenitor (CLP)** and is distinguished from LMPP by high levels of expression of the IL-7Rα chain. A third progenitor cell is the **early thymic progenitor (ETP)**, which is the major subset of T-cell progenitors; these cells express the Notch protein, a cell-surface receptor that transduces signals essential for T-cell lineage commitment. Progenitor cell transfer and lineage repopulation experiments have shown that the CLP population is actually heterogeneous; while some CLPs have broad potential to generate B cells, T cells, and NK cells, the majority of CLPs are biased toward the B-cell lineage. B cell–committed CLPs give rise to **pro-B cells** (see Fig. 8.3).

The production of lymphocyte progenitors from the LMPP is accompanied by expression of the receptor for interleukin-7 (IL-7). The cytokine IL-7, secreted by bone marrow stromal cells, is essential for the growth and survival of innate lymphoid cells, the majority of developing T cells, and in mice (but possibly not in humans) of developing B cells. The IL-7 receptor is composed of two polypeptides, the IL-7 receptor α chain and the common cytokine receptor γ chain (γ-c), so called because it is also a subunit of five additional cytokine receptors. This family of cytokine receptors includes the receptors for IL-2, IL-4, IL-9, IL-15, and IL-21, in addition to IL-7. These receptors also share the tyrosine kinase Jak3, a signaling protein that binds exclusively to γ-c and is required for productive signaling by each of these receptors. Because of the importance of IL-7 for murine lymphocyte development, mice with a genetic deficiency in IL-7, IL-7 receptor α, γ-c, or Jak3 all exhibit a severe block in B-cell and innate lymphoid cell development and have greatly reduced numbers of T cells.

X-linked Severe Combined Immune Deficiency

8-2 Commitment to B cell, T cell, or innate lymphoid cell lineages is regulated by distinct networks of transcription factors.

B-cell development is initiated by the activation of the helix–loop–helix transcription factor E2A (see Fig. 8.3). In CLPs, E2A induces the expression of a second transcription factor FOXO1, which together with E2A promotes the expression of the early B-cell factor (EBF). EBF and FOXO1 then act in a positive amplification pathway that orchestrates the B lineage–specific programs of gene expression that include the up-regulation of PAX5. After these changes, the CLP cells transition to become pro-B cells, which receive proliferation and survival signals from IL-7.

As B-lineage cells mature, they migrate within the marrow, remaining in contact with the stromal cells. The earliest stem cells lie in a region called the **endosteum**, which lines the inner cavity of the long bones such as the femur and tibia. Developing B-lineage cells make contact with reticular stromal cells in the trabecular spaces, and as they mature they move toward the central sinus of the marrow cavity. The final stages of development of immature B cells into mature B cells occur in peripheral lymphoid organs, such as the spleen, which we describe in Sections 8-8 and 8-9 of this chapter.

Innate lymphoid cells also develop in the bone marrow. A key aspect of innate lymphoid cell development is the expression of a transcriptional regulator, Id2. This protein acts as a competitive inhibitor of E2A and prevents the E2A proteins from promoting B-cell development. Additional transcription factors, such as NFIL3 and TOX, are essential for innate lymphoid cell development. In contrast to B cells and innate lymphoid cells, T cells develop in the thymus rather than in the bone marrow. Once in the thymus, the ETP receives signals through the Notch receptor, a key step in driving T-cell commitment, a process that will be discussed in more detail in Section 8-14.

8-3 B-cell development begins by rearrangement of the heavy-chain locus.

The stages of B-cell development are, in the order they occur, **early pro-B cell**, **late pro-B cell**, **large pre-B cell**, **small pre-B cell**, **immature B cell**, and **mature B cell** (Fig. 8.4). Rearrangement of the heavy-chain locus is initiated in the pro-B cell when E2A and EBF induce the expression of several key proteins that enable gene rearrangement to occur, including the RAG-1 and RAG-2 components of the V(D)J recombinase (see Chapter 5). Only one gene locus is rearranged at a time, in a fixed sequence. The first rearrangement to take place is the joining of a D gene segment to a J segment at the immunoglobulin heavy-chain locus (*Igh*). D to J_H rearrangement takes place mostly in the early pro-B-cell stage but can be seen as early as the common lymphoid progenitor. In the absence of E2A or EBF, this initial rearrangement event fails to occur. Another key protein induced by E2A and EBF is the transcription factor PAX5, one isoform of which is known as the B-cell activator protein (BSAP) (see Fig. 8.3). Among the targets of PAX5 are the gene for the B-cell co-receptor component CD19 and the gene for Igα, a signaling component of both the pre-B-cell receptor and the B-cell receptor (see Section 7-7). In the absence of PAX5, pro-B cells fail to develop further down the B-cell pathway but can be induced to give rise to T cells and myeloid cell types, indicating that PAX5 is required for commitment of the pro-B cell to the B-cell lineage. PAX5 also induces the expression of the B-cell linker protein (BLNK), an SH2-containing scaffold protein that is required for further development of the pro-B cell and for signaling from the mature B-cell antigen receptor (see Section 7-20). The temporal expressions of some of the transcription factors, surface proteins, and receptors required for B-cell development are listed in Fig. 8.3 and Fig. 8.4.

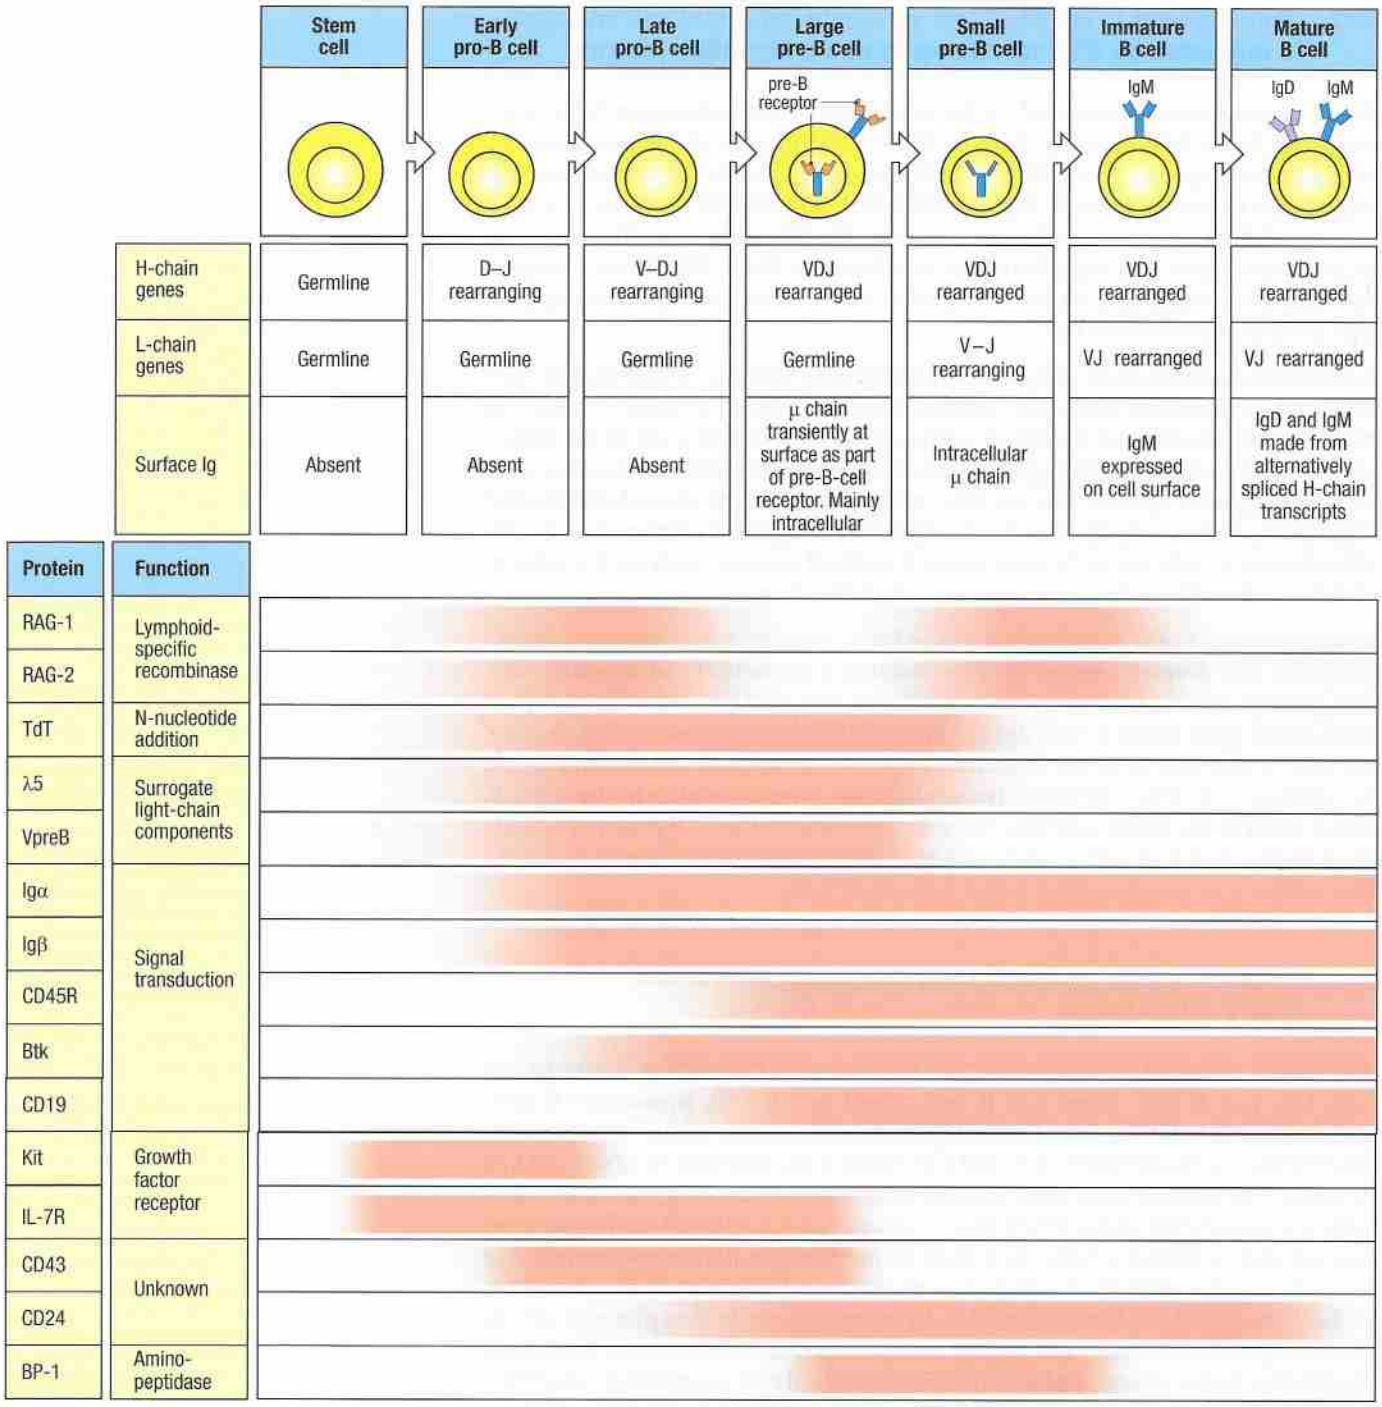

Fig. 8.4 The development of a B-lineage cell proceeds through several stages marked by the rearrangement and expression of the immunoglobulin genes. The stem cell has not yet begun to rearrange its immunoglobulin (Ig) gene segments; they are in the germline configuration found in all nonlymphoid cells. The heavy-chain (H-chain) locus rearranges first. Rearrangement of a D gene segment to a J_H gene segment starts in the common lymphoid progenitor and occurs mostly in early pro-B cells, generating late pro-B cells in which V_H to DJ_H rearrangement occurs. A successful VDJ_H rearrangement leads to the expression of a complete immunoglobulin heavy chain as part of the pre-B-cell receptor, which signals via Igα, Igβ, and Btk (see Fig 7.28). Once this occurs, the cell is stimulated to become a large pre-B cell, which proliferates to become small resting pre-B cells; at this point the cells cease expression of the surrogate light chains (λ5 and VpreB) and express the μ heavy chain alone as an intracellular protein. Small pre-B cells reexpress the RAG proteins and start to rearrange the light-chain (L-chain) genes. Upon successfully assembling a light-chain gene, a cell becomes an immature B cell that expresses a complete IgM molecule at the cell surface, which also signals via Igα and Igβ. Mature B cells produce a δ heavy chain as well as a μ heavy chain, by a mechanism of alternative mRNA splicing (see Fig. 5.12), and are marked by the additional appearance of IgD on the cell surface. All stages through the development of immature B cells take place in the bone marrow; the final maturation to IgM^+IgD^+ mature B cells occurs in the spleen. The earliest B-lineage surface markers are CD19 and CD45R (B220 in the mouse), which are expressed throughout B-cell development. A pro-B cell is also distinguished by the expression of CD43 (a marker of unknown function), Kit (CD117), and the IL-7 receptor. A late pro-B cell starts to express CD24 (a marker of unknown function). A pre-B cell is phenotypically distinguished by the expression of the enzyme BP-1, whereas Kit is no longer expressed.

Although the V(D)J recombinase system operates in both B- and T-lineage cells and uses the same core enzymes, rearrangements of T-cell receptor genes do not occur in B-lineage cells, nor do complete rearrangements of immunoglobulin genes occur in T cells. The ordered rearrangement events that do occur are associated with lineage-specific low-level transcription of the gene segments about to be joined.

The initial D to J_H rearrangements in the immunoglobulin heavy-chain locus (Fig. 8.5) typically occur on both alleles, at which point the cell becomes a late pro-B cell. Most D to J_H joins in humans are potentially useful, because most human D gene segments can be translated in all three reading frames without encountering a stop codon. Thus, there is no need for a special mechanism to distinguish successful D to J_H joints, and at this early stage there is also no need to ensure that only one allele undergoes rearrangement. Indeed, given the likely rate of failure at later stages, starting off with two successfully rearranged D–J_H sequences may be an advantage.

To produce a complete immunoglobulin heavy chain, the late pro-B cell now proceeds with a rearrangement of a V_H gene segment to a DJ_H sequence. In

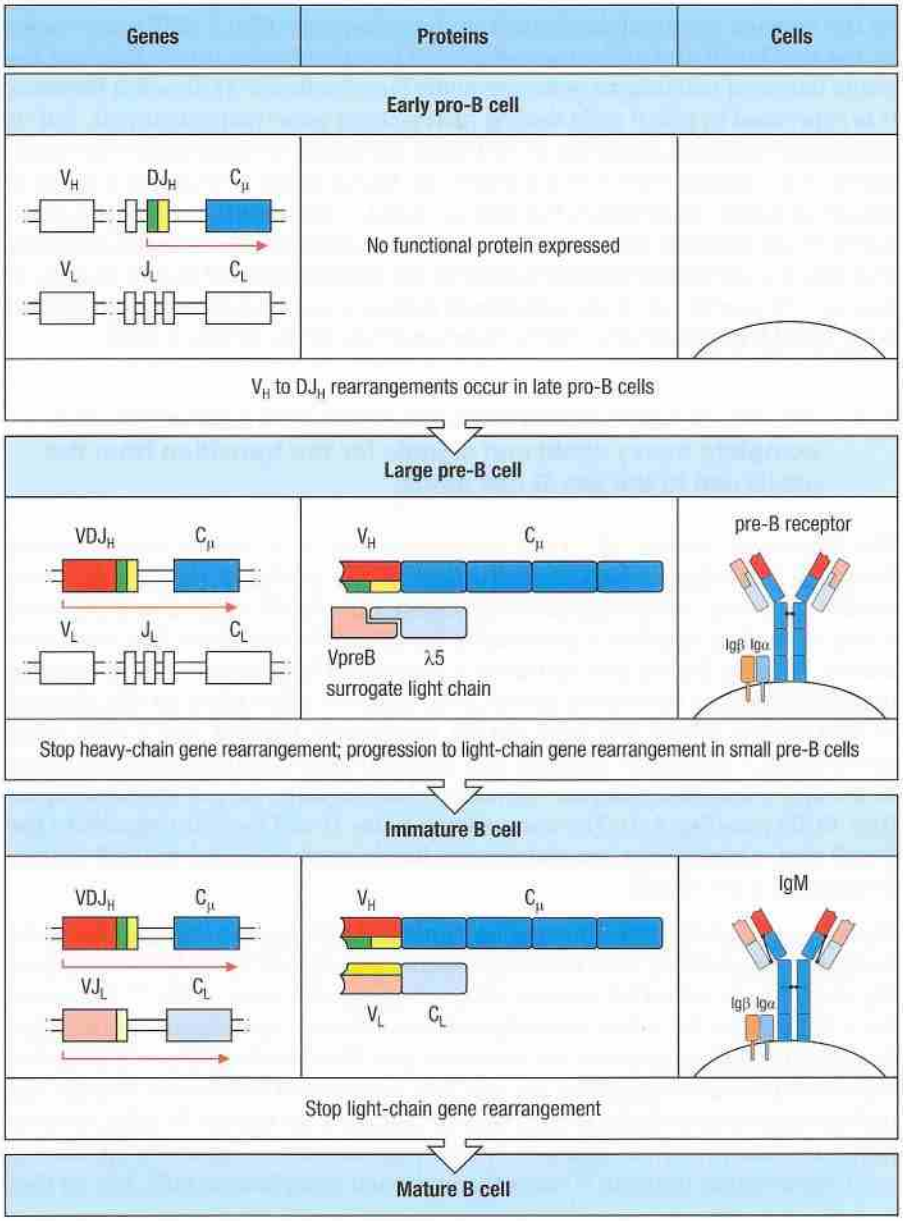

Fig. 8.5 A productively rearranged immunoglobulin gene is immediately expressed as a protein by the developing B cell. In early pro-B cells, heavy-chain gene rearrangement is initiated with D to J_H rearrangements. As shown in the top panels, no functional μ protein is expressed, although transcription occurs (red arrow). In late pro-B cells, V_H to DJ_H rearrangement occurs on one chromosome first. If no functional H-chain is produced, V_H to DJ_H rearrangement occurs on the second chromosome. As soon as a productive heavy-chain gene rearrangement takes place, μ chains are expressed by the cell in a complex with two other chains, λ5 and VpreB, which together make up a surrogate light chain. The whole immunoglobulin-like complex is known as the pre-B-cell receptor (center panels). It is associated with two other protein chains, Igα and Igβ, which signal the B cell to halt heavy-chain gene rearrangement; this drives the transition to the large pre-B-cell stage by inducing proliferation. Failure to produce a functional H-chain leading to a pre-B-cell receptor signal leads to cell death. The progeny of large pre-B cells stop dividing and become small pre-B cells, in which light-chain gene rearrangements commence. V_κ–J_κ rearrangement (see Section 5-2) occurs first, and if unsuccessful, V_λ to J_λ rearrangement occurs next. Successful light-chain gene rearrangement results in the production of a light chain that binds the μ chain to form a complete IgM molecule, which is expressed together with Igα and Igβ at the cell surface, as shown in the bottom panels. Signaling via this surface receptor complex is thought to trigger the cessation of light-chain gene rearrangement. Failure to produce a functional L chain leads to cell death.

contrast to D to J_H rearrangement, V_H to DJ_H rearrangement occurs first on only one chromosome. A successful rearrangement leads to the production of intact μ heavy chains, after which V_H to DJ_H rearrangement ceases and the cell becomes a pre-B cell. Pro-B cells that do not produce a μ chain are eliminated, as they fail to receive an important survival signal mediated by the **pre-B-cell receptor** (see Section 8-3). At least 45% of pro-B cells are lost at this stage. In at least two out of three cases, the first V_H to DJ_H rearrangement is nonproductive. Because each amino acid is encoded by a triplet of nucleotides, only one out of three rearrangements produces an in-frame junction. When this initial rearrangement is out of frame, rearrangement then occurs on the other chromosome, again with a theoretical two in three chance of failure. A rough estimate of the chance of generating a pre-B cell is thus 55% [1-(2/3 × 2/3)]. The actual frequency is somewhat lower, because the V gene segment repertoire contains pseudogenes that can rearrange yet have major defects that prevent the expression of a functional protein. An initial nonproductive rearrangement does not automatically lead to pro-B-cell elimination, as it is possible for most loci to undergo successive rearrangements on the same chromosome, and where that fails, the locus on the other chromosome will rearrange.

The diversity of the B-cell antigen-receptor repertoire is enhanced at this stage by the enzyme terminal deoxynucleotidyl transferase (TdT). TdT is expressed by the pro-B cell and adds non-templated nucleotides (N-nucleotides) at the joints between rearranged gene segments (see Section 5-4). In adult humans, it is expressed in pro-B cells during heavy-chain gene rearrangement, but its expression declines at the pre-B-cell stage during light-chain gene rearrangement. This explains why N-nucleotides are found in the V–D and D–J joints of nearly all heavy-chain genes but only in about a quarter of human light-chain joints. N-nucleotides are rarely found in mouse light-chain V–J joints, showing that TdT is switched off slightly earlier in the development of mouse B cells. In fetal development, when the peripheral immune system is first being supplied with T and B lymphocytes, TdT is expressed only at low levels, if at all.

8-4 The pre-B-cell receptor tests for successful production of a complete heavy chain and signals for the transition from the pro-B cell to the pre-B cell stage.

The imprecise nature of V(D)J recombination is a double-edged sword. Although it produces increased diversity in the antibody repertoire, it also results in many unsuccessful rearrangements. Pro-B cells therefore need a way of testing whether a potentially functional heavy chain has been produced. They do this by incorporating a functional heavy chain into a receptor that can signal its successful production. This test takes place in the absence of light chains, whose loci have not yet rearranged. Instead, pro-B cells make two invariant 'surrogate' proteins that together have a structural resemblance to the light chain and can pair with the μ chain to form the pre-B-cell receptor (pre-BCR) (see Fig. 8.5). The assembly of a pre-B-cell receptor signals to the B cell that a productive rearrangement has been made, and the cell is then considered a pre-B cell.

The surrogate chains are encoded by nonrearranging genes separate from the antigen receptor loci, and their expression is induced by E2A and EBF (see Fig. 8.4). One is called **λ5** because of its close resemblance to the C domain of the λ light chain; the other, called **VpreB**, resembles a light-chain V domain but has an extra region at the amino-terminal end. Pro-B cells and pre-B cells also express the invariant proteins Igα and Igβ, introduced in Chapter 7 as the signaling components of the B-cell receptor complex on mature B cells. As components of the pre-B-cell receptor, Igα and Igβ transduce signals by interacting with intracellular tyrosine kinases through their cytoplasmic tails, just as they

function to transduce signals through the antigen receptor on mature B cells (see Section 7-7).

Formation of the pre-B-cell receptor and signaling through this receptor provide an important checkpoint that mediates the transition between the pro-B cell and the pre-B cell. In mice that either lack λ5 or have mutant heavy-chain genes that cannot form the pre-B-cell receptor, B-cell development is blocked after heavy-chain gene rearrangement. In normal B-cell development, the pre-B-cell receptor complex is expressed transiently, perhaps because the production of λ5 mRNA stops as soon as pre-B-cell receptors begin to be formed. Although present at only low levels on the cell surface, the pre-B-cell receptor generates signals required for the transition from pro-B cell to pre-B cell. No antigen or other external ligand seems to be involved in signaling by the receptor. Instead, pre-B-cell receptors are thought to interact with each other, forming dimers or oligomers that generate signals as described in Section 7-8. Dimerization involves 'unique' regions in the amino termini of λ5 and VpreB proteins that are not present in other immunoglobulin-like domains and which mediate the cross-linking of adjacent pre-B-cell receptors on the cell surface (Fig. 8.6). Pre-B-cell receptor signaling requires the scaffold protein BLNK and Bruton's tyrosine kinase (Btk), an intracellular Tec-family tyrosine kinase (see Section 7-20). In humans and mice, deficiency of BLNK leads to a block in B-cell development at the pro-B-cell stage. In humans, mutations in the BTK gene cause a profound B lineage–specific immune deficiency, **Bruton's X-linked agammaglobulinemia (XLA)**, in which no mature B cells are produced. The block in B-cell development caused by mutations in *BTK*

Fig. 8.6 The pre-B-cell receptor initiates signaling through spontaneous dimerization induced by the unique regions of VpreB and λ5. Two surrogate protein chains, VpreB (orange) and λ5 (green), substitute for a light chain and bind to a heavy chain, thus allowing its surface expression. VpreB substitutes for the light-chain V region in this surrogate interaction, while λ5 takes the part of the light-chain constant region. Both VpreB and λ5 contain 'unique' amino-terminal regions that are not present in other immunoglobulin-like domains, shown here as unstructured tails extending out from the globular domains. These amino-terminal regions associated with one pre-B-cell receptor can interact with the corresponding regions on the adjacent pre-B-cell receptor, promoting the spontaneous formation of pre-B-cell receptor dimers on the cell surface. Dimerization generates signaling from the pre-B-cell receptor that is dependent on the presence of the ITAM-containing signaling chains Igα and Igβ. The signals cause the inhibition of RAG-1 and RAG-2 expression and the proliferation of the large pre-B cell.

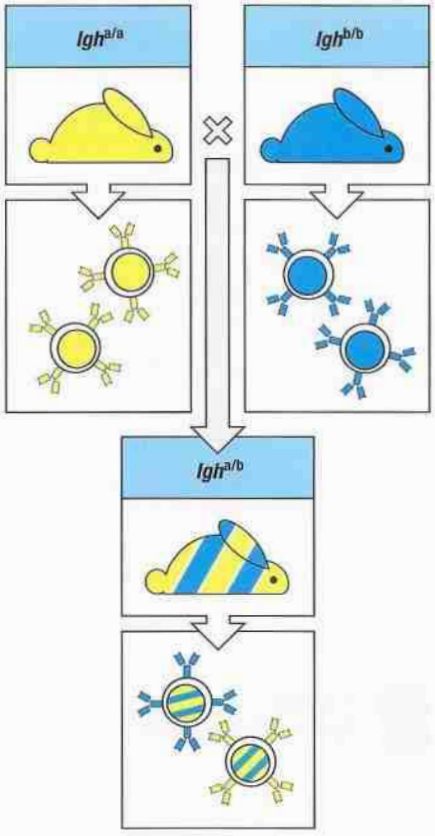

Fig. 8.7 Allelic exclusion in individual B cells. Most species have genetic polymorphisms of the constant regions of their immunoglobulin heavy-chain and light-chain genes; these polymorphisms lead to amino acid differences between the encoded proteins. These variants of heavy-chain or light-chain proteins expressed by different individuals in a species are known as allotypes. In rabbits, for example, all of the B cells in an individual homozygous for the *a* allele of the immunoglobulin heavy-chain locus ($Igh^{a/a}$) will express immunoglobulin of allotype a, whereas in an individual homozygous for the *b* allele ($Igh^{b/b}$) all the B cells make immunoglobulin of allotype b. In a heterozygous animal ($Igh^{a/b}$), which carries the *a* allele at one of the Igh loci and the *b* allele at the other, individual B cells can be shown to express surface immunoglobulin of either the a-allotype or the b-allotype, but not both (bottom panel). This allelic exclusion reflects the productive rearrangement of only one of the two *Igh* alleles in the B cell, because the production of a successfully rearranged immunoglobulin heavy chain forms a pre-B-cell receptor, which signals the cessation of further heavy-chain gene rearrangement.

is almost total, interrupting the transition from pre-B cell to immature B cell. A similar but less severe defect called **X-linked immunodeficiency, or xid**, arises from mutations in the Btk gene in mice.

8-5 Pre-B-cell receptor signaling inhibits further heavy-chain locus rearrangement and enforces allelic exclusion.

The signaling generated by pre-B-cell receptor clustering halts further rearrangement of the heavy-chain locus. Successful rearrangements at both heavy-chain alleles could result in a B cell producing two receptors of different antigen specificities. To prevent this, signaling by the pre-B-cell receptor enforces **allelic exclusion**, the state in which only one of the two alleles of a gene is expressed in a diploid cell. Allelic exclusion, which occurs at both the heavy-chain locus and the light-chain loci, was discovered in the 1960s and provided one of the original pieces of experimental support for the theory that one lymphocyte expresses one type of antigen receptor (Fig. 8.7).

Signaling from the pre-B-cell receptor promotes heavy-chain allelic exclusion in three ways. First, it reduces V(D)J recombinase activity by directly reducing the expression of the RAG1 and RAG2 genes. Second, it further reduces levels of RAG-2 by indirectly causing this protein to be targeted for degradation, which occurs when RAG-2 is phosphorylated in response to the entry of the pro-B cell into S phase (the DNA synthesis phase) of the cell cycle. Finally, pre-B-cell receptor signaling reduces access of the heavy-chain locus to the recombinase machinery, although the precise details of this process are not clear. At a later stage of B-cell development, RAG proteins will again be expressed in order to carry out light-chain locus rearrangement, but at that point the heavy-chain locus does not undergo further rearrangement. In the absence of pre-B-cell receptor signaling, allelic exclusion of the heavy-chain locus does not occur.

A second important role of pre-B-cell receptor signaling is to stimulate proliferative expansion of B-cell precursors with a successful heavy-chain rearrangement, initiating their transition into the large pre-B-cell stage. In response to IL-7, the cells undergo several rounds of cell division, expanding the population by about 30- to 60-fold. Thus, a deficiency in pre-B-cell receptor signaling causes a profound reduction in the numbers of pre-B cells and mature B cells that develop.

8-6 Pre-B cells rearrange the light-chain locus and express cell-surface immunoglobulin.

After several rounds of cell division, large pre-B cells transition to become resting small pre-B cells. RAG proteins are produced again in the small pre-B cells, and rearrangement of the light-chain locus begins. Each of these cells can make a different rearranged light-chain gene, and so cells with many different antigen specificities are generated from a single pre-B cell, a process that makes an important contribution to overall B-cell receptor diversity.

Light-chain rearrangement also exhibits allelic exclusion. Rearrangements at the light-chain locus generally take place at only one allele at a time, a process regulated by a mechanism not currently understood. The light-chain loci lack D segments, and rearrangement occurs by V to J joining, and if a particular VJ rearrangement fails to produce a functional light chain, repeated rearrangements of unused V and J gene segments at the same allele can occur (Fig. 8.8). Several attempts at productive rearrangement of a light-chain gene can therefore be made on one chromosome before initiating any rearrangements on the second chromosome. This greatly

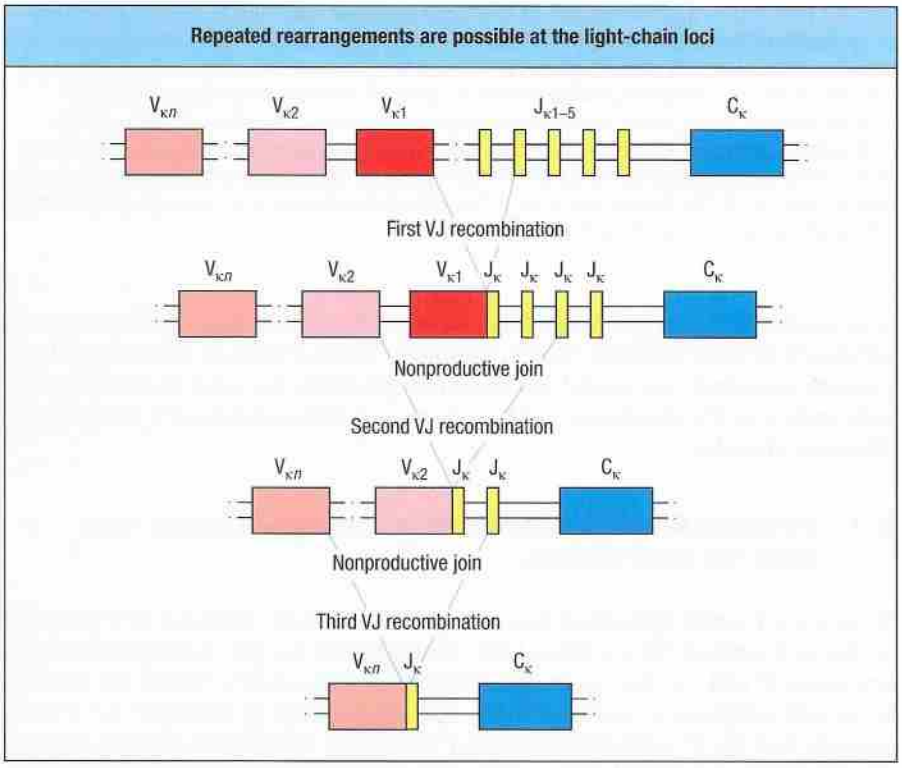

Fig. 8.8 Nonproductive light-chain gene rearrangements can be rescued by further rearrangement. The organization of the light-chain loci in mice and humans offers many opportunities for the rescue of pre-B cells that initially make an out-of-frame rearrangement. Light-chain rescue is illustrated here at the human κ locus. If the first rearrangement is nonproductive, a 5′ V_κ gene segment can recombine with a 3′ J_κ gene segment to remove the out-of-frame join located between them and to replace it with a new rearrangement. In principle, this can happen up to five times on each chromosome, because there are five functional J_κ gene segments in humans. If all rearrangements of κ-chain genes fail to yield a productive light-chain join, λ-chain gene rearrangement may succeed (not shown).

increases the chances of eventually generating an intact light chain, especially as there are two different light-chain loci. As a result, many cells that reach the pre-B-cell stage succeed in generating progeny that bear intact IgM molecules and can be classified as immature B cells. Figure 8.4 lists some of the proteins involved in V(D)J recombination and shows how their expression is regulated throughout B-cell development. Figure 8.5 summarizes the stages of B-cell development up to the point of assembly of a complete surface immunoglobulin. Developing B cells that fail to assemble a complete surface immunoglobulin undergo apoptosis in the bone marrow and are eliminated from the B-cell pool.

As well as allelic exclusion, light chains also display **isotypic exclusion**; that is, the expression of only one type of light chain—κ or λ—by an individual B cell. Again, the mechanism regulating this process is not known. In mice and humans, the κ light-chain locus tends to rearrange before the λ locus. This was deduced from the observation that myeloma cells secreting λ light chains generally have both their κ and λ light-chain genes rearranged, whereas in myelomas secreting κ light chains, generally only the κ genes are rearranged. This order is occasionally reversed, however, and λ gene rearrangement does not absolutely require the previous rearrangement of the κ genes. The ratios of κ-expressing versus λ-expressing mature B cells vary from one extreme to the other in different species. In mice and rats it is 95% κ to 5% λ, in humans it is typically 65%:35%, and in cats it is 5%:95%, the opposite of that in mice. These ratios correlate most strongly with the number of functional V_κ and V_λ

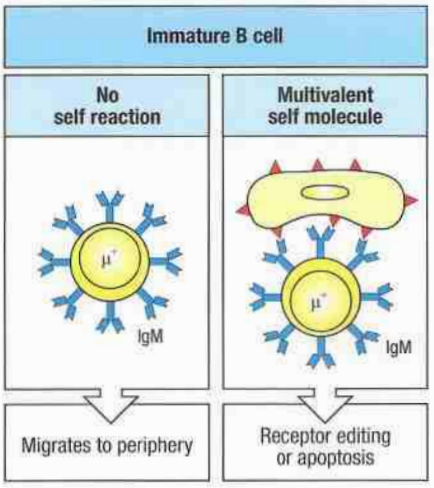

Fig. 8.9 Binding to self molecules in the bone marrow can lead to receptor editing or to death of immature B cells. Left panel: Immature B cells that do not encounter antigen mature normally; they migrate from the bone marrow to the peripheral lymphoid tissues, where they may become mature recirculating B cells bearing both IgM and IgD on their surface. Right panel: When developing B cells express receptors that recognize multivalent ligands, for example, ubiquitous cell-surface self molecules such as those of the MHC, these receptors are eliminated from the repertoire. The B cells either undergo receptor editing (see Fig. 8.10), thereby eliminating the self-reactive receptor, or undergo programmed cell death (apoptosis), resulting in clonal deletion.

gene segments in the genome of the species. They also reflect the kinetics and efficiency of gene segment rearrangements. The κ:λ ratio in the mature lymphocyte population is useful in clinical diagnostics, because an aberrant κ:λ ratio indicates the dominance of one clone and the presence of a lymphoproliferative disorder.

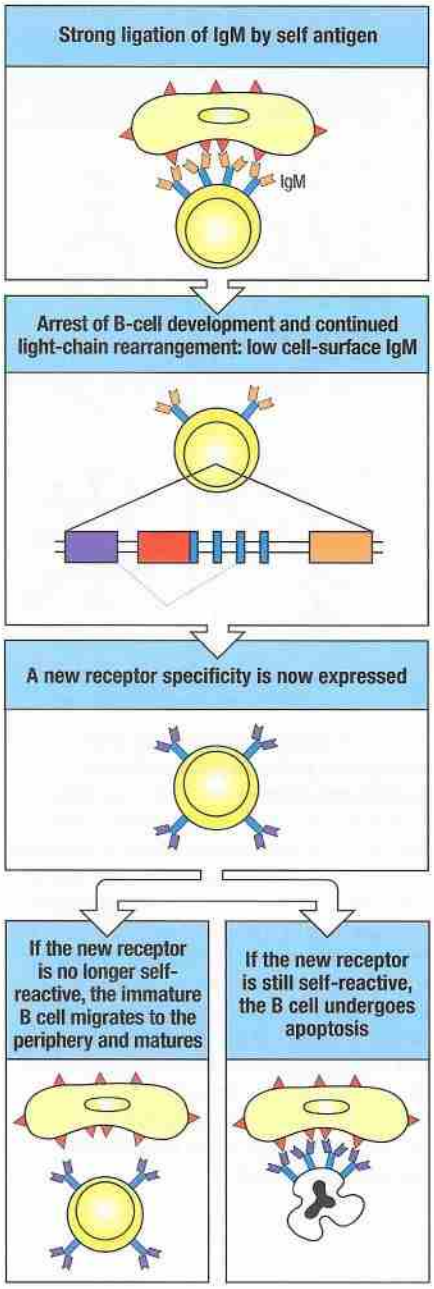
8-7 Immature B cells are tested for autoreactivity before they leave the bone marrow.

Once a rearranged light chain has paired with a μ chain, IgM can be expressed on the cell surface (as a surface IgM, or sIgM) and the pre-B cell becomes an immature B cell. At this stage, the antigen receptor is first tested for reactivity to self antigens, or autoreactivity. The elimination of autoreactive B cells ensures that the B-cell population as a whole will be tolerant of self antigens. The **tolerance** produced at this stage of B-cell development is known as **central tolerance** because it arises in a central lymphoid organ, the bone marrow. However, B cells leaving the bone marrow are not fully mature and require additional maturation steps that take place in peripheral lymphoid organs (see Sections 8-8 and 8-9). As we shall see later in the chapter and in Chapter 15, self-reactive B cells that escape central tolerance may still be removed from the repertoire after they have left the bone marrow, a process that takes place during the final peripheral stages of B-cell maturation and is referred to as peripheral tolerance, described in Section 8-8.

sIgM associates with Igα and Igβ to form a functional B-cell receptor complex, and the fate of an immature B cell in the bone marrow depends on signals delivered from this receptor complex when it interacts with ligands in the environment. Igα signaling is particularly important in dictating the emigration of B cells from the bone marrow and/or their survival in the periphery: mice that express Igα with a truncated cytoplasmic domain that cannot signal show a fourfold reduction in the number of immature B cells in the marrow and a hundredfold reduction in the number of peripheral B cells. The release of immature B cells from the bone marrow into the circulation is also dependent on their expression of **S1PR1**, a G protein–coupled receptor that binds to the lipid ligand S1P and promotes cell migration toward the high concentrations of S1P that exist in the blood (see Section 8-28).

Immature B cells that have no strong reactivity to self antigens continue to mature (Fig. 8.9). They leave the marrow via sinusoids that enter the central sinus, enter the circulation, and are carried by the venous blood supply to the spleen. If, however, the newly expressed receptor encounters a strongly cross-linking antigen in the bone marrow—that is, if the B cell is strongly self-reactive—development is arrested at this stage, and the cell undergoes further gene rearrangements in an attempt to replace the autoreactive receptor with a new receptor that is not self-reactive. This mechanism is termed **receptor editing**.

Receptor editing is the predominant mechanism of central tolerance for B cells in the bone marrow (Fig. 8.10). When an immature B cell first produces sIgM, RAG proteins are still being made. If the receptor is not self-reactive, the



Strong ligation of IgM by self antigen
IgM
Arrest of B-cell development and continued light-chain rearrangement: low cell-surface IgM
A new receptor specificity is now expressed
If the new receptor is no longer self-reactive, the immature B cell migrates to the periphery and matures
If the new receptor is still self-reactive, the B cell undergoes apoptosis

Fig. 8.10 Replacement of light chains by receptor editing can rescue some self-reactive B cells by changing their antigen specificity. When a developing B cell expresses antigen receptors that are strongly cross-linked by multivalent self antigens such as MHC molecules on cell surfaces (top panel), its development is arrested. The cell decreases surface expression of IgM and does not turn off the RAG genes (second panel). Continued synthesis of RAG proteins allows the cell to continue light-chain gene rearrangement. This usually leads to a new productive rearrangement and the expression of a new light chain, which combines with the previous heavy chain to form a new receptor; the process is called receptor editing (third panel). If this new receptor is not self-reactive, the cell is 'rescued' and continues normal development, much like a cell that had never reacted with self antigen (bottom left panel). If the cell remains self-reactive, it may be rescued by another cycle of rearrangement; however, if it continues to react strongly with self antigen, it will undergo apoptosis, resulting in clonal deletion of the self-reactive cell from the repertoire of B cells (bottom right panel).

absence of sIgM cross-linking allows gene rearrangement to cease, and B-cell development continues, with RAG proteins eventually disappearing. For an autoreactive receptor, however, an encounter with the self antigen results in strong cross-linking of sIgM; RAG expression continues, and light-chain gene rearrangement can continue, as described in Fig. 8.8. These secondary rearrangements can rescue immature self-reactive B cells by deleting the self-reactive light-chain gene and replacing it with another sequence. If the new light chain is not autoreactive, the B cell continues normal development. If the receptor remains autoreactive, rearrangement continues until a non-autoreactive receptor is produced or until no additional light-chain V and J gene segments are available for recombination, at which time the immature B cell undergoes apoptosis, a process known as **clonal deletion**. The importance of receptor editing as a mechanism of tolerance is well established, as defects in this process contribute to the human autoimmune diseases systemic lupus erythematosus and rheumatoid arthritis, two diseases characterized by high levels of autoreactive antibodies (see Chapter 15).

It was originally thought that the successful production of a heavy chain and a light chain caused the almost instantaneous shutdown of light-chain locus rearrangement and that this ensured both allelic and isotypic exclusion. The unexpected ability of self-reactive B cells to continue to rearrange their light-chain genes, even after having made a productive rearrangement, suggests an alternative mechanism of allelic exclusion, in which the fall in the level of RAG proteins that follows a successful non-autoreactive rearrangement could be the principal means by which light-chain rearrangement is terminated. It is now apparent that allelic exclusion is not absolute, as there are rare B cells that express two different light chains.

The fact that central tolerance is not perfect and some self-reactive B cells are allowed to mature reflects the balance that the immune system strikes between purging all self-reactivity and maintaining the ability to respond to pathogens. If the elimination of self-reactive cells were too efficient, the receptor repertoire might become too limited and thus unable to recognize a wide variety of pathogens. Some autoimmune disease is the price of this balance: we shall see in Chapter 15 that weakly self-reactive lymphocytes can be activated and cause disease under conditions such as inflammation or when the self antigen becomes available or reaches an unusually high concentration because of tissue damage.

Rheumatoid Arthritis

Systemic Lupus Erythematosus

8-8 Lymphocytes that encounter sufficient quantities of self antigens in the periphery are eliminated.

While large numbers of self-reactive B cells are purged from the population of new lymphocytes in the bone marrow, only lymphocytes specific for self antigens that are expressed in or can reach this organ are affected. Some antigens, like the thyroid product thyroglobulin, are highly tissue specific or are

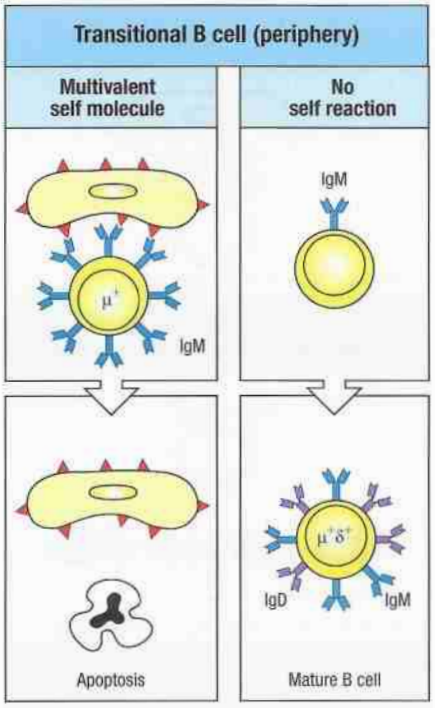


Fig. 8.11 Transitional B cells that recognize self antigens undergo peripheral tolerance. After emigrating from the bone marrow and entering the circulation, B cells are known as transitional B cells. Not yet fully mature, these cells are still subject to tolerance in the spleen after engagement of their sIgM receptor by a self antigen. Transitional B cells that encounter a multivalent self antigen receive a strong B-cell receptor signal and undergo cell death. Transitional B cells with no strong self reaction continue their maturation into mature B cells. The final stages of B-cell maturation lead to up-regulation of surface IgD (sIgD) and take place in the B-cell follicles in the spleen.

compartmentalized so that little if any is available in the circulation. Therefore, newly emigrated self-reactive B cells that encounter their specific self antigen in the periphery must also be eliminated (Fig. 8.11). This tolerance mechanism, which acts on newly emigrated B cells that are not yet functionally mature, is known as **peripheral tolerance**.

In the absence of an infection, newly emigrated B cells that encounter a strongly cross-linking antigen in the periphery will undergo clonal deletion. This was elegantly shown in studies of B cells expressing B-cell receptors specific for H-2K^b MHC class I molecules. These B cells are deleted even when, in transgenic animals, the expression of the H-2K^b molecule is restricted to the liver by the use of a liver-specific gene promoter. There is no receptor editing: B cells that encounter multivalent self-antigens in the periphery undergo apoptosis directly, unlike their counterparts in the bone marrow, which attempt further receptor rearrangements. This difference may be due to the fact that the B cells in the periphery are somewhat more mature and can no longer rearrange their light-chain loci.

8-9 Newly formed B cells arriving in the spleen turn over rapidly and require cytokines and positive signals through the B-cell receptor for maturation and long-term survival.

When B cells emerge from the bone marrow into the periphery, they are not yet functionally mature and are referred to as **transitional B cells**. As discussed above, their final maturation in the periphery provides an opportunity for these B cells to encounter peripheral self antigens and to undergo tolerance. Transitional B cells express high levels of sIgM but little surface IgD (sIgD), whereas mature B cells express low levels of IgM and high levels of IgD; while the changes in expression of sIgM and sIgD as B cells mature is well documented, the function of sIgD on mature B cells is not known.

Most B cells leaving the bone marrow will not survive to become fully mature B cells. Figure 8.12 shows the possible fates of newly produced B cells that enter the periphery. The daily output of new B cells from the bone marrow is roughly 5–10% of the total B-lymphocyte population in the steady-state peripheral pool. In unimmunized animals, the size of this pool seems to remain constant, due to homeostasis, which means that the stream of new B cells needs to be balanced by the removal of an equal number of peripheral B cells. However, the majority of peripheral mature B cells are long-lived, and only 1–2% of these die each day. Thus, most of the B cells that die are in the rapidly turning-over peripheral population of transitional B-cells, of which more than 50% die every 3 days. The failure of most newly formed B cells to survive for more than a few days in the periphery seems to be due to competition between peripheral B cells for access to the follicles in the spleen. If newly produced transitional B cells do not enter a follicle, their passage through the periphery is halted and they eventually die. The limited number of lymphoid follicles cannot accommodate all of the B cells generated each day, and so there is continual competition for entry.

The follicle provides signals necessary for B-cell survival. In particular, the TNF family member **BAFF** (for B-cell activating factor belonging to the TNF family) is made by several cell types but is produced abundantly by the follicular dendritic cells (FDCs). FDCs are non-hematopoietic cells resident in the B-cell follicles that are specialized to capture antigens for recognition by B-cell antigen receptors (see Section 9-1). B cells express three different receptors for BAFF; namely, BAFF-R, BCMA, and TACI. BAFF-R is the most important for follicular B-cell survival, because mutant mice lacking BAFF-R have mainly transitional B cells and few long-lived peripheral B cells. BCMA and TACI also bind the related TNF family cytokine APRIL, which is not required for the survival of transitional B cells but is important for IgA antibody production, as we shall see in Chapter 10.

Fig. 8.12 Transitional B cells complete their maturation in B-cell follicles in the spleen. The micrograph in the top panel shows a cross-sectional view of a mouse spleen indicating the distribution of B cells (anti-B220; brown) and T cells (anti-CD3; blue) composing the white pulp. Surrounding the B cell–rich follicles (intense brown staining) are the marginal zones (also brown due to presence of $B220^+$ B cells). The white pulp cords sit within the red pulp, which is rich in myeloid cells (mostly macrophages), plasma cells, and passing red blood cells. Transitional B cells that have left the bone marrow must complete their maturation in the B-cell follicles of the spleen, where they receive necessary maturation and survival signals (middle panel). One essential component is a low level of signaling through the B-cell receptor. A second essential factor is the expression of BAFF, a TNF family member, on follicular dendritic cells (FDCs). BAFF stimulates the receptor BAFF-R on transitional B cells, promoting B-cell survival. Newly emigrated transitional B cells (T1) exhibit high levels of surface IgM, little surface IgD, and the BAFF-R. In the B-cell follicles, these cells up-regulate CD21 to become transitional stage 2 B cells (T2). Finally, the cells up-regulate surface IgD and become long-lived mature B cells. The majority of long-lived B cells are recirculating B cells, known as follicular B cells. A second, less numerous subset is the marginal zone B-cell population. Marginal zone B cells are thought to be weakly self-reactive and express very high levels of the complement receptor CD21. These cells migrate to the marginal zones of the splenic white pulp, an area at the white pulp–red pulp junctions. In this location, marginal zone B cells are poised to make rapid responses to blood-borne antigens or pathogens. Transitional T1 B cells that are excluded from the follicles fail to receive maturation and survival signals and will die within 2–3 days of leaving the bone marrow (bottom panel).

Transitional B cells in the spleen proceed through two distinct **transitional stages**, called T1 and T2, defined by the absence or presence of the B-cell co-receptor component CD21 (complement receptor 2) (see Section 2-13 and Section 7-20). In mice lacking BAFF, newly arising B cells progress to the T1 stage in the spleen but fail to express CD21, and the mice lack mature B cells. Signaling through the B-cell receptor is also required for transitional B cells in the spleen to progress through the T1 and T2 stages and enter the long-lived peripheral B-cell pool. In this case, the B-cell receptor signals do not arise from high-affinity interactions between the sIgM of the B-cell receptor and an antigen, which would induce strong signals; instead, these B-cell receptor signals are thought to be weak signals that are potentially generated by low-affinity recognition of self antigens, although the precise mechanism responsible for this signaling is not known. These weak B-cell receptor signals together with the BAFF-R signals are essential to promote the final stages of B-cell maturation in the periphery. Dysregulation of the appropriate balance between B-cell receptor and BAFF-R signaling occurs in individuals who overexpress BAFF and has been linked to the development of autoimmune diseases that result from a failure to purge autoreactive B cells, such as Sjögren's syndrome.

The majority of peripheral B cells that reside in the spleen and other peripheral lymphoid organs are known as **follicular B cells**, sometimes referred to as B-2 B cells. A second, minor population of B cells found in the spleen consists of **marginal zone B cells**, named for their predominance at the marginal zones that lie at the white pulp–red pulp junctions (see Fig. 8.12). Follicular and marginal zone B cells both derive from a common lineage that develops in the bone marrow and bifurcates during the final stage of B-cell maturation in the splenic follicles. Experiments reconstituting the signals promoting peripheral B-cell maturation in cell culture, starting from immature B-cell precursors, indicate that follicular versus marginal zone B-cell lineages diverge at the transitional T2 stage, as cells transition to the fully mature stage. Like follicular B cells, marginal zone B cells are dependent on BAFF signals and are missing in mice lacking BAFF expression. Marginal zone B cells can be identified by their expression of very high levels of the complement receptor CD21. Studies using rearranged immunoglobulin gene knock-in mice that express a single B-cell receptor specificity on all developing B cells have demonstrated that some B-cell receptors predominantly generate follicular B cells, whereas others generate marginal zone B cells. These findings indicate that the specificity of the B-cell receptor is a major factor in determining the final commitment of

transitional B cells to the follicular versus the marginal zone lineage; however, the details of this process are still not fully understood. Because of their location, marginal zone B cells are poised to make rapid responses to antigens or pathogens filtered from the blood. Therefore, it is thought that marginal zone B cells represent an early line of defense for blood-borne pathogens.

Peripheral B cells also include memory B cells, which are generated in addition to antibody-producing plasma cells from mature B cells after their first encounter with antigen; we will return to B-cell memory in Chapter 11. Competition for follicular entry favors mature B cells that are already established in the relatively long-lived and stable peripheral B-cell pool. Mature B cells have undergone phenotypic changes that might make their access to the follicles easier; for example, they express CXCR5, the receptor for CXCL13, which is expressed by FDCs (see Section 10-3). They also have increased expression of CD21 compared with immature newly developed B cells, which enhances the signaling capacity of the B cell.

The B-cell receptor plays a positive role in the maturation and continued recirculation of peripheral B cells. Mice that lack the tyrosine kinase Syk, which is involved in signaling from the B-cell receptor (see Section 7-20), have transitional B cells but fail to develop mature B cells. Thus, a Syk-transduced signal may be required for final B-cell maturation or for the survival of mature B cells. Furthermore, continual expression of the B-cell receptor is required for B-cell survival, as is evident from the loss of all B cells in mice whose B-cell receptor is conditionally deleted specifically in mature B cells. Although each B-cell receptor has a unique specificity, antigen-specific interactions may not induce the signals used for final B-cell maturation and survival; the receptor could, for example, be responsible for 'tonic' signaling, in which a weak but important signal is generated by the assembly of the receptor complex and infrequently triggers some or all of the downstream signaling events.

8-10 B-1 B cells are an innate lymphocyte subset that arises early in development.

Thus far, this chapter has focused on the development of the majority populations of B cells that reside in peripheral lymphoid organs, such as follicular B cells and marginal zone B cells. These two populations compose the B-cell arm of the adaptive immune response. A third important subset of B cells, called **B-1 B cells**, is part of the innate immune system. These cells are present only in low numbers in peripheral lymphoid organs but are found in large numbers in the peritoneal and pleural cavities. B-1 B cells are the major source of 'natural' antibodies, which are constitutively produced circulating antibodies that are secreted by these B cells prior to any infections. Most antibodies made by B-1 B cells recognize capsular polysaccharide antigens, and B-1 B cells are important in controlling infections of pathogenic viruses and bacteria.

One important feature of B-1 B cells is that they can produce antibodies of the IgM class without 'help' from T cells. Although this response can be enhanced by T-cell cooperation, the antibodies first appear within 48 hours of exposure to antigen, when T cells cannot be involved. The lack of an antigen-specific interaction with helper T cells might explain why immunological memory is not generated as a result of B-1 cell responses: repeated exposures to the same antigen elicit similar or decreased responses with each exposure. While the precise functions of B-1 B cells are still not clear, mice deficient in B-1 B cells are more susceptible to infection with *Streptococcus pneumoniae* because they fail to produce an anti-phosphocholine antibody that provides protection against this bacterium. Because a significant fraction of the B-1 B cells can make antibodies of this specificity, and because no antigen-specific T-cell help is required, a potent response can be produced early in infection with this pathogen. Whether human B-1 B cells have the same role is not certain.

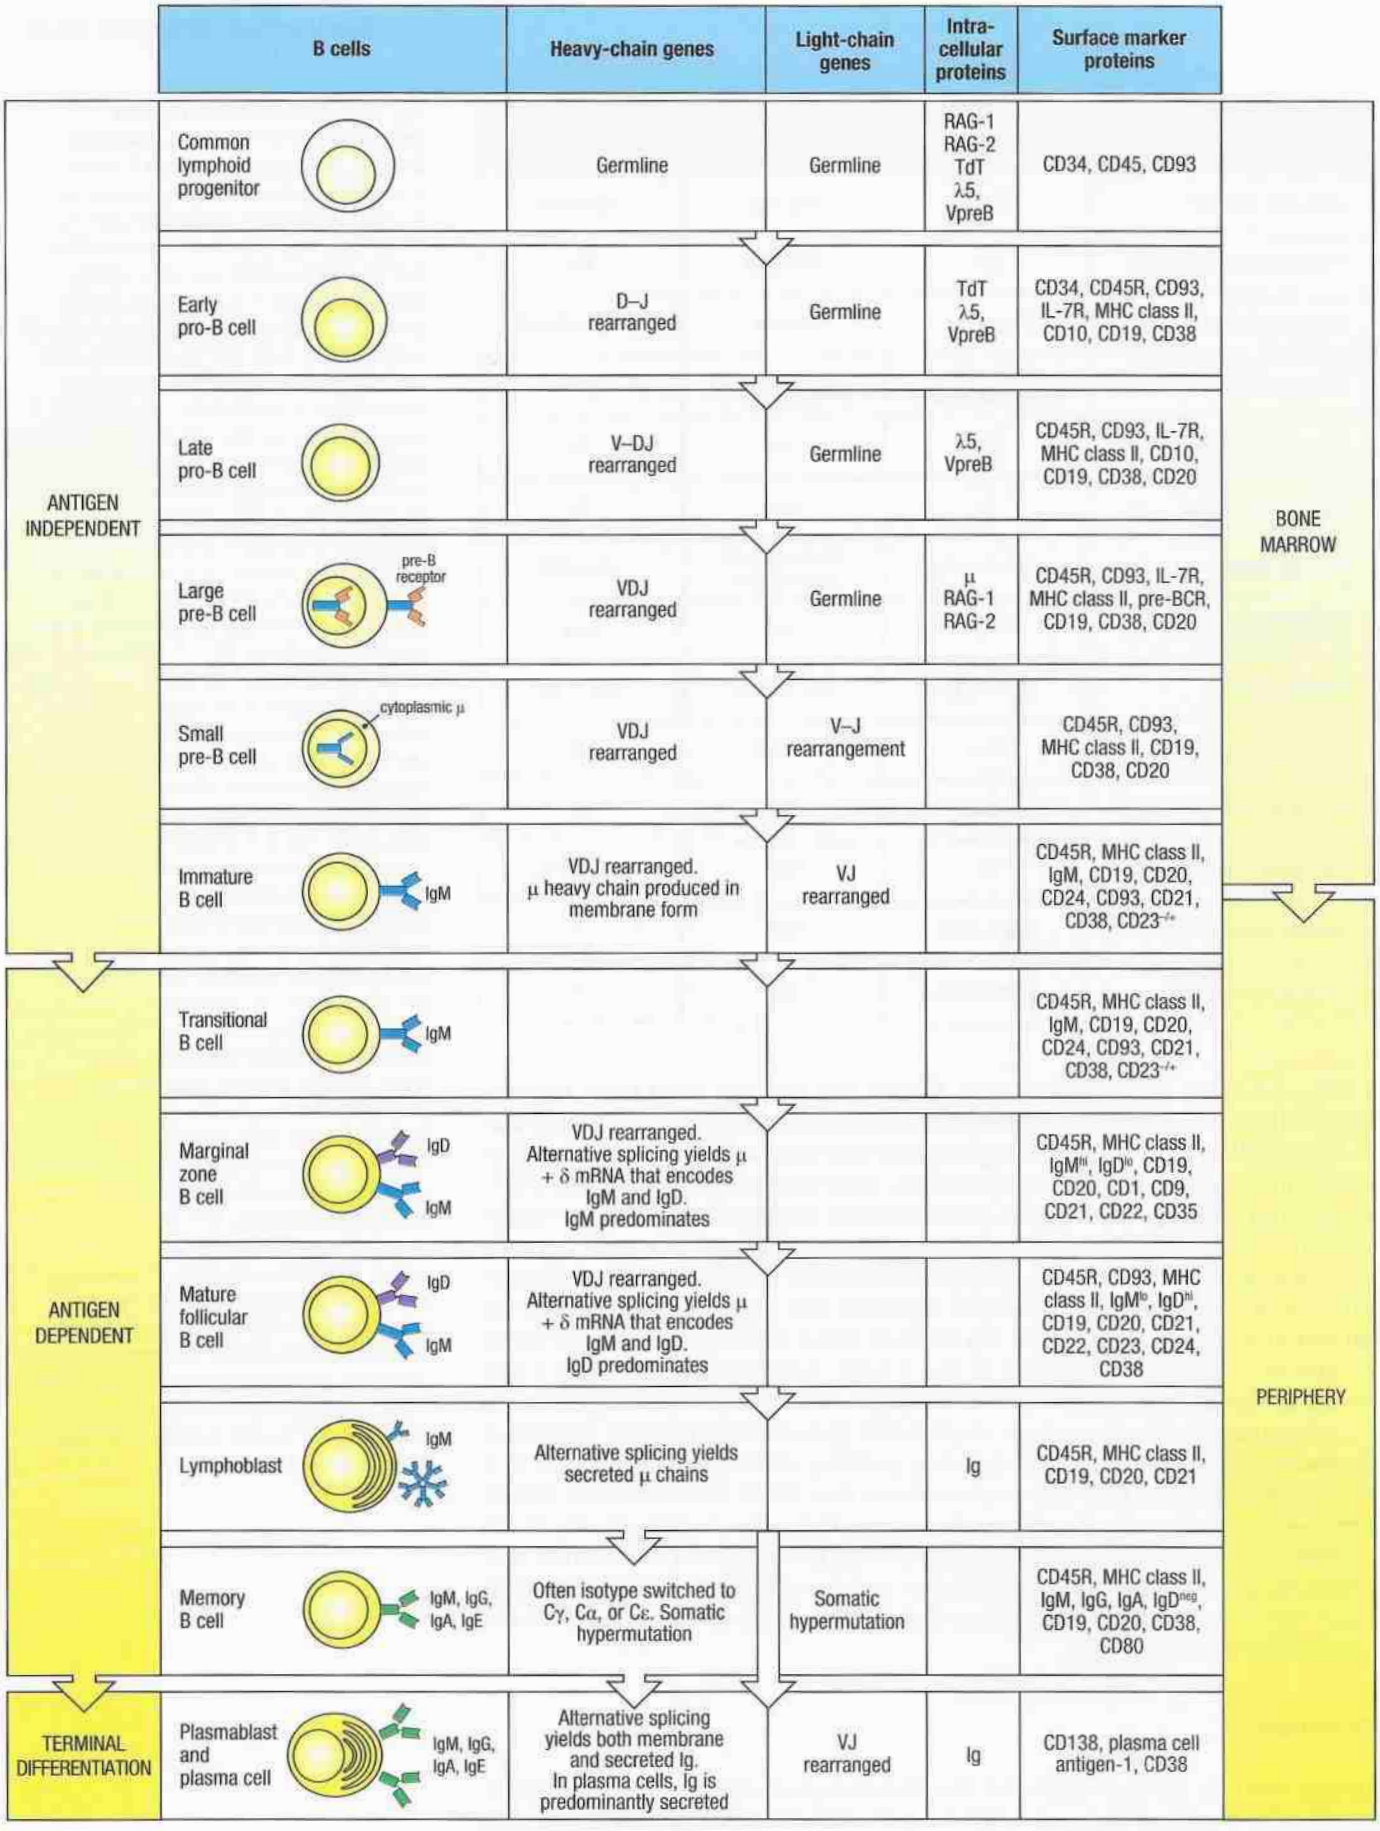
Property	B-1 B cells	Follicular B cells	Marginal zone B cells
When first produced	Fetus	After birth	After birth
N-regions in VDJ junctions	Few	Extensive	Yes
V-region repertoire	Restricted	Diverse	Partly restricted
Primary location	Body cavities (peritoneal, pleural)	Peripheral lymphoid organs	Spleen
Dependence on BAFF	No	Yes	Yes
Dependence on IL-7	No	Yes	Yes
Mode of renewal	Self-renewing	Replaced from bone marrow	Long-lived
Spontaneous production of immunoglobulin	High	Low	Low
Isotypes secreted	IgM >> IgG	IgG > IgM	IgM > IgG
Response to carbohydrate antigen	Yes	Maybe	Yes
Response to protein antigen	Maybe	Yes	Yes
Requirement for T-cell help	No	Yes	Sometimes
Somatic hypermutation	Low to none	High	?
Memory development	Little or none	Yes	?

Fig. 8.13 A comparison of the properties of B-1 B cells, follicular B cells, and marginal zone B cells. In addition to developing in the liver, B-1 B cells can develop in unusual sites in the mouse fetus, such as the omentum. B-1 B cells predominate in the young animal, although they probably can be produced throughout life. Being produced mainly during fetal and neonatal life, their rearranged variable-region sequences contain few N-nucleotides. In contrast, marginal zone B cells accumulate after birth and do not reach peak levels in the mouse until 8 weeks of age. Follicular B cells and marginal zone B cells share a common precursor population, the transitional T2 B cells in the spleen; as a consequence, both subsets are dependent on IL-7 and BAFF signals for their development in the mouse. In contrast, B-1 B cell development does not require IL-7 or BAFF. B-1 B cells are best thought of as a partly activated self-renewing pool of lymphocytes that are selected by ubiquitous self and foreign antigens. Because of this selection, and possibly because the cells are produced early in life, the B-1 B cells have a restricted repertoire of variable regions and antigen-binding specificities. Marginal zone B cells also have a restricted repertoire of V-region specificities that may be selected by a set of antigens similar to those that select B-1 B cells. B-1 B cells seem to be the major population of B cells in certain body cavities, most likely because of exposure at these sites to antigens that drive B-1 B cell proliferation. Marginal zone B cells remain in the marginal zone of the spleen and are not thought to recirculate. Partial activation of B-1 B cells leads to the secretion of mainly IgM antibody; B-1 B cells contribute much of the IgM that circulates in the blood. The limited diversity of both the B-1 and marginal zone B-cell repertoire and the propensity of these cells to react with common bacterial carbohydrate antigens suggest that they carry out a more primitive, less adaptive immune response than follicular B cells. In this regard they are comparable to γδ T cells.

Unlike follicular and marginal zone B cells that develop from bone marrow stem cells, the majority of B-1 B cells are generated from progenitor cells found in the fetal liver (Fig. 8.13). During late fetal and early neonatal stages in mice, B-1 B cells are produced in large numbers. After birth, the development of follicular and marginal zone B cells predominates, and few B-1 B cells are made. Current evidence indicates that the progenitor cells giving rise to B-1 B cells are committed to this lineage and are distinct from those producing follicular and marginal zone B cells. Whereas follicular and marginal zone B cells are absent in mice lacking BAFF or the BAFF-R, these deficiencies have no effect on the development or survival of B-1 B cells. Additionally, the weak B-cell receptor signals that promote the final stages of follicular and marginal zone B-cell maturation in the spleen require the non-canonical NFκB activation pathway (see Section 7-24), a signaling pathway that is dispensable for B-1 B-cell development. Cytokine requirements also differ between these developmental pathways. B-1 B cells develop normally in mice lacking IL-7 or IL-7R signaling components, defects that prevent the development of follicular and marginal zone B cells. Finally, follicular and marginal zone B-cell development also requires the transcription factor PU.1, which is not needed for the development of B-1 B cells.

Summary.

In this section, we have followed B-cell development from the earliest progenitors in the bone marrow to the long-lived mature peripheral B-cell pool (Fig. 8.14). The heavy-chain locus is rearranged first and, if this is successful, a μ heavy chain is produced that combines with surrogate light chains to form the pre-B-cell receptor; this is the first checkpoint in B-cell development.



B cells

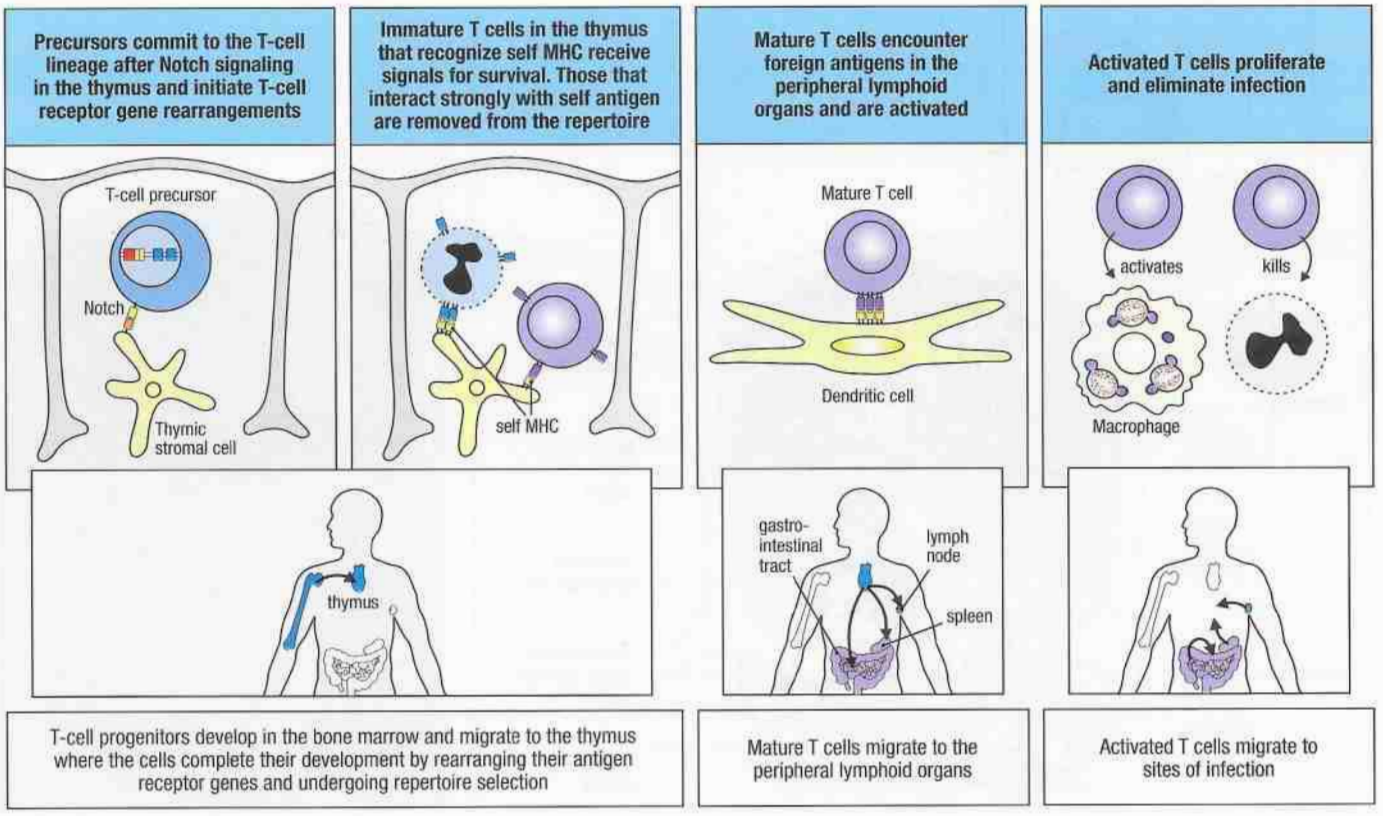
Fig. 8.14 A summary of the development of B-lineage cells. The state of the immunoglobulin genes, the expression of some essential intracellular proteins, and the expression of some cell-surface molecules are shown for successive stages of conventional B-cell development. During antigen-driven B-cell differentiation, the immunoglobulin genes undergo further changes, such as class switching and somatic hypermutation (see Chapter 10), which are evident in the immunoglobulins produced by memory cells and plasma cells.

Production of the pre-B-cell receptor signals successful heavy-chain gene rearrangement and causes cessation of this rearrangement, thus enforcing allelic exclusion. It also initiates pre-B-cell proliferation, generating numerous progeny in which subsequent light-chain rearrangement can be attempted. If the initial light-chain gene rearrangement is productive, a complete immunoglobulin B-cell receptor is formed, gene rearrangement again ceases, and the B cell continues its development. If the first light-chain gene rearrangement is unsuccessful, rearrangement continues until either a productive rearrangement is made or all available J regions are used up. If no productive rearrangement is made, the developing B cell dies. Once a complete immunoglobulin receptor is expressed on the surface of the cell, immature B cells undergo tolerance to self antigens. This process begins in the bone marrow and continues for a short time after immature B cells emigrate to the periphery. For the majority of B cells, the final stages of maturation occur in the B-cell follicles of the spleen and require the TNF family member BAFF as well as signals through the B-cell receptor.

Development of T lymphocytes.

Like B cells, T lymphocytes derive from the multipotent hematopoietic stem cells in the bone marrow. However, T-cell progenitors migrate from the bone marrow via the blood to the thymus, where they mature (Fig. 8.15); this is the reason for the name thymus-dependent (T) lymphocytes, or T cells. T-cell development parallels that of B cells in many ways, including the orderly and stepwise rearrangement of antigen receptor genes, the sequential testing for successful gene rearrangement, and the eventual assembly of a heterodimeric antigen receptor. Nevertheless, T-cell development in the thymus has some features not seen for B cells, such as the generation of two distinct lineages of T cells expressing antigen receptors encoded by distinct genes, the

Fig. 8.15 T cells undergo development in the thymus and migrate to the peripheral lymphoid organs, where they are activated by foreign antigens. T-cell precursors migrate from the bone marrow to the thymus, where they commit to the T-cell lineage after Notch receptor signaling. In the thymus, T-cell receptor genes are rearranged (top first panel); αβ T-cell receptors that are compatible with self MHC molecules transmit a survival signal on interacting with thymic epithelium, leading to positive selection of the cells that bear them. Self-reactive receptors transmit a signal that leads to cell death, and cells bearing them are removed from the repertoire in a process of negative selection (top second panel). T cells that survive selection mature and leave the thymus to circulate in the periphery; they repeatedly leave the blood to migrate through the peripheral lymphoid organs, where they may encounter their specific foreign antigen and become activated (top third panel). Activation leads to clonal expansion and differentiation into effector T cells. Some of these are attracted to sites of infection, where they can kill infected cells or activate macrophages and other innate immune cells not pictured (top fourth panel); others are attracted into B-cell areas, where they help to activate an antibody response (not shown).



Precursors commit to the T-cell lineage after Notch signaling in the thymus and initiate T-cell receptor gene rearrangements

Mature T cells migrate to the peripheral lymphoid organs
Activated T cells migrate to sites of infection

γδ lineage and the αβ lineage. Developing T cells, which are known generally as **thymocytes**, also undergo rigorous selection that depends on interactions with thymic cells and that shapes the mature repertoire of T cells to ensure self MHC restriction as well as self-tolerance. We begin with a general overview of the stages of thymocyte development and its relationship to thymic anatomy before considering gene rearrangement and the mechanisms of selection.

8-11 T-cell progenitors originate in the bone marrow, but all the important events in T-cell development occur in the thymus.

The thymus is situated in the upper anterior thorax, just above the heart. It consists of numerous lobules, each clearly differentiated into an outer cortical region—the **thymic cortex**—and an inner **medulla** (Fig. 8.16). In young individuals, the thymus contains large numbers of developing T-cell precursors embedded in a network of epithelia known as the **thymic stroma**. This provides a unique microenvironment for T-cell development analogous to that provided for B cells by the stromal cells of the bone marrow.

The thymic epithelium arises early in embryonic development from endoderm-derived structures known as the third pharyngeal pouches. These epithelial tissues form a rudimentary thymus, or **thymic anlage**. The thymic anlage is colonized by cells of hematopoietic origin that give rise to large numbers of thymocytes, which are committed to the T-cell lineage, and to **intrathymic dendritic cells**. Thymocytes are not simply passengers within the thymus: they influence the arrangement of the thymic epithelial cells on which they depend for survival, inducing the formation of a reticular epithelial structure that surrounds the developing thymocytes.

The cellular architecture of the human thymus is illustrated in Fig. 8.16. Bone marrow–derived cells are differentially distributed between the thymic cortex and medulla. The cortex contains only immature thymocytes and scattered

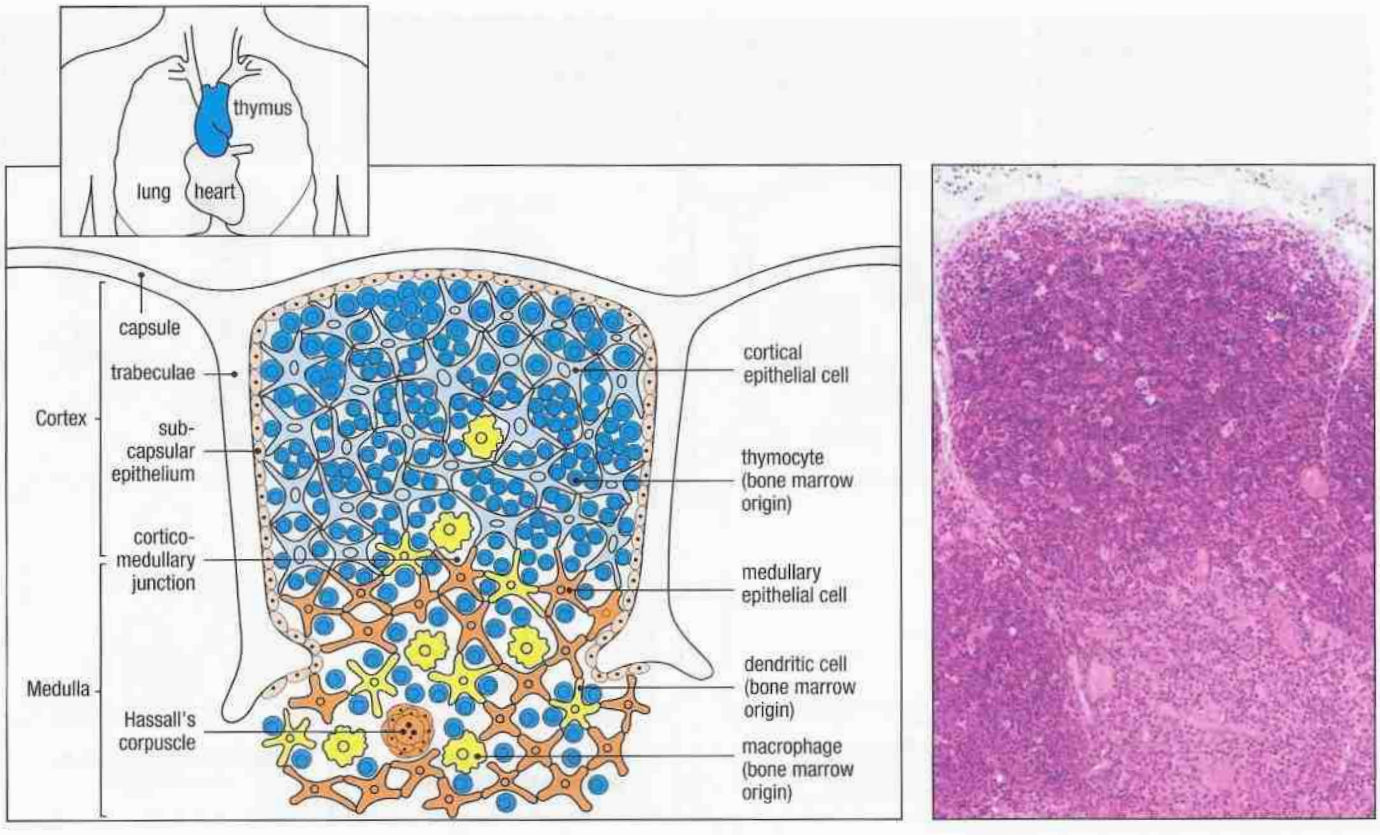

Fig. 8.16 The cellular organization of the human thymus. The thymus, which lies in the midline of the body, above the heart, is made up of several lobules, each of which contains discrete cortical (outer) and medullary (central) regions. As shown in the diagram on the left, the cortex consists of immature thymocytes (dark blue); branched cortical epithelial cells (pale blue), with which the immature cortical thymocytes are closely associated; and scattered macrophages (yellow), which are involved in clearing apoptotic thymocytes. The medulla consists of mature thymocytes (dark blue) and medullary epithelial cells (orange), along with macrophages (yellow) and dendritic cells (yellow) of bone marrow origin. Hassall's corpuscles are probably also sites of cell degradation. The thymocytes in the outer cortical cell layer are proliferating immature cells, whereas the deeper cortical thymocytes are mainly immature T cells undergoing thymic selection. The photograph shows the equivalent section of a human thymus, stained with hematoxylin and eosin. The cortex is darkly stained, whereas the medulla is lightly stained.

macrophages, whereas more mature thymocytes, along with dendritic cells, macrophages, and some B cells, are found in the medulla. As will be discussed later, this organization reflects the different developmental events that occur in these two compartments.

The importance of the thymus in immunity was first discovered through experiments on mice; indeed, most of our knowledge of T-cell development in the thymus comes from the mouse. It was found that surgical removal of the thymus (**thymectomy**) at birth resulted in immunodeficient mice, focusing interest on this organ at a time when the difference between T and B lymphocytes in mammals had not yet been defined. Much evidence, including observations in immunodeficient children, has since confirmed the importance of the thymus in T-cell development. In **DiGeorge syndrome** in humans and in mice with the ***nude*** mutation, the thymus does not form, and the affected individual produces B lymphocytes but few T lymphocytes. DiGeorge syndrome is a complex combination of cardiac, facial, endocrine, and immune defects associated with deletions of chromosome 22q11. The *nude* mutation in mice is due to a defect in the gene for Foxn1, a transcription factor required for terminal epithelial-cell differentiation; the name *nude* was given to this mutation because it also causes hairlessness. Rare cases of a defect in the human FOXN1 gene (which is on chromosome 17) have been associated with T-cell immunodeficiency, absence of a thymus, congenital alopecia, and nail dystrophy.

DiGeorge Syndrome

In mice, the thymus continues to develop for 3–4 weeks after birth, whereas in humans it is fully developed at birth. The rate of T-cell production by the thymus is greatest before puberty. After puberty, the thymus begins to shrink, and the production of new T cells in adults is reduced, although it does continue throughout life. In both mice and humans, removal of the thymus after puberty is not accompanied by any notable loss of T-cell function or numbers. Thus, it seems that once the T-cell repertoire is established, immunity can be sustained without the production of significant numbers of new T cells; the pool of peripheral T cells is instead maintained by long-lived T cells and also by division of some mature T cells.

8-12 T-cell precursors proliferate extensively in the thymus, but most die there.

T-cell precursors arriving in the thymus from the bone marrow spend up to a week differentiating there before they enter a phase of intense proliferation. In a young adult mouse the thymus contains about 10^8 to 2×10^8 thymocytes. About 5×10^7 new cells are generated each day; however, only about 10^6 to 2×10^6 (roughly 2–4%) of these leave the thymus each day as mature T cells. Despite the disparity between the number of T cells generated in the thymus and the number leaving, the thymus does not continue to grow in size or cell number. This is because about 98% of the thymocytes developing in the thymus die by apoptosis (see Section 1-13). Cells undergoing apoptosis are recognized and ingested by macrophages, and apoptotic bodies, which are the residual condensed chromatin of apoptotic cells, are seen inside macrophages throughout the thymic cortex (Fig. 8.17). This apparently profligate waste of thymocytes is a crucial part of T-cell development because it reflects the intensive screening that each thymocyte undergoes for the ability to recognize self peptide:self MHC complexes and for self-tolerance.

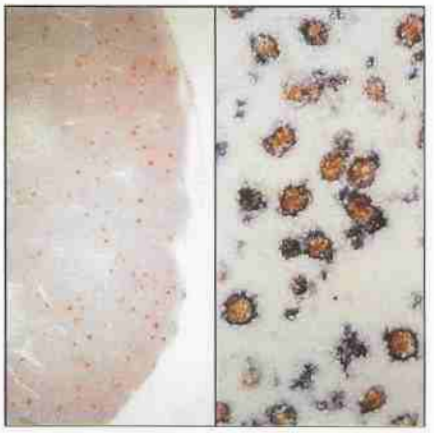

Fig. 8.17 Developing T cells that undergo apoptosis are ingested by macrophages in the thymic cortex. The left panel shows a section through the thymic cortex and part of the medulla in which cells have been stained for apoptosis using a red dye. The thymic cortex is to the right in the photograph. Apoptotic cells are scattered throughout the cortex but are rare in the medulla likely due to the lower density of thymocytes in the medulla. The right panel shows at higher magnification a section of thymic cortex that has been stained red for apoptotic cells and blue for macrophages. The apoptotic cells can be seen within macrophages. Magnifications: left panel, ×45; right panel, ×164.

8-13 Successive stages in the development of thymocytes are marked by changes in cell-surface molecules.

Like developing B cells, developing thymocytes pass through a series of distinct stages. These are marked by changes in the status of the T-cell receptor genes and in the expression of the T-cell receptor, and by changes in the

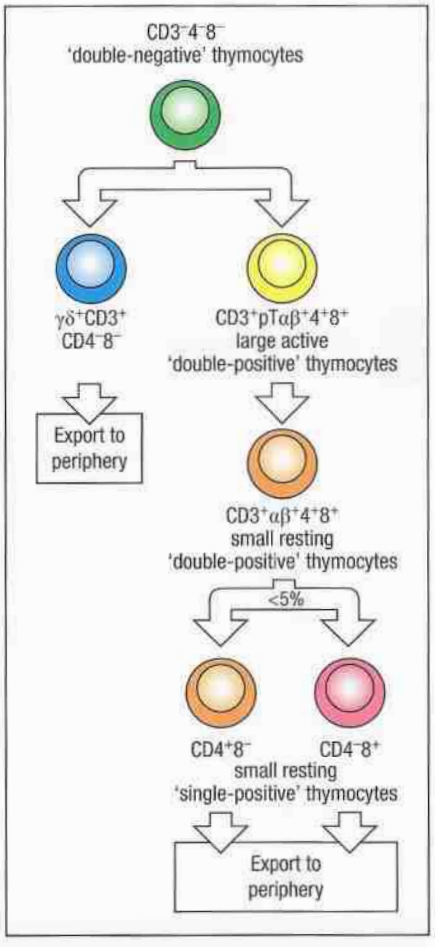

Fig. 8.18 Distinct lineages of thymocytes are produced in the thymus. CD4, CD8, and T-cell receptor complex molecules (CD3, and the T-cell receptor α and β chains) are important cell-surface molecules for identifying thymocyte subpopulations. The earliest cell population in the thymus does not express any of these proteins, and because these cells do not express CD4 or CD8, they are called 'double-negative' thymocytes. These cells include precursors that give rise to two T-cell lineages: the minority population of γδ T cells (which lack CD4 or CD8 even when mature), and the majority αβ T-cell lineage. The development of prospective αβ T cells proceeds through stages in which both CD4 and CD8 are expressed by the same cell; these are known as 'double-positive' thymocytes. Early on, these cells are large proliferating cells. Later, they become small resting double-positive cells that express low levels of the T-cell receptor. Most thymocytes die within the thymus after becoming small double-positive cells, but those cells whose receptors can interact with self peptide:self MHC molecular complexes lose expression of either CD4 or CD8 and increase the level of expression of the T-cell receptor. The outcome of this process is the 'single-positive' thymocytes, which, after maturation, are exported from the thymus as mature single-positive CD4 or CD8 T cells.

expression of cell-surface proteins such as the CD3 complex (see Section 7-7) and the co-receptor proteins CD4 and CD8 (see Section 4-21). These surface changes reflect the state of functional maturation of the cell, and particular combinations of cell-surface proteins are used as markers for T cells at different stages of differentiation. Two distinct lineages of T cells—αβ and γδ, which have different types of T-cell receptor chains—are produced early in T-cell development. Later, αβ T cells develop into two distinct functional subsets—CD4 T cells and CD8 T cells.

When progenitor cells first enter the thymus from the bone marrow, they lack most of the surface molecules characteristic of mature T cells, and their receptor genes are not rearranged. These cells are often referred to as 'double-negative' thymocytes, as they lack expression of both CD4 and CD8. Double-negative thymocytes give rise to the major population of αβ T cells and the minor population of γδ T cells (Fig. 8.18). If injected into the peripheral circulation, these lymphoid progenitors can even give rise to B cells and NK cells, although it is uncertain whether individual thymic progenitor cells retain this multipotency or whether the progenitor-cell population consists of a mixture of cells, only some of which are fully committed to the αβ or γδ T-cell lineage.

In the postnatal thymus, only ~60% of the double-negative thymocytes are immature T cells. The double-negative thymocyte pool (about 5% of all thymocytes) also includes two populations of more mature T cells that belong to minority lineages, including T cells expressing γδ T-cell receptors (Fig. 8.18) and T cells bearing αβ T-cell receptors of very limited diversity (iNKT cells; see Section 6-18). Here and in subsequent discussions, we reserve the term 'double-negative thymocytes' for the immature thymocytes that do not yet express a complete T-cell receptor molecule. These double-negative thymocytes give rise to both γδ and αβ T cells (see Fig. 8.18), although most of them develop along the αβ pathway. Mature γδ T cells remain double-negative and are exported to the periphery to populate various tissue sites (see Section 8-17). αβ T cells progress through several additional stages before leaving the thymus. First the double-negative thymocytes progress to a stage known as 'double-positive,' where thymocytes co-express both CD4 and CD8 receptors. Lastly, thymocyte development generates two different subsets: one subset expressing CD4 but not CD8 ($CD4^+8^-$) and a second subset expressing CD8 but not CD4 ($CD4^-8^+$), both of which are exported from the thymus into the periphery (Fig. 8.18).

8-14 Commitment to the T-cell lineage occurs in the thymus after Notch signaling.

T lymphocytes develop from a lymphoid progenitor in the bone marrow that also gives rise to B lymphocytes. Some of these progenitors leave the bone marrow and migrate to the thymus. In the thymus, these progenitor cells

are known as early thymic progenitors (ETPs). ETPs receive a signal from thymic epithelial cells that is transduced through a receptor called Notch to switch-on specific genes. Notch signaling is widely used in animal development to specify tissue differentiation; in lymphocyte development, the Notch signal instructs the precursor to commit to the T-cell lineage rather than the B-cell lineage. Notch signaling is required throughout T-cell development and is also thought to help regulate other T-cell lineage choices, including the αβ versus γδ choice.

Notch signaling in thymic progenitor cells is essential to initiate the T cell–specific gene expression program and commitment to the T-cell lineage (Fig. 8.19). Notch signaling induces the expression of two transcription factors, T-cell factor-1 (TCF1) and GATA3, both of which are required for T-cell development. Together, TCF1 and GATA3 initiate expression of several T lineage–specific genes, such as those encoding components of the CD3 complex, as well as *RAG1*, a gene required for T-cell receptor and B-cell receptor gene rearrangements. However, TCF1 and GATA3 are not sufficient to induce the entire program of T cell–specific gene expression. A third transcription factor, Bcl11b, is required to induce T-lineage commitment by restricting progenitor cells from adopting alternative fates; this final phase of T-cell commitment is a necessary prerequisite for activating the complete T-cell gene expression program.

Notch signaling also induces the expression of the IL-7 receptor α chain. IL-7 is an important cytokine that is produced by the thymic stroma, and IL-7 receptor signaling is essential for maintaining the survival of thymic progenitor cells. The receptor for IL-7 is composed of the IL-7 receptor α chain and a receptor subunit called γ-c that is shared with several other cytokine receptors (see Sections 3-15 and 3-16). All of the cytokine receptors that use γ-c as a subunit activate the tyrosine kinase Jak3, which is essential for receptor signaling. In the absence of IL-7, IL-7 receptor α, γ-c, or Jak3, a severe block in T-cell development occurs in both mice and humans. In fact, the human primary immunodeficiency disease characterized by a lack of T cells and NK cells, X-linked severe combined immune deficiency (X-linked SCID) disease, is caused by a genetic deficiency leading to the absence of γ-c protein expression.

X-linked Severe Combined Immune Deficiency

Interactions with the thymic stroma trigger an initial phase of differentiation along the T-cell lineage pathway, followed by cell proliferation and the expression of the first cell-surface molecules specific for T cells; for example, CD2 and (in mice) Thy-1. At the end of this phase, which can last about a week, the thymocytes bear distinctive markers of the T-cell lineage but do not express any of the three cell-surface markers that define mature T cells. These are the CD3:T-cell receptor complex and the co-receptors CD4 or CD8. Because of the absence of CD4 and CD8, such cells are called **double-negative thymocytes** (see Fig. 8.18).

The αβ pathway is shown in more detail in Fig. 8.19. The double-negative stage can be further subdivided into four stages on the basis of the state of differentiation. The earliest stage of thymocyte development is the early thymic progenitor (ETP), sometimes referred to as **DN1** cells. ETPs express Kit, the receptor for stem-cell factor (SCF) (see Figure 8.3); in these cells, the genes encoding both chains of the T-cell receptor are in the germline configuration, and the cells retain the potential to develop into T cells, B cells, NK cells, and some myeloid cells. As thymocytes mature, they begin to express CD25 (the α chain of the IL-2 receptor) along with Kit on their surface and gradually lose the potential to develop into non-T-cell lineages; these cells are called **pro-T cells**, sometimes referred to as **DN2** cells. Kit expression is lost at the next stage of thymocyte maturation; these cells are **pre-T cells**, or **DN3** cells, and are fully committed to develop into T cells, having lost the potential to develop into any other hematopoietic lineages.

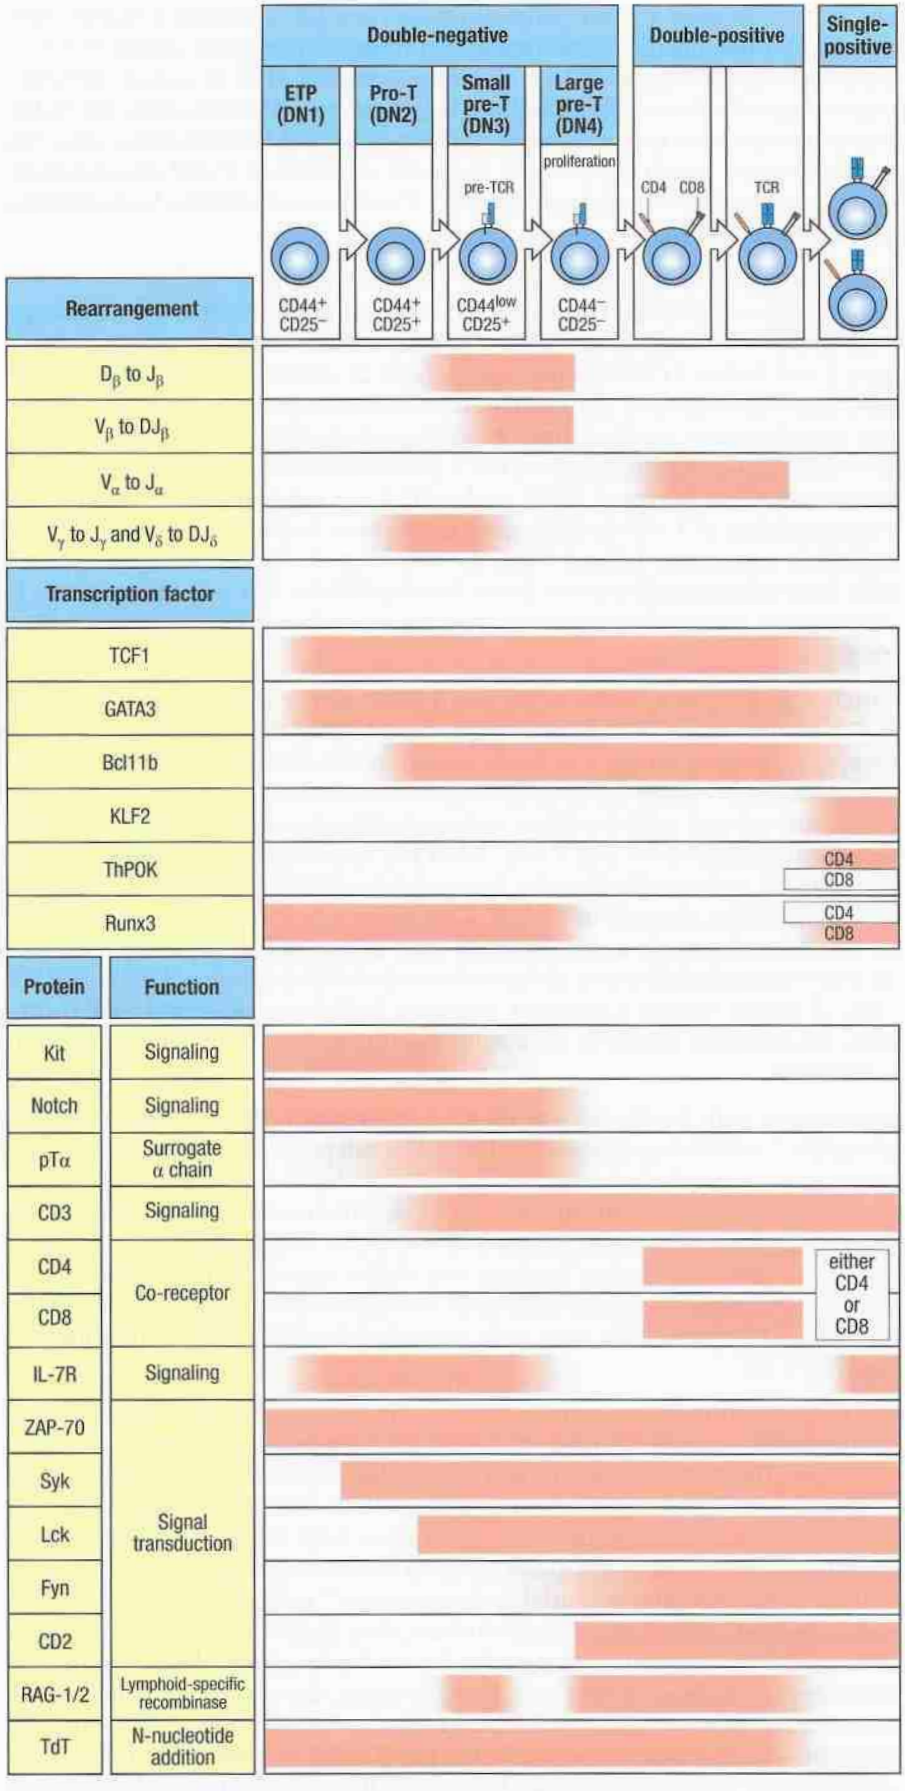

Fig. 8.19 The stages of αβ T-cell development in the mouse thymus correlate with the program of gene rearrangement and the expression of cell-surface proteins, signaling proteins, and transcription factors. Early thymic progenitors (ETPs) are triggered to proliferate and become thymocytes committed to the T-cell lineage through interactions with Notch ligands expressed on the thymic stroma. T-cell commitment requires Notch signaling to induce the expression of TCF1 and GATA3, which in turn induce the expression of Bcl11b. This gene expression program begins in the ETP [also known as double-negative (DN1)] cells that express CD44 and Kit. Cells become irreversibly committed to the T-cell lineage at the subsequent (pro-T; DN2) stage, which is marked by expression of CD25, the α chain of the IL-2 receptor. Then the pro-T ($CD44^+CD25^+$) cells begin to rearrange the β-chain locus, becoming $CD44^{low}$ and Kit^{low}, and they become pre-T (DN3) cells. The small pre-T cells are arrested in the $CD44^{low}CD25^+$ stage until they productively rearrange the β-chain locus; the in-frame β chain then pairs with a surrogate chain called pTα to form the pre-T-cell receptor (pre-TCR), which is expressed on the cell surface and triggers entry into the cell cycle. Expression of small amounts of pTα:β on the cell surface in association with CD3 signals the cessation of β-chain gene rearrangement and triggers rapid cell proliferation, which causes the loss of CD25. The cells are then known as large pre-T (DN4) cells. CD4 and CD8 expression is initiated, and the $CD4^+CD8^+$ double-positive cells cease to proliferate. These nonproliferating small $CD4^+CD8^+$ double-positive cells begin efficient rearrangement at the α-chain locus. The cells then express low levels of an αβ T-cell receptor and the associated CD3 complex and are ready for selection. Most cells die by failing to be positively selected or as a consequence of negative selection, but some are selected to mature into CD4 or CD8 single-positive cells and eventually to leave the thymus. Maturation of $CD4^+CD8^+$ double-positive cells into CD4 or CD8 single-positive cells is regulated by transcription factors ThPOK and Runx3, respectively. KLF2 is first expressed at the single-positive stage; if it is absent, thymocytes exhibit a defect in emigrating to peripheral lymphoid tissues, due in part to their failure to express receptors involved in trafficking, such as the sphingosine 1-phosphate (S1P) receptor, S1PR1 (see Fig. 8.32). The individual contributions to T-cell development of the other proteins are discussed in the text.

8-15 After T-cell commitment, thymocyte development is regulated by T-cell receptor rearrangement, expression, and signaling.

Rearrangement of the T-cell receptor β-chain locus begins in pro-T cells with some D_β to J_β rearrangements and continues in pre-T cells with V_β to DJ_β rearrangement. Cells that fail to make a successful rearrangement of the β-chain locus remain at the pre-T stage and soon die, whereas cells that make productive β-chain gene rearrangements and express the β-chain protein progress to a large pre-T cell stage, often called the **DN4** stage. These cells undergo proliferation, leading to the loss of CD25 expression. In spite of its usefulness in identifying these thymocyte subsets, the functional significance of the transient expression of CD25 is unclear: conventional CD4 and CD8 T cells develop normally in mice in which the IL-2 gene has been deleted by gene knockout (see Appendix I, Section A-36). By contrast, Kit is quite important for the development of the earliest double-negative thymocytes, in that mice lacking Kit have a much smaller number of double-negative T cells. In addition, continual Notch signaling is important for progression through each stage of T-cell development.

In thymocytes at the pre-T cell stage (see Fig. 8.19), the expressed β chains pair with a surrogate pre-T-cell receptor α chain called **pTα** (pre-T-cell **α**), which allows the assembly of a complete **pre-T-cell receptor** (pre-TCR) that is analogous in structure and function to the pre-B-cell receptor. The pre-TCR is expressed on the cell surface in a complex with the CD3 molecules that provide the signaling components of T-cell receptors (see Section 7-7). As with the pre-B-cell receptor, the assembly of the CD3:pre-T-cell receptor complex causes constitutive signaling that does not require interaction with a ligand. Recent structural evidence shows that the pre-TCR forms dimers in a manner similar to pre-BCR dimerization. The pTα Ig domain makes two important contacts. It associates with the constant-region Ig domain of the V_β subunit to form the pre-TCR itself. A distinct surface of the pTα then binds to a V_β domain from another pre-TCR molecule, forming a bridge between two different pre-TCRs. The region of contact with the V_β involves residues that are highly conserved across many V_β families. In this way, expression of the pre-TCR induces ligand-independent dimerization, which leads to cell proliferation, the arrest of further β-chain gene rearrangement, and the expression of both CD8 and CD4.

Double-positive thymocytes make up the vast majority of thymocytes. Once the large double-positive thymocytes have ceased to proliferate and have become small double-positive cells, the α-chain locus begins to rearrange. As we will see later in this chapter, the structure of the α locus (see Section 5-10) allows multiple successive attempts at rearrangement, so that it is successfully rearranged in most developing thymocytes. Thus, most double-positive cells produce an αβ T-cell receptor during their relatively short life span. Small double-positive thymocytes initially express low levels of the T-cell receptor. Not all double-positive thymocytes continue the developmental process to become mature T cells. On the basis of selection processes that depend on T-cell receptor signaling, a small subset of double-positive cells down-regulates one of the two co-receptor molecules, becoming either CD4 or CD8 **single-positive thymocytes** (see Fig. 8.18 and Fig. 8.19). Single-positive thymocytes continue to undergo selection processes that shape the T-cell repertoire and promote the development of multiple T-cell lineages, including conventional CD4 and CD8 T cells, T_{reg} cells, NK-T cells, MAIT cells, and others (see Section 8-27). Thus, of the original pool of double-positive thymocytes, only about 2% survive and are exported from the thymus to form the peripheral T-cell repertoire. Overall, the time between the entry of a T-cell progenitor into the thymus and the export of its mature progeny is estimated to be about 3 weeks in the mouse.

8-16 Thymocytes at different developmental stages are found in distinct parts of the thymus.

ANIMATION 8.1

The thymus is divided into two main regions, a peripheral cortex and a central medulla (see Fig. 8.16). Most T-cell development takes place in the cortex; only mature single-positive thymocytes are seen in the medulla. Initially, progenitors from the bone marrow enter the thymus from the blood at the cortico-medullary junction and migrate to the outer cortex (Fig. 8.20). At the outer edge of the cortex, in the subcapsular region of the thymus, large immature double-negative thymocytes proliferate vigorously; these cells are thought to represent committed thymocyte progenitors and their immediate progeny and will give rise to all subsequent thymocyte populations. Deeper in the cortex, most of the thymocytes are small double-positive cells. The cortical stroma is composed of epithelial cells with long branching processes that express both MHC class II and MHC class I molecules on their surface. The thymic cortex is densely packed with thymocytes, and the branching processes of the thymic cortical epithelial cells make contact with almost all cortical thymocytes. Contact between the MHC molecules on thymic cortical epithelial cells and the receptors of developing T cells has a crucial role in positive selection, as we will see later in this chapter.

After positive selection, developing T cells migrate from the cortex to the medulla. The medulla contains fewer lymphocytes, and those present are predominantly the newly matured single-positive T cells that will eventually leave the thymus. The medulla plays a role in negative selection. The antigen-presenting cells in this environment include dendritic cells that express co-stimulatory molecules, which are generally absent from the cortex. In addition, specialized medullary epithelial cells present peripheral antigens for the negative selection of T cells reactive for these self antigens.

8-17 T cells with αβ or γδ receptors arise from a common progenitor.

T cells bearing γδ receptors differ from αβ T cells in that they are found primarily in epithelial and mucosal sites and lack expression of the CD4 and CD8 co-receptors; in comparison with αβ T cells, relatively little is known about the ligands recognized by the γδ T-cell receptors, which are thought not to be MHC restricted (see Section 4-23). Recall from Section 5-10 that different genetic loci are used to make these two types of T-cell receptors. The γ and δ loci are

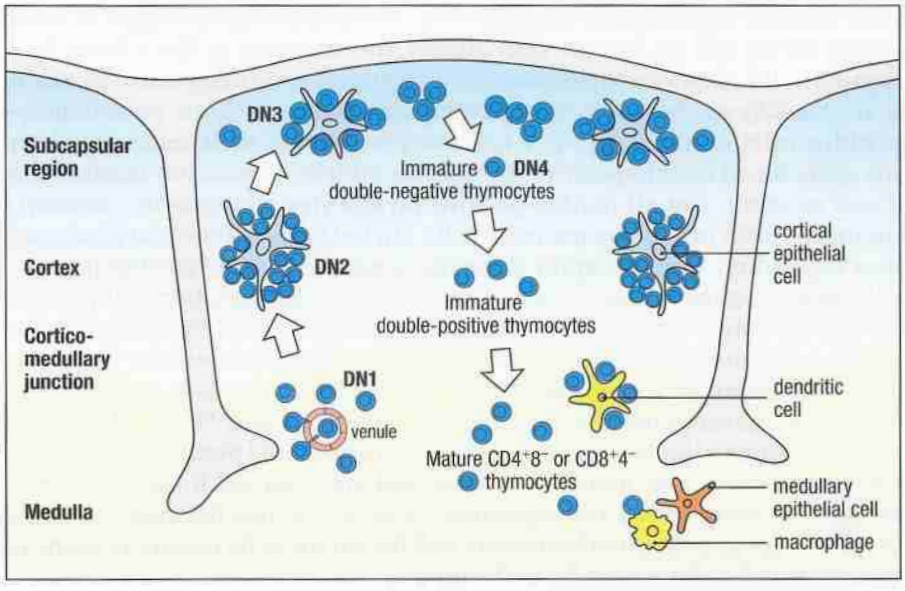

Fig. 8.20 Thymocytes at different developmental stages are found in distinct parts of the thymus. The earliest precursor thymocytes enter the thymus from the bloodstream via venules near the cortico-medullary junction. Ligands that interact with the receptor Notch are expressed in the thymus and act on the immigrant cells to commit them to the T-cell lineage. As these cells differentiate through the early $CD4^-CD8^-$ double-negative (DN) stages described in the text, they migrate from the cortico-medullary junction to the outer cortex. DN3 cells reside near the subcapsular region, where they undergo proliferation. As the progenitor matures further to the $CD4^+CD8^+$ double-positive stage, it migrates back through the cortex. Finally, the medulla contains mature single-positive T cells, which eventually leave the thymus.

the first to undergo rearrangement, followed shortly thereafter by the β locus. In addition, the δ locus is contained within the α locus, so rearrangements at the α locus eliminate the δ coding sequences on the chromosome. While the mechanism regulating commitment of individual precursor cells to the αβ versus the γδ lineage is still not understood, there is some plasticity in this process. This can be deduced from the pattern of gene rearrangements found in thymocytes and in mature γδ and αβ T cells. Mature γδ T cells can contain rearranged β-chain genes, although 80% of these are nonproductive, and mature αβ T cells often contain rearranged, but mostly out-of-frame, γ-chain genes.

8-18 T cells expressing γδ T-cell receptors arise in two distinct phases during development.

Although γδ T cells arise from the same progenitors as αβ T cells, most mature γδ T cells are components of the innate rather than the adaptive immune system. When their maturation in the thymus is complete, the cells have acquired a defined effector function that can be rapidly elicited after their activation. After emigration from the thymus, most γδ T cells home to mucosal and epithelial sites in the body and take up stable residence in these locations.

In mice, the majority of γδ T cells in the body arise during embryonic development and the early neonatal period. In the fetal thymus, the first T cells to develop are γδ T cells that all express T-cell receptors assembled from the same V_γ and V_δ regions (Fig 8.21). These cells populate the epidermis; the T cells become wedged among the keratinocytes and adopt a dendritic-like form that has given them the name of **dendritic epidermal T cells (DETCs)** (Fig. 8.22). The DETCs provide surveillance of the skin and respond to infection and injury by producing cytokines and chemokines. These factors induce inflammation to enhance pathogen clearance, and they promote wound healing to repair lesions in the skin. In steady-state conditions, DETCs also produce growth factors that help maintain epidermal growth and survival.

After the development of DETC cells, a second subset of γδ T cells develops in the fetal thymus. These cells home to mucosal epithelia of tissues such as the reproductive tract and the lung, and also to the dermis of the skin. This subset is programmed to produce inflammatory cytokines such as IL-17 when stimulated and is thought to play a role in responses to infection and injury. Like the DETCs, these IL-17–producing γδ T ($T_{\gamma\delta}$-17) cells express T-cell receptors that are essentially invariant, being composed of a single V_γ–V_δ combination. However, the two subsets, DETCs and the fetal $T_{\gamma\delta}$-17 cells, express T-cell receptors that use distinct V_γ gene segments—$V_{\gamma5}$ in the DETCs and $V_{\gamma6}$ in the $T_{\gamma\delta}$-17 cells. As fetal thymocytes do not express the enzyme TdT, there are no N-nucleotides contributing additional diversity at the junctions between V, D, and J gene segments of the T-cell receptors in these two fetally derived subsets of γδ T cells. Why certain V, D, and J gene segments are selected for rearrangement at particular times during embryonic development remains incompletely understood.

DETCs and the $V_{\gamma6}$-positive $T_{\gamma\delta}$-17 cells develop exclusively from the early wave of hematopoietic stem cells derived from the fetal liver (see Fig. 8.21). Consequently, these two γδ T-cell subsets arise only for a brief period of time in the fetal thymus, and then never again. A second phase of γδ T-cell development is initiated in the fetal thymus just before birth. This phase persists at a low level in the adult thymus throughout life and produces several subsets of cells, each with distinct effector functions and tissue-homing properties. Like the DETCs and fetal $T_{\gamma\delta}$-17 cells, these later-developing γδ T cells can be generally classified by their usage of distinct V_γ–V_δ regions in their T-cell receptors (see Fig. 8.21), although the receptor sequences within each population are more diverse because of the presence of N-region nucleotides added by TdT.

Fig. 8.21 The rearrangement of T-cell receptor γ and δ genes in the mouse proceeds in waves of cells expressing different V_{γ} and V_{δ} gene segments. At about 2 weeks of gestation in the mouse, the $C_{\gamma 1}$ locus is expressed with its closest V gene ($V_{\gamma 5}$). After a few days, $V_{\gamma 5}$-bearing cells decline in number in the thymus (first row of panels) and are replaced by cells expressing the next most proximal gene, $V_{\gamma 6}$. Both these rearranged γ chains are expressed with the same rearranged δ-chain gene, as shown in the lower panels, and there is little junctional diversity in either the V_{γ} or the V_{δ} chain. As a consequence, most of the γδ T cells produced in each of these early waves share the same specificity, although the antigen recognized in each case is not known. The $V_{\gamma 5}$-bearing cells become established selectively in the epidermis; they are programmed to secrete keratinocyte growth factor and inflammatory cytokines and chemokines. In contrast, $V_{\gamma 6}$-bearing cells become established in the lung, the dermis of the skin, and the epithelium of the reproductive tract and are programmed to secrete IL-17. The next wave of γδ development begins on day 17 of gestation and produces two different populations. One population rearranges and expresses the $V_{\gamma 4}$ chain, which pairs with heterogeneous delta chains. These $V_{\gamma 4}$-bearing cells are the second subset of $T_{\gamma\delta}$-17 (IL-17–secreting) cells and home to lymph nodes, spleen, lung, and the dermis of the skin. The second population in this wave expresses $V_{\gamma 1}$ and homes to lymph nodes, spleen, and liver. Some of these cells are paired with $V_{\delta 6}$ chains and are programmed to secrete IL-4 and IFN-γ, and represent γδ NKT cells. Finally, the last wave of γδ T-cell development begins late during fetal development and persists into adulthood. This last wave includes a heterogeneous population of cells bearing $V_{\gamma 1}$, $V_{\gamma 2}$, and $V_{\gamma 4}$ chains paired with many different delta chains. These cells home to lymphoid organs and are programmed to secrete IFN-γ. The other population in this last wave are cells bearing the $V_{\gamma 7}$ chain paired with heterogeneous delta chains. These γδ cells home to the intestinal epithelium and are programmed to secrete IFN-γ as well as antimicrobial compounds. Although γδ T cells continue to be produced after birth, at this stage the αβ T-cell lineage becomes the dominant population developing in the thymus.

One population of these later-developing γδ T cells is programmed to secrete IL-17 when activated; these represent a second subset of $T_{\gamma\delta}$-17 cells that express a different V_γ region than do the fetal $T_{\gamma\delta}$-17 cells. Specifically, these later-developing $T_{\gamma\delta}$-17 cells express T-cell receptors using the $V_{\gamma4}$ region. This $T_{\gamma\delta}$-17 subset is found in all lymphoid organs, as well as in the skin dermis and the intestinal epithelium, where the cells provide rapid inflammatory signals in response to bacterial and parasitic infections. In addition, γδ T cells using the $V_{\gamma7}$ region in their T-cell receptors also develop in this second phase. The $V_{\gamma7}$-positive γδ T cells home specifically to the intestinal epithelium. In that location, the cells are poised to respond to gut microbes that breach the epithelial barrier and are important producers of antibacterial compounds as well as IFN-γ.

In contrast to the γδ T-cell subsets that reside in barrier tissues such as the skin and intestinal epithelium, γδ T cells are also found in lymphoid organs. The majority of the lymphoid-resident γδ T cells arise during the late fetal–early neonatal period as well as thereafter, and represent a more diverse population expressing the $V_{\gamma1}$ region. $V_{\gamma1}$-positive T cells are composed of two major groups—an IFN-γ– plus IL-4–producing subset that homes to the liver as well as several lymphoid organs, and an IFN-γ–producing subset that homes to all lymphoid organs. The former population of cells, which can be identified by their expression of a unique TCRδ chain ($V_{\delta6}$) that is paired to a $V_{\gamma1}$ chain, is remarkably similar to the αβ T-cell receptor–expressing subset of iNKT cells, and the cells are therefore often referred to as γδ NKT cells. Unlike the mucosal and epithelial resident γδ T-cell populations, whose importance in tissue homeostasis, repair, and innate defense against infections has been well established, the functions of γδ T cells within secondary lymphoid organs are still not well understood.

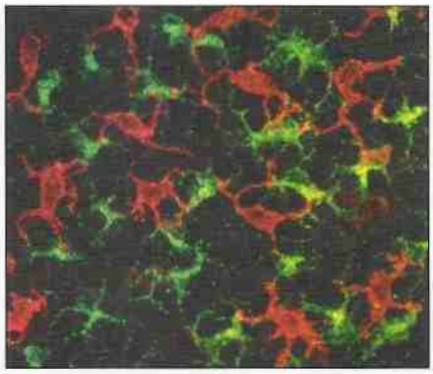

Fig. 8.22 Dendritic epidermal T cells reside within the epithelial layer, forming an interdigitating network with Langerhans cells. This face-on view of a murine epidermal sheet shows Langerhans cells (green) and dendritic epidermal T cells (DETCs; red) forming an interdigitating network within the layers of the epidermis. The epidermal epithelial cells are not visible in this fluorescence image. The branching dendritic-like form of these γδ T cells is the source of their name. Although the ligands for all γδ T-cell receptors are not known, some γδ T cells recognize nonclassical MHC molecules (see Sections 6-16, 6-17, and 6-20), which can be induced in epithelia by stresses such as UV damage or pathogens. Thus, DETCs may serve as sentinels of such damage, producing cytokines that activate the innate immune response and, in turn, adaptive immunity.

8-19 Successful synthesis of a rearranged β chain allows the production of a pre-T-cell receptor that triggers cell proliferation and blocks further β-chain gene rearrangement.

We now return to the development of αβ T cells. The rearrangement of the β- and α-chain loci closely parallels the rearrangement of immunoglobulin heavy-chain and light-chain loci during B-cell development (see Sections 8-3 through 8-6). As shown in Fig. 8.23, the β-chain gene segments rearrange first, with the D_β gene segments rearranging to J_β gene segments, and this is followed by V_β to DJ_β rearrangement. If no functional β chain can be synthesized from this rearrangement, the cell will not be able to produce a pre-T-cell receptor and will die. However, unlike B cells with nonproductive heavy-chain gene rearrangements, thymocytes with nonproductive β-chain VDJ rearrangements can be rescued by further rearrangement, which is possible because of the two clusters of D_β and J_β gene segments upstream of two C_β genes (see Fig. 5.14). The likelihood of a productive VDJ join at the β locus is therefore somewhat higher than the 55% chance for a productive immunoglobulin heavy-chain gene arrangement.

Once a productive β-chain gene rearrangement has occurred, the β chain is expressed together with the invariant pTα and the CD3 molecules (see Fig. 8.23) and is transported in this complex to the cell surface. The pTα:β complex is a functional pre-T-cell receptor analogous to the μ:VpreB:λ5 pre-B-cell receptor complex in B-cell development (see Section 8-4). Expression of the pre-T-cell receptor at the small pre-T cell (DN3) stage of thymocyte development induces signals that cause the phosphorylation and degradation of RAG-2, thus halting β-chain gene rearrangement and ensuring allelic exclusion at the β locus. These signals also induce the large pre-T cell (DN4) stage, in which rapid cell proliferation occurs, and eventually the co-receptor proteins CD4 and CD8 are expressed. The pre-T-cell receptor signals constitutively via the

Fig. 8.23 The stages of gene rearrangement in αβ T cells. The sequence of gene rearrangements is shown, together with an indication of the stage at which the events take place and the nature of the cell-surface receptor molecules expressed at each stage. The β-chain locus rearranges first, in $CD4^-CD8^-$ double-negative thymocytes expressing CD25 and low levels of CD44. As with immunoglobulin heavy-chain genes, D to J gene segments rearrange before V gene segments rearrange to DJ (second and third panels). It is possible to make up to four attempts to generate a productive rearrangement at the β-chain locus, because there are four D gene segments with two sets of J gene segments associated with each TCRβ-chain locus (not shown). The productively rearranged gene is expressed initially within the cell and then at low levels on the cell surface. It associates with pTα, a surrogate 33-kDa α chain that is equivalent to λ5 in B-cell development, and this pTα:β heterodimer forms a complex with the CD3 chains (fourth panel). The expression of the pre-T-cell receptor signals the developing thymocytes to halt b-chain gene rearrangement and to undergo multiple cycles of division. At the end of this proliferative burst, the CD4 and CD8 molecules are expressed, the cell ceases cycling, and the α chain is now able to undergo rearrangement. The first α-chain gene rearrangement deletes all δ D, J, and C gene segments on the chromosome, although these are retained as a circular DNA, indicating that these are nondividing cells (bottom panel). This permanently inactivates the δ-chain gene. Rearrangements at the α-chain locus can proceed through several cycles, because of the large number of V_α and J_α gene segments, so that productive rearrangements almost always occur. When a functional α chain is produced that pairs efficiently with the b chain, the $CD3^{low}CD4^+CD8^+$ thymocyte is ready to undergo selection for its ability to recognize self peptides in association with self MHC molecules.

cytoplasmic protein kinase Lck, an Src family tyrosine kinase (see Fig. 7.12), but seems not to require a ligand on the thymic epithelium. Lck subsequently associates with the co-receptor proteins. In mice genetically deficient in Lck, T-cell development is arrested before the $CD4^+CD8^+$ double-positive stage, and no α-chain gene rearrangements can be made.

The role of the expressed β chain in suppressing further β-locus rearrangement can be demonstrated in mice containing a rearranged TCRβ transgene: these mice express the transgenic β chain on virtually 100% of their T cells, and

rearrangement of their endogenous β-chain genes is strongly suppressed. The importance of pTα has been shown in mice deficient in pTα, in which there is a hundredfold decrease in αβ T cells and an absence of allelic exclusion at the β locus.

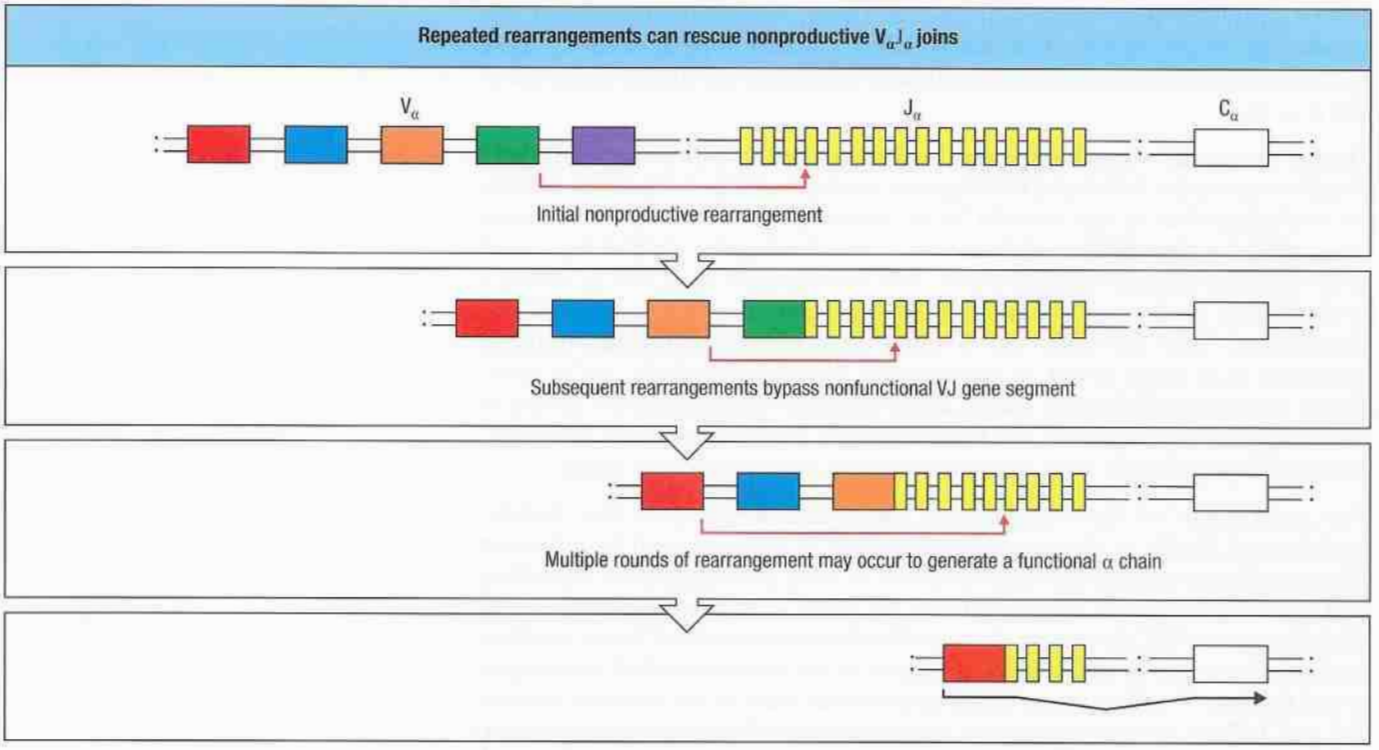
During the proliferation of large pre-T cells triggered by expression of the pre-T-cell receptor, the RAG1 and RAG2 genes are repressed (see Fig. 8.19). Hence, no rearrangement of the α-chain locus occurs until the proliferative phase ends, at which time *RAG1* and *RAG2* are transcribed again, and the functional RAG-1:RAG-2 complex accumulates. This ensures that each cell in which a β-chain gene has been successfully rearranged gives rise to many $CD4^+CD8^+$ thymocytes. Once the cells stop dividing, each of them can independently rearrange its α-chain genes, so that a single functional β chain can be associated with many different α chains in the progeny cells. During the period of α-chain gene rearrangement, αβ T-cell receptors are first expressed, and selection by self peptide:self MHC complexes on the thymus cells can begin.

The progression of thymocytes from the double-negative to the double-positive and finally to the single-positive stage is accompanied by a distinct pattern of expression of proteins involved in DNA rearrangement, signaling, and T cell–specific gene expression (see Fig. 8.19). Postnatal thymocytes continually express TdT, the enzyme responsible for the insertion of N-nucleotides, and consequently, N-nucleotides are found at the junctions of all rearranged α and β genes. T-cell receptor signaling proteins, such as the tyrosine kinases Lck and ZAP-70, are expressed from an early stage in thymocyte development. Lck is important in signaling from the pre-T-cell receptor, thereby playing a role in αβ T-cell development; Lck is also important for γδ T-cell development. In contrast, gene knockout studies (see Appendix I, Section A-36) show that ZAP-70, although expressed from the double-negative stage onward, is not essential for pre-T-cell receptor signaling, as double-negative thymocytes also express the related Syk kinase, which is capable of fulfilling this role. ZAP-70 is required later, to promote the development of single-positive thymocytes from double-positive thymocytes, as Syk is no longer expressed at this stage. Fyn, a Src family kinase similar to Lck, is expressed at increasing levels from the double-positive stage onward. It is not essential for the development of αβ thymocytes as long as Lck is present but is required for the development of iNKT cells (see Section 8-27).

8-20 T-cell α-chain genes undergo successive rearrangements until positive selection or cell death intervenes.

The T-cell receptor α-chain genes are comparable to the immunoglobulin κ and λ light-chain genes in that they do not have D gene segments and are rearranged only after their partner receptor chain has been expressed. As with the light-chain genes, repeated attempts at α-chain gene rearrangement are possible, as illustrated in Fig. 8.24. The presence of multiple V_α gene segments, and about 60 J_α gene segments spread over some 80 kilobases of DNA, allows many successive V_α to J_α rearrangements to take place at both α-chain alleles. This means T cells with an initial nonproductive α-gene rearrangement are much more likely to be rescued by a subsequent rearrangement than are B cells with a nonproductive light-chain gene rearrangement.

One key difference between B and T cells is that the final assembly of an immunoglobulin leads to the cessation of gene rearrangement and initiates the further differentiation of the B cell, whereas rearrangement of the V_α gene segments continues in T cells unless there is signaling by a self peptide:self MHC complex that positively selects the receptor (see Section 8-22). This means many T cells have in-frame rearrangements on both chromosomes and so can produce two types of α chains. This is possible because expression of the T-cell receptor is not in itself sufficient to shut off gene rearrangement.



Repeated rearrangements can rescue nonproductive $V_\alpha J_\alpha$ joins
V_α
J_α
C_α
Initial nonproductive rearrangement
Subsequent rearrangements bypass nonfunctional VJ gene segment
Multiple rounds of rearrangement may occur to generate a functional α chain

Fig. 8.24 Multiple successive rearrangement events can rescue nonproductive T-cell receptor α-chain gene rearrangements. The multiplicity of V and J gene segments at the α-chain locus allows successive rearrangement events to 'leapfrog' over previously rearranged VJ segments, deleting any intervening gene segments. The α-chain rescue pathway resembles that of the immunoglobulin κ light-chain genes (see Section 8-6), but the number of possible successive rearrangements is greater. α-chain gene rearrangement continues until either a productive rearrangement leads to positive selection or the cell dies.

Continued rearrangements on both chromosomes can allow several different α chains to be produced successively as well as simultaneously in each developing T cell and to be tested for self peptide:self MHC recognition in partnership with the same β chain. This phase of gene rearrangement lasts for 3 or 4 days in the mouse and ceases only when positive selection occurs as a consequence of receptor engagement or when the cell dies. One can predict that if the frequency of positive selection is sufficiently low, roughly one in three mature T cells will express two productively rearranged α chains at the cell surface. This has been confirmed for both human and mouse T cells. Thus, in the strict sense, T-cell receptor α-chain genes are not subject to allelic exclusion.

T cells with dual specificity might be expected to give rise to inappropriate immune responses if the cell is activated through one receptor yet can act upon target cells recognized by the second receptor. However, only one of the two receptors is likely to be able to recognize peptide presented by a self MHC molecule expressed in that individual, and so each T cell will still have only a single T-cell receptor that can function in antigen recognition. This is because once a thymocyte has been positively selected by self peptide:self MHC recognition, α-chain gene rearrangement ceases. Thus, the existence of cells with two α-chain genes productively rearranged and two α chains expressed at the cell surface does not truly challenge the idea that a single functional specificity is expressed by each cell.

Summary.

The thymus provides a specialized and architecturally organized microenvironment for the development of mature T cells. Precursors of T cells migrate from the bone marrow to the thymus, where they interact with environmental cues, such as ligands for the Notch receptor, that drive commitment to the T lineage. Developing thymocytes develop along one of several T-cell lineages: the most prominent subsets in the thymus are γδ T cells, conventional αβ T cells, and αβ T cells with receptors of very limited diversity, such as iNKT cells.

T-cell progenitors develop along the γδ or the αβ T-cell lineages. Early in ontogeny, the production of γδ T cells predominates over production of αβ T cells, and these cells populate several peripheral tissues, including the skin, the intestine, and other mucosal and epithelial surfaces. These subsets predominantly develop from fetal liver (rather than bone marrow) stem cells. Later, more than 90% of thymocytes express αβ T-cell receptors. In developing thymocytes, the γ, δ, and β genes are the first to rearrange. Cells of the αβ lineage that rearrange a functional β chain form a pre-T-cell receptor that signals thymocyte proliferation, α-chain gene rearrangement, and CD4 and CD8 expression. Most steps in T-cell development take place in the thymic cortex, whereas the medulla contains mainly mature T cells.

Positive and negative selection of T cells.

Up to the stage at which an αβ receptor is produced, T-cell development is independent of MHC proteins or antigen. From this point onward, developmental decisions in the αβ T-cell lineage depend on the interaction of the receptor with peptide:MHC ligands it encounters in the thymus. Here we consider this phase of T-cell development.

8-21 Overview of positive and negative selection of αβ lineage T cells.

T-cell precursors committed to the αβ lineage at the pre-T (DN3) stage undergo vigorous proliferation in the subcapsular region and progress to the large pre-T (DN4) transitional stage. These cells then rapidly transit through an immature CD4 or CD8 single-positive stage and become double-positive cells that express low levels of the T-cell receptor and both the CD4 and CD8 co-receptors as they move deeper into the thymic cortex. These double-positive cells have a life span of only about 3–4 days unless they are rescued by engagement of their T-cell receptor. The rescue of double-positive cells from programmed cell death and their maturation into CD4 or CD8 single-positive cells is the process known as positive selection. Only about 10–30% of the T-cell receptors generated by gene rearrangement will be able to recognize self peptide:self MHC complexes and thus function in self MHC–restricted responses to foreign antigens (see Chapter 4); those that have this capability are initially selected for survival in the thymus.

After this initial selection, thymocytes undergo additional selection events on the basis of their T-cell receptor recognition properties (Fig. 8.25). Some very strongly self-reactive thymocytes undergo negative selection as double-positive cells while still in the thymic cortex; these cells die by

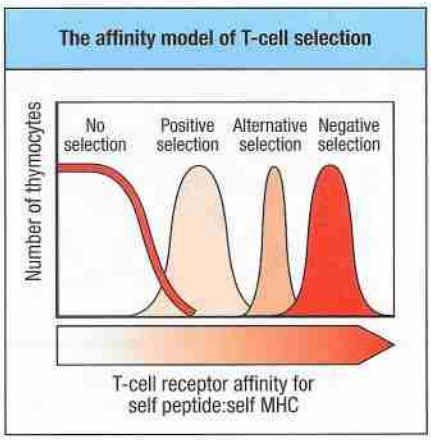


Fig. 8.25 The affinity model of T-cell positive and negative selection. Random TCRα- and TCRβ-chain gene rearrangements generate a large pool of immature thymocytes expressing a varied repertoire of specificities. The T-cell receptors on many of these cells fail to have sufficient binding strength to the self peptide:self MHC complexes on thymic epithelium and so receive no signals. These cells, labeled 'No selection,' die by neglect. Another fraction of immature thymocytes is positively selected because their T-cell receptors bind with sufficient strength to the self peptide:self MHC complexes on thymic epithelium to generate T-cell receptor–dependent survival signals ('Positive selection'). From this cohort of positively selected thymocytes, negative selection removes those thymocytes whose receptors have excessively strong reactivity to self peptides complexed with self MHC molecules (resulting in clonal deletion), thereby establishing self-tolerance of the mature T-cell population ('Negative selection'). A small subset of positively selected cells receiving signals slightly weaker than those inducing negative selection is induced into alternative lineages, such as regulatory T cells (T_{reg} cells), NK-T cells, intraepithelial lymphocytes (IELs) or MAIT cell subsets ('Alternative selection'). Maturation of thymocytes into these alternative lineages often involves specific cytokine signals or recognition of MHC class Ib molecules.

apoptosis. The remaining surviving thymocytes begin their maturation into CD4 or CD8 single-positive cells and move into the thymic medulla. The unique environment of the thymic medulla includes a variety of cell types that interact with maturing thymocytes. If the maturing thymocyte has strong reactivity to a self antigen found in the medulla, negative selection will occur. Cells with weaker levels of self-reactivity can be induced to differentiate into alternative T-cell lineages. One alternative lineage is regulatory T cells, a population of T cells (primarily CD4 T cells) that is important in preventing onset of autoimmune disease (see Chapter 15). Additional subsets of T cells whose T-cell receptors recognize MHC class Ib molecules (see Chapter 6) are also selected in the thymic medulla after recognition of their self MHC molecules. These less abundant alternative T-cell lineages include invariant NKT (iNKT) cells and mucosal-associated invariant T (MAIT) cells, which recognize CD1d and MR-1 MHC class Ib molecules, respectively.

8-22 Only thymocytes whose receptors interact with self peptide:self MHC complexes can survive and mature.

Early experiments using bone marrow chimeras (see Appendix I, Section A-33) and thymic grafting provided evidence that MHC molecules in the thymus influence the MHC-restricted T-cell repertoire. However, mice transgenic for rearranged T-cell receptor genes provided the first conclusive evidence that the interaction of the T cell with self peptide:self MHC complexes is necessary for the survival of immature T cells and their maturation into naive CD4 or CD8 T cells. For these experiments, the rearranged α- and β-chain genes were cloned from a T-cell clone (see Appendix I, Section A-21) whose origin, antigen specificity, and MHC restriction were known. When such genes are introduced into the mouse genome, they are expressed early during thymocyte development. As a consequence of expressing functional transgene-encoded TCRα- and TCRβ-chain proteins in developing T cells, the rearrangement of endogenous T-cell receptor genes is inhibited, albeit to different degrees. In general, endogenous β-chain gene rearrangement is inhibited completely, but that of α-chain genes is inhibited only incompletely, because the mechanism for terminating α-chain rearrangements requires T-cell receptor signaling as well as the expression of an α-chain protein (see Section 8-20). The result is that most of the developing thymocytes in TCR transgenic mouse lines express the T-cell receptor encoded by the transgenes. Studies using T-cell receptor αβ transgenic mice showed that thymocytes bearing a particular T-cell receptor could develop to the double-positive stage independently of the MHC class I or class II proteins expressed in that thymus. In contrast, the transgenic thymocytes developed into mature CD4 or CD8 single-positive thymocytes only if the thymus expressed the same self MHC molecule as that on which the original T-cell

stroma expressing MHC[b]
No single-positive T cells mature

Fig. 8.26 Positive selection is demonstrated by the development of T cells expressing rearranged T-cell receptor transgenes. In mice transgenic for rearranged αβ T-cell receptor genes, the maturation of T cells depends on the MHC allele expressed in the thymus. If the transgenic mice express the same MHC allele in their thymic stromal cells as that of the mouse from which the rearranged TCRα-chain and TCRβ-chain genes originally developed (both MHC^a; top panel), then the T cells expressing the transgenic T-cell receptor will develop from the double-positive stage (pale green) into mature single-positive T cells (dark green). If the MHC^a-restricted TCR transgenes are genetically crossed into a different MHC background (MHC^b; yellow, bottom panel), then developing T cells expressing the transgenic receptor will progress to the double-positive stage but will fail to mature further. This failure is due to the absence of an interaction between the transgenic T-cell receptor and MHC molecules on the thymic cortex, and thus no signal for positive selection is delivered, leading to apoptotic death by neglect.

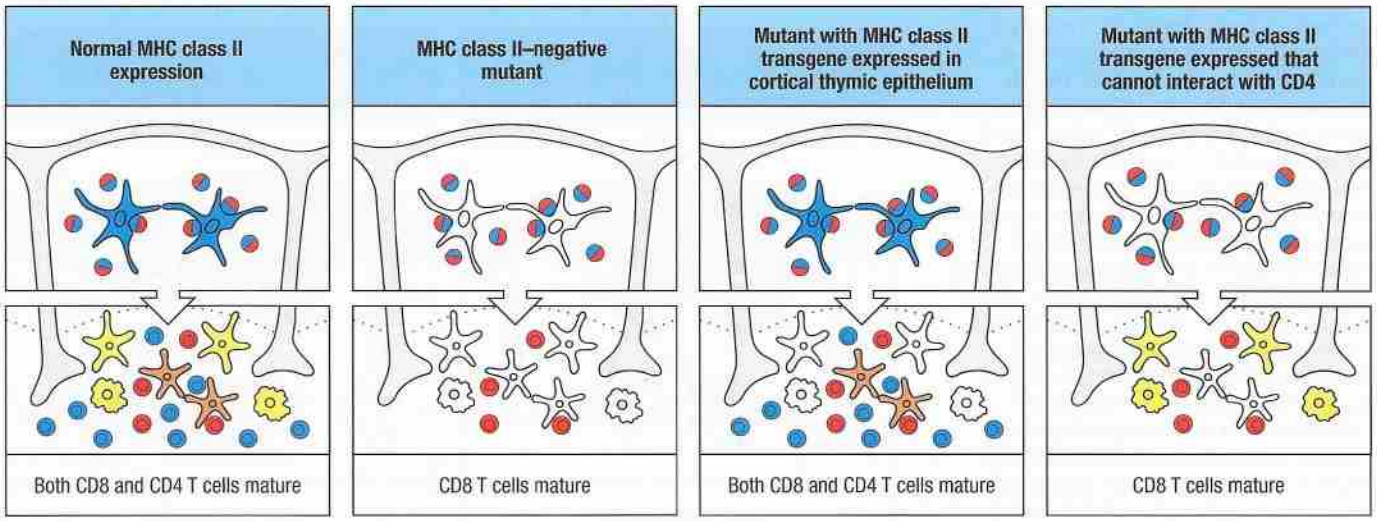
clone was selected (Fig. 8.26). Additional experimental strategies have confirmed that thymocytes require TCR interactions with self peptide:self MHC for positive selection. One striking example is the finding that mice lacking all MHC class I and class II expression show a complete arrest of thymocyte maturation at the $CD4^+CD8^+$ stage.

8-23 Positive selection coordinates the expression of CD4 or CD8 with the specificity of the T-cell receptor and the potential effector functions of the T cell.

At the time of positive selection, the thymocyte expresses both CD4 and CD8 co-receptor molecules. By the end of thymic selection, mature αβ T cells ready for export to the periphery have stopped expressing one of these co-receptors. The majority of these cells belong to the conventional CD4 or CD8 T-cell lineages. Less abundant subsets, such as iNKT cells (discussed further in Section 8-27) and a subset of regulatory T cells expressing CD4 and high levels of CD25 (the IL-2 receptor α chain), also develop in the thymus from $CD4^+CD8^+$ cells. Moreover, almost all mature T cells that express CD4 have receptors that recognize peptides bound to self MHC class II molecules and are programmed to become cytokine-secreting helper T cells. In contrast, most of the cells that express CD8 have receptors that recognize peptides bound to self MHC class I molecules and are programmed to become cytotoxic effector cells. Thus, positive selection also determines the cell-surface phenotype and functional potential of the mature T cell, selecting the appropriate co-receptor for efficient antigen recognition and the appropriate program for the T cell's eventual functional differentiation in an immune response.

The importance of MHC molecules in this selection is illustrated by the human immunodeficiency diseases caused by mutations that lead to an absence of MHC molecules on lymphocytes and thymic epithelial cells. People who lack MHC class II molecules have CD8 T cells, but only a few, highly abnormal CD4 T cells; a similar result has been obtained in mice in which MHC class II expression has been eliminated by targeted gene disruption (Fig. 8.27) (see Appendix I, Section A-36). Likewise, mice and humans that lack MHC class I molecules have few CD8 T cells. Thus, MHC class II molecules are predominantly required for CD4 T-cell development, whereas MHC class I molecules are predominantly required for CD8 T-cell development.

In mature T cells, the co-receptor functions of CD8 and CD4 depend on their respective abilities to bind invariant sites on MHC class I and MHC class II



Normal MHC class II expression
MHC class II–negative mutant
Mutant with MHC class II transgene expressed in cortical thymic epithelium
Mutant with MHC class II transgene expressed that cannot interact with CD4
Both CD8 and CD4 T cells mature
CD8 T cells mature
Both CD8 and CD4 T cells mature
CD8 T cells mature

Fig. 8.27 Thymic cortical epithelial cells mediate positive selection. In the thymus of normal mice (first panels), which express MHC class II molecules on epithelial cells in the thymic cortex (blue) as well as on medullary epithelial cells (orange) and bone marrow–derived cells (yellow), both CD4 (blue) and CD8 (red) T cells mature. Double-positive thymocytes are shown as half red and half blue. The second panels represent mutant mice in which MHC class II expression has been eliminated by targeted gene disruption; in these mice, few CD4 T cells develop, although CD8 T cells develop normally. In MHC class II–negative mice containing an MHC class II transgene engineered so that it is expressed only on the epithelial cells of the thymic cortex (third panels), normal numbers of CD4 T cells mature. In contrast, if a mutant MHC class II molecule with a defective CD4-binding site is expressed (fourth panel), positive selection of CD4 T cells does not take place. This indicates that the cortical epithelial cells are the critical cell type mediating positive selection and that the MHC class II molecule needs to be able to interact with the CD4 protein.

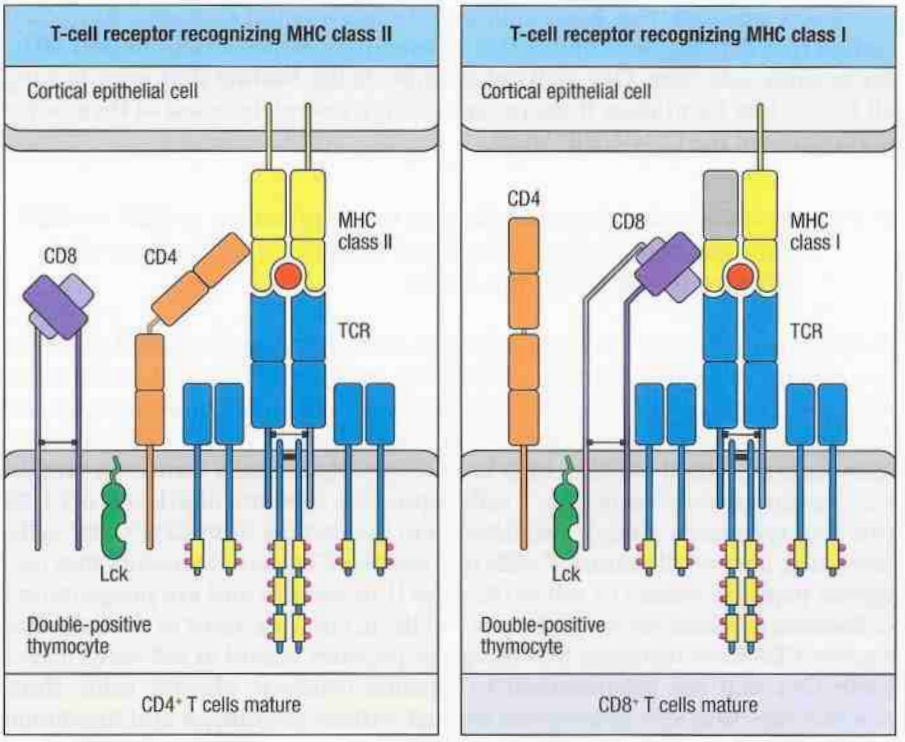


Fig. 8.28 Positive-selection signaling requires cooperation between the T-cell receptor and the CD4 or CD8 co-receptor. In double-positive thymocytes with T-cell receptors recognizing peptide:MHC class II complexes, the CD4 co-receptor recruits the Lck tyrosine kinase to the receptor to initiate signaling, leading to the maturation of CD4+ T cells (left panel). In contrast, double-positive thymocytes with T-cell receptors recognizing peptide:MHC class I complexes have cooperative recognition of peptide:MHC by the T-cell receptor plus the CD8 co-receptor. This also recruits Lck to the receptor to initiate signaling, leading to the maturation of CD8+ T cells (right panel). This cooperation between the T-cell receptor and the co-receptor is required for efficient positive selection of double-positive thymocytes.

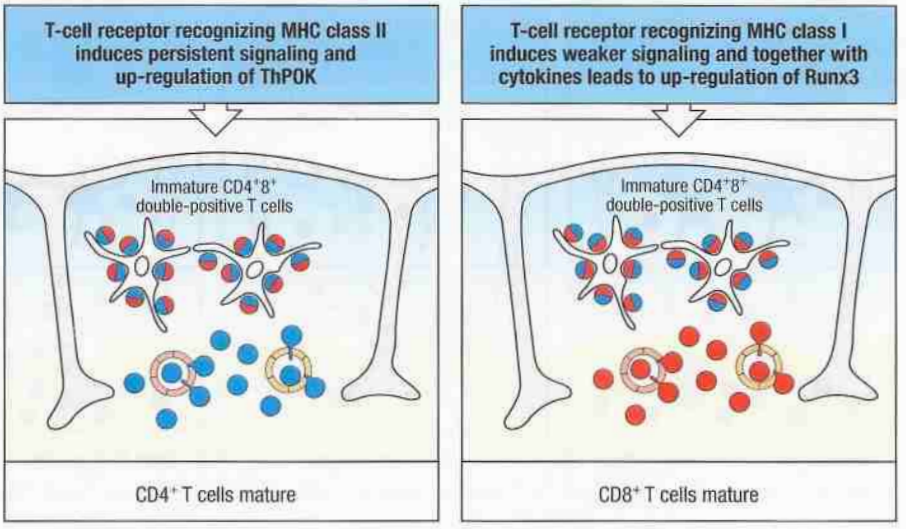
molecules (see Section 4-21). Co-receptor binding to an MHC molecule is also required for normal positive selection. In thymocytes, nearly all of the Lck is associated with CD4 and CD8 co-receptors, providing a mechanism to ensure that signaling is initiated only in thymocytes bearing T-cell receptors that bind to MHC molecules. Thus, positive selection depends on engagement of both the antigen receptor and co-receptor by an MHC molecule, and this signal determines the survival of single-positive cells that express the appropriate co-receptor (Fig. 8.28).

T-cell receptor signaling regulates this choice of the CD4 versus the CD8 lineage by controlling the expression of two transcription factors, ThPOK and Runx3 (Fig. 8.29). The role of ThPOK was identified through a naturally occurring loss-of-function mutation in mice that lacked CD4 T-cell development. In mice lacking ThPOK, MHC class II–restricted thymocytes are redirected toward the CD8 lineage. ThPOK is up-regulated in preselection

MHC Class II Deficiency

MHC Class I Deficiency



T-cell receptor recognizing MHC class II induces persistent signaling and up-regulation of ThPOK
Immature CD4+8+ double-positive T cells
CD4+ T cells mature
T-cell receptor recognizing MHC class I induces weaker signaling and together with cytokines leads to up-regulation of Runx3
Immature CD4+8+ double-positive T cells
CD8+ T cells mature

Fig. 8.29 The MHC molecules that induce positive selection determine CD4 versus CD8 lineage development and transcriptional programming. Double-positive thymocytes with T-cell receptors recognizing peptide:MHC class II complexes receive strong and persistent signaling, leading to the up-regulation of the transcription factor ThPOK. ThPOK induces the maturation of CD4+ T cells and promotes the expression of 'helper' T-cell genes (left panel). In contrast, double-positive thymocytes with T-cell receptors recognizing peptide:MHC class I complexes receive curtailed signaling. This weaker signaling together with cytokines induces the expression of the transcription factor Runx3 and the maturation of CD8+ T cells. Runx3 promotes the expression of 'cytotoxic' T-cell genes (right panel). This mechanism ensures that mature CD4+ and CD8+ T cells acquire the functional properties of cytokine production and target-cell killing, respectively, that match their T-cell receptor specificity for peptides bound to MHC class II versus MHC class I molecules.

double-positive thymocytes by strong and persistent T-cell receptor signaling, where it reinforces its own expression and represses expression of Runx3; together, the expression of ThPOK and absence of Runx3 lead to CD4 commitment and the ability to express cytokine genes typical of CD4 cells. If T-cell signaling is of insufficient strength or duration, however, ThPOK is not induced; instead, this T-cell receptor signal, together with intrathymic cytokines, induces Runx3 up-regulation. Runx3 functions to silence CD4 expression, maintain CD8 expression, and promote the expression of genes typical of CD8 T cells; namely, genes that encode proteins involved in target-cell killing.

While the majority of double-positive thymocytes that undergo positive selection develop into either CD4 or CD8 single-positive T cells, the thymus also generates less numerous populations of other T-cell subsets with specialized functions; these will be discussed further in Section 8-27.

8-24 Thymic cortical epithelial cells mediate positive selection of developing thymocytes.

Thymus transplantation studies indicate that stromal cells are important for positive selection. These cells form a web of cell processes that make close contacts with the double-positive T cells undergoing positive selection. Direct evidence that thymic cortical epithelial cells mediate positive selection comes from an ingenious manipulation of mice whose MHC class II genes have been eliminated by targeted gene disruption (see Fig. 8.27). Mutant mice that lack MHC class II molecules do not normally produce CD4 T cells. To test the role of the thymic epithelium in positive selection, an MHC class II gene was placed under the control of a promoter that restricted the gene's expression to thymic cortical epithelial cells. This was then introduced as a transgene into the MHC class II–mutant mice, and CD4 T-cell development was restored. A variant of this experiment showed that, to promote the development of CD4 T cells, the MHC class II molecule on the thymic cortical epithelium must be able to interact effectively with CD4. Thus, when the MHC class II transgene expressed in the thymus contains a mutation that prevents binding of the MHC to CD4, very few CD4 T cells develop. Equivalent studies of CD8 interaction with MHC class I molecules showed that co-receptor binding is also necessary for the positive selection of CD8 cells.

The critical role of the thymic cortical epithelium in positive selection raises the question whether there is anything distinctive about the antigen-presenting properties of these cells. The thymic stromal cells may simply be in closest proximity to the developing thymocytes, as there are very few macrophages and dendritic cells in the cortex to perform the antigen presentation. In addition, however, thymic epithelium differs from other tissues in the expression of key proteases that are involved in MHC class I and class II antigen processing (see Chapter 6). Cortical epithelial cells express cathepsin L as opposed to the more widely expressed cathepsin S, and mice deficient in cathepsin L have severely impaired CD4 T-cell development. Thymic epithelial cells from mice lacking cathepsin L exhibit a relatively high proportion of MHC class II molecules on their surface that retain the class II–associated invariant chain peptide (CLIP) (see Fig. 6.11). Cortical epithelial cells also express a unique proteasome subunit, β5T, whereas other cells express β5 or β5i. Mice deficient in β5T have severely impaired CD8 T-cell development. Because mice that lack either cathepsin L or β5T still have normal levels of MHC on the surface of their thymic cortical cells, it would seem that it is the peptide repertoire displayed by the MHC molecules on cortical epithelial cells that is responsible for altering T-cell development, although the mechanism is still unclear.

8-25 T cells that react strongly with self antigens are deleted in the thymus.

When the T-cell receptor of a mature naive T cell is strongly ligated by a peptide:MHC complex displayed on a specialized antigen-presenting cell in a peripheral lymphoid organ, the T cell is activated to proliferate and produce effector T cells. In contrast, when the T-cell receptor of a developing thymocyte is similarly ligated by a self peptide:self MHC complex in the thymus, it dies by apoptosis. The response of immature T cells to stimulation by antigen is the basis of negative selection. Elimination of immature T cells in the thymus prevents their potentially harmful activation later, should they encounter the same self peptide:self MHC complexes when they are mature T cells.

Negative selection has been demonstrated using TCR-transgenic mice expressing T-cell receptors specific for self peptides derived from proteins encoded on the Y chromosome, and thus expressed only in male mice. Thymocytes bearing these receptors disappear from the developing T-cell population in male mice at the double-positive stage of development, and no single-positive cells bearing the transgenic receptors mature. By contrast, in female mice, which lack the male-specific peptide, T cells bearing the transgenic receptors mature normally. Negative selection to male-specific peptides has also been demonstrated in nontransgenic mice and also occurs by deletion of T cells.

TCR-transgenic mice were very useful for the classic experiments above, but they express a functional T-cell receptor earlier during development than normal mice and have a very high frequency of cells reactive to any particular peptide. A more realistic system for evaluating negative selection involves the transgenic expression of only the β chain of a T-cell receptor reactive to a given peptide antigen. In such mice, the β chain pairs with endogenous α chains, yet the frequency of peptide-reactive T cells is sufficient for detection using peptide:MHC tetramers (see Appendix I, Section A-24). These and other more physiologic approaches showed that clonal deletion can occur at either the double-positive or the single-positive stage, presumably depending on where the T cell encounters the antigen that causes deletion. Thus, negative selection of developing T cells can take place in the thymic cortex to self antigens presented on bone marrow–derived antigen-presenting cells, as well as in the thymic medulla, as discussed below.

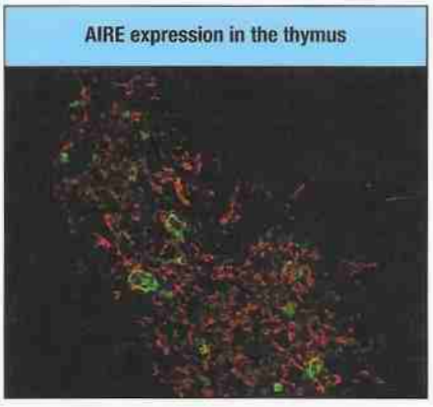


Fig. 8.30 AIRE is expressed in the medulla of the thymus and promotes the expression of proteins normally expressed in peripheral tissues. Expression of AIRE by thymic medullary cells is limited to the medullary region of the thymus, where it is expressed in a subset of epithelial-like cells. The expression of the thymic medullary epithelial marker MTS10 is shown in red. AIRE expression is shown in green by immunofluorescence and is present in only a fraction of the medullary epithelial cells.

The experiments outlined above illustrate the principle that self peptide:self MHC complexes encountered in the thymus purge the mature T-cell repertoire of cells bearing self-reactive receptors. One obvious problem with this scheme is that many tissue-specific proteins, such as pancreatic insulin, would not be expected to be expressed in the thymus. However, it is now clear that many such 'tissue-specific' proteins are expressed by certain stromal cells in the thymic medulla, providing a mechanism for intrathymic negative selection to proteins that are otherwise restricted to tissues outside the thymus. Another important function of the intrathymic expression of tissue-specific proteins is to promote the development of CD4 regulatory T cells, a subset of self-reactive T cells (see Fig. 8.26) with an important role in maintaining self-tolerance (discussed further in Section 8-27 and Chapter 15). The expression of some, but not all, tissue-specific proteins in the thymic medulla is controlled by a gene called ***AIRE*** **(autoimmune regulator)**. AIRE is expressed in medullary stromal cells (Fig. 8.30), interacts with many proteins involved in transcription, and seems to lengthen transcripts that would otherwise terminate earlier. Mutations in *AIRE* give rise to the human autoimmune disease known as **autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) or autoimmune polyglandular syndrome type I**, highlighting the important role of intrathymic expression of tissue-specific proteins in maintaining tolerance to self. Together, negative selection and the development of self-reactive regulatory T cells provide two major mechanisms of

self-tolerance. There are, however, additional mechanisms operating in the periphery that can prevent mature T cells from responding to tissue-specific self antigens; these are discussed in Chapter 15, when we consider the problem of autoimmune responses and their avoidance.

Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy (APECED)

As negative selection occurs throughout thymocyte development, both in the thymic cortex and in the medulla, it is likely to be mediated by antigen presentation by several different cell types. Bone marrow–derived dendritic cells present self antigens expressed by the cells or acquired by uptake from their environment or by handoff from medullary epithelial cells. In addition, medullary epithelial cells expressing AIRE, and thus presenting a wide range of self antigens, can directly induce thymocyte negative selection.

8-26 The specificity and/or the strength of signals for negative and positive selection must differ.

T cells undergo both positive selection for self MHC restriction and negative selection for self-tolerance by interacting with self peptide:self MHC complexes expressed on stromal cells in the thymus. An unresolved issue is how the interaction of the T-cell receptor with self peptide:self MHC complexes distinguishes between these opposite outcomes. First, more receptor specificities must be positively selected than are negatively selected. Otherwise, all the cells that were positively selected in the thymic cortex would be eliminated by negative selection, and no T cells would ever be produced. Second, the consequences of the interactions that lead to positive and negative selection must differ: cells that recognize self peptide:self MHC complexes on cortical epithelial cells are induced to mature, whereas those whose receptors might confer strong and potentially damaging autoreactivity are induced to die.

Currently, the choice between positive and negative selection is thought to hinge on the strength of self peptide:self MHC binding by the T-cell receptor, an idea known as the **affinity hypothesis** (see Fig. 8.26). Low-affinity interactions rescue the cell from death by neglect, leading to positive selection; high-affinity interactions induce apoptosis and thus negative selection. Because more complexes are likely to bind weakly than strongly, this model explains the positive selection of a larger repertoire of cells than are negatively selected. How this quantitative difference in receptor affinity translates into a qualitatively distinct cell fate is still an area of active investigation. Many of the biochemical signals induced by low-affinity interactions are weaker or of shorter duration than those from high-affinity interactions. However, low-affinity interactions lead to sustained activation of the protein kinase Erk, whereas high-affinity interactions lead to only transient activation of Erk, suggesting that differential activation of this or other MAPKs might determine the outcome of thymic selection. Indeed, experiments showed that developing T cells need to engage low-affinity ligands for more than 24 hours for positive selection to occur.

8-27 αβ T cells diverge into multiple lineages at the $CD4^+$ and $CD8^+$ single-positive stage in the thymic medulla.

Positive and negative selection of conventional $CD4^+$ and $CD8^+$ αβ T cells are not the only processes that occur during the late stages of thymocyte maturation. Once $CD4^+$ and $CD8^+$ single-positive cells arise and migrate into the thymic medulla, additional T-cell receptor and cytokine signals can divert thymocytes into one of several alternative cell lineages (see Fig. 8.26). As discussed earlier (see Section 8-25), thymocytes with strong reactivity to self-peptide:MHC complexes on medullary dendritic cells or AIRE-expressing epithelial cells can undergo negative selection; the remaining $CD4^+$ and $CD8^+$ single-positive thymocytes continue their maturation into conventional CD4

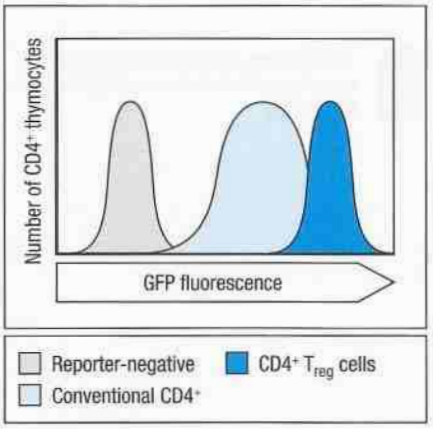

Fig. 8.31 The selection of CD4+ T_{reg} cells in the thymic medulla requires moderately high affinity for self peptide:self MHC. Thymocytes from mice expressing a fluorescent reporter that monitors T-cell receptor signal strength were analyzed by flow cytometry. CD4+ T_{reg} cells, identified by their expression of the transcription factor FoxP3 (not shown), were compared with conventional CD4+ single-positive thymocytes. The increased fluorescence seen in the T_{reg} subset indicates that these cells are receiving stronger T-cell receptor stimulation in the thymus than that received by the conventional CD4+ cells undergoing maturation. For comparison, the fluorescent signal from thymocytes that do not carry the fluorescent reporter gene are shown ('Reporter-negative').

and CD8 T cells, T_{reg} cells, iNKT cells (see Section 6-18), or CD8+ intraepithelial lymphocytes (IELs). Additional lineages of T cells also develop at this stage, but as these are not as well understood, they will not be discussed further.

One important subset that develops in the thymic medulla is the thymically derived T_{reg} cell subset, a population of CD4+ T cells that function to maintain self-tolerance. T_{reg} cells develop from CD4+ single-positive thymocytes whose T-cell receptors have moderately high affinity for self peptide:self MHC complexes (see Fig. 8.26), as indicated by studies using mice expressing a fluorescent reporter that monitors T-cell receptor signal strength. Examination of thymocytes from these mice showed that T_{reg} cells express high levels of the fluorescent reporter, indicating that they likely express T-cell receptors with high affinity for self (Fig. 8.31). During their maturation, T_{reg} cells up-regulate the transcription factor FoxP3 and express high levels of CD25, the IL-2 receptor α chain. Furthermore, T_{reg} cell development depends on IL-2 receptor signaling, a cytokine signal that is not required for the development of conventional T cells.

A second specialized subset of T cells that develops in the thymic medulla is a lineage known as **invariant NKT cells (iNKT cells)** based on their use of a restricted T-cell receptor repertoire and their expression of the NK1.1 receptor commonly found on NK cells. iNKT cells are activated as part of the early response to many infections; they differ from the major lineage of αβ T cells in recognizing CD1 molecules rather than MHC class I or MHC class II molecules (see Section 6-18). Unlike other T cells, iNKT cells require for their development a T-cell receptor interaction with CD1 molecules expressed on thymocytes and a signal through the adaptor protein SAP. iNKT cells, like γδ T cells, acquire a defined effector program during their development in the thymus. Therefore, these cells exhibit a memory-cell phenotype when they leave the thymus and migrate to peripheral lymphoid tissues and mucosal surfaces. iNKT cells have been suggested to develop in response to 'agonist' signaling. Recent studies have revealed that CD1-binding lipid antigens produced by the commensal microbes in the gut are an important source of these agonist ligands, and that the composition of the gut microbiome regulates the development of iNKT cells early in life. Because agonist stimulation of immature T cells is also known to cause clonal deletion, it is not yet clear which activating interactions lead to clonal deletion in the thymus and which lead to selection of T_{reg} cells or the nonconventional iNKT cells.

A third important subset of specialized αβ T-cell receptor–expressing T cells are CD8+ intraepithelial lymphocytes (IELs). Unlike conventional CD8+ T cells, IELs express a homodimer of the CD8α chain, rather than the CD8αβ heterodimer found on conventional T cells. Mature CD8αα IELs are found in the intestinal epithelium, interdigitated between epithelial cells. Although these cells appear capable of self-renewal in the intestinal tissue, current evidence indicates that they develop from thymic progenitor cells, which then migrate to the intestine and become resident IELs. In the intestinal tissue, these cells function to protect the mucosal barrier against infection or injury caused by gut microbes, especially at the time of gut colonization immediately after birth. Like thymically derived T_{reg} cells and iNKT cells, T-cell receptor αβ IELs require strong T-cell receptor signaling for their development.

8-28 Thymic emigration is controlled by signaling through a G protein–coupled receptor.

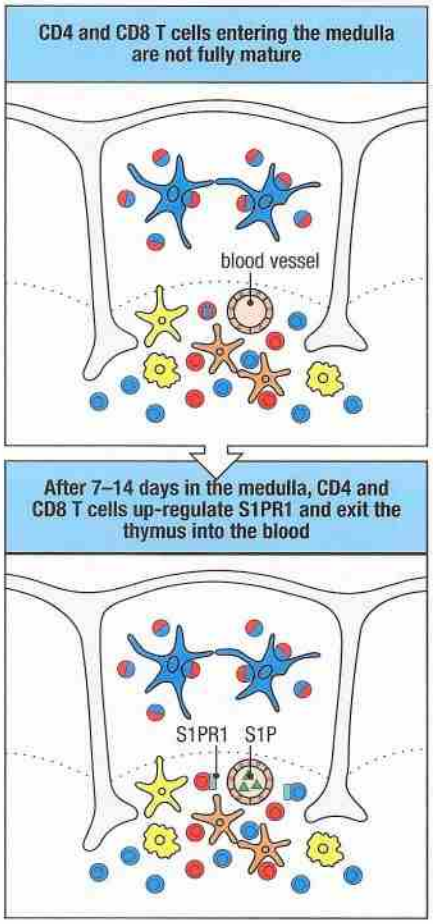
After completing their maturation in the thymic medulla, a process that takes 1–2 weeks, surviving thymocytes emigrate from the thymus and enter the bloodstream (Fig. 8.32). Emigration requires recognition of the lipid molecule sphingosine 1-phosphate (S1P) by the G protein–coupled receptor S1PR1, which is expressed by thymocytes during their final maturation. S1P is present

in high concentration in blood and lymph, and mature thymocytes are drawn toward it. Mature thymocytes also express CD62L (L-selectin), a lymph node–homing receptor that facilitates the localization of mature naive T cells to peripheral lymphoid organs after their emigration from the thymus.

8-29 T cells that encounter sufficient quantities of self antigens for the first time in the periphery are eliminated or inactivated.

Many autoreactive T cells are purged during their development in the thymus. As discussed in Section 8-25, this negative selection process is facilitated by the AIRE protein, which promotes the expression of many tissue-specific antigens in thymic medullary epithelial cells. Nonetheless, not all self antigens are expressed in the thymus, and some autoreactive T cells complete their maturation and migrate to the periphery. Our understanding of the fates of autoreactive T cells in the periphery comes mainly from the study of mice transgenic for self-reactive T-cell receptors. In some cases, T cells reacting to self antigens in the periphery are eliminated. This usually follows a brief period of activation and cell division and so is known as **activation-induced cell death**.

The question immediately arises: If the encounter of a mature naive lymphocyte and a self antigen leads to cell death, why does this not also happen to a mature lymphocyte that recognizes a pathogen-derived antigen? The answer is that infection sets up inflammation, which induces the expression of co-stimulatory molecules on the antigen-presenting dendritic cells and the production of cytokines promoting lymphocyte activation. The outcome of an encounter with antigen in these conditions is the activation, proliferation, and differentiation of the lymphocyte to effector-cell status. In the absence of infection or inflammation, dendritic cells still process and present self antigens, but in the absence of co-stimulatory and other signals, any interaction of a mature lymphocyte with its specific antigen seems to result in a tolerance-inducing (**tolerogenic**) signal from the antigen receptor.



CD4 and CD8 T cells entering the medulla are not fully mature
blood vessel
After 7–14 days in the medulla, CD4 and CD8 T cells up-regulate S1PR1 and exit the thymus into the blood
S1PR1
S1P

Fig. 8.32 Thymocyte emigration is induced by signaling through the sphingosine 1-phosphate receptor, S1PR1. CD4 and CD8 single-positive thymocytes that have successfully survived positive and negative selection are found in the medulla but are not yet fully mature. At the termination of the maturation process, which takes 7–14 days, the CD4 and CD8 single-positive thymocytes up-regulate the sphingosine 1-phosphate (S1P) receptor, known as S1PR1. S1PR1 is a G protein–coupled receptor that promotes chemotaxis of the cells toward the ligand S1P. Because of the high levels of S1P in the blood, single-positive thymocytes are induced to leave the thymus by entering the blood, where they become part of the recirculating naive T-cell population.

Summary.

The stages of thymocyte development up to the expression of the pre-T-cell receptor—including the decision between commitment to either the αβ or the γδ lineage—are all independent of interactions with peptide:MHC antigens. With the successful rearrangement of α-chain genes and expression of the T-cell receptor, αβ thymocytes undergo further development that is determined by the interactions of their T-cell receptors with self peptides presented by the MHC molecules on the thymic stroma. $CD4^+CD8^+$ double-positive thymocytes whose receptors interact with self peptide:self MHC complexes on thymic cortical epithelial cells are positively selected and will eventually mature into CD4 or CD8 single-positive cells. T cells that react too strongly with self antigens are deleted in the thymus, a process driven by bone marrow–derived antigen-presenting cells and AIRE-expressing epithelial cells in the medullary region of the thymus. The outcome of positive and negative selection is the generation of a mature conventional T-cell repertoire that is both MHC-restricted and self-tolerant. Some nonconventional T-cell lineages undergo 'agonist' selection after strong T-cell receptor signaling. Precisely how the recognition of self peptide:self MHC ligands by the T-cell receptor leads to either positive or negative selection remains an unsolved problem.

Summary to Chapter 8.

B-cell and T-cell lineages form from an uncommitted hematopoietic stem cell. The somatic gene rearrangements that generate the highly diverse repertoire of antigen receptors—immunoglobulin for B cells, and the T-cell receptor for

T cells—occur in the early stages of the development of T cells and B cells from a common bone marrow–derived lymphoid progenitor. Mammalian B-cell development takes place in fetal liver and, after birth, in the bone marrow; T cells also originate from stem cells in the fetal liver or in the bone marrow but undergo most of their development in the thymus. Much of the somatic recombination machinery, including the RAG proteins that are an essential part of the V(D)J recombinase, is common to both B and T cells. In both B and T cells, gene rearrangements begin with the loci that contain D gene segments and proceed successively at each locus. The first step in B-cell development is the rearrangement of the locus for the immunoglobulin heavy chain, and for T cells it is the β chain. In each case, the developing cell is allowed to proceed to the next stage of development only if the rearrangement has produced an in-frame sequence that can be translated into a protein expressed on the cell surface: either the pre-B-cell receptor or the pre-T-cell receptor. Cells that do not generate successful rearrangements for both receptor chains die by apoptosis.

Once a functional antigen receptor has appeared on the cell surface, the lymphocyte is tested in two ways. Positive selection tests for the potential usefulness of the antigen receptor, whereas negative selection removes self-reactive cells from the lymphocyte repertoire, rendering it tolerant to the antigens of the body. Positive selection is particularly important for T cells, because it ensures that only cells bearing T-cell receptors that can recognize antigen in combination with self MHC molecules will continue to mature. Positive selection also coordinates the choice of co-receptor expression. CD4 becomes expressed by T cells harboring MHC class II–restricted receptors, and CD8 becomes expressed by cells harboring MHC class I–restricted receptors. This ensures the optimal use of these receptors in responses to pathogens. For B cells, positive selection seems to occur at the final transition from immature to mature B cells, which occurs in peripheral lymphoid tissues. Tolerance to self antigens is enforced by negative selection at different stages throughout the development of both B and T cells, and positive selection likewise seems to represent a continual process.

Discussion Questions

8.1 Hematopoietic progenitor cells found in the adult bone marrow, such as lymphoid–myeloid primed multipotent progenitor cells, are the precursors to several lineages of more committed progenitors. On the basis of your knowledge of these more committed progenitors, such as the common lymphoid progenitor or the common granulocyte/megakaryocyte/erythrocyte progenitor, what might be the advantage of having progenitors that are not committed to generating only a single lineage of mature hematopoietic cells?

8.2 Multiple checkpoints are in place during B-cell development in the bone marrow, to ensure the most efficient generation of mature B cells expressing a functional immunoglobulin protein. What is the first of these checkpoints, and how is this checkpoint enforced?

8.3 When recombination processes are impaired during B-cell development, such as occurs when RAG-1 or RAG-2 is defective, the number of pre-B cells in the bone marrow is profoundly reduced. What is the explanation for this observed reduction in pre-B cells?

8.4 Why might individuals with defects in receptor editing in the bone marrow have increased susceptibility to autoimmune diseases such as systemic lupus erythematosus or rheumatoid arthritis?

8.5 In a healthy individual, the number of circulating B cells remains relatively constant over time. As a consequence, large variations in the number of circulating B cells in an individual are used as a diagnostic indicator of disease, such as an infection or a malignancy. What process during B-cell maturation ensures that an individual maintains a relatively constant number of circulating B cells?

8.6 The bone marrow progenitor cells that enter the thymus and develop into T cells have the potential to generate other lineages of lymphocytes (for example, B cells). What key signaling pathway is required for these progenitor cells to commit to the T-cell lineage, and how is this accomplished?

8.7 As for B cells, antigen receptor gene rearrangements in developing T cells occur in an ordered series of

steps. For T cells developing in the αβ T-cell lineage, which rearrangements occur first, and what are the consequences of success versus failure in generating a productive antigen receptor chain protein at this step?

8.8 Positive selection of αβ T cells in the thymus is coordinated with commitment to the CD4 or CD8 T-cell lineage. Why is it important that these two processes are coordinately regulated?

8.9 The immunomodulatory drug FTY720 causes rapid and profound reductions in the number of circulating T cells. This drug is an inhibitor of a G protein–coupled receptor expressed on medullary thymocytes and circulating naive T cells. What is the likely target of FTY720, and why does it cause rapid reduction in the number of T cells in the blood?

PART IV
THE ADAPTIVE IMMUNE RESPONSE

9 T Cell–Mediated Immunity
10 The Humoral Immune Response
11 Integrated Dynamics of Innate and Adaptive Immunity
12 The Barrier Immune System

9 T Cell–Mediated Immunity

IN THIS CHAPTER

Development and function of secondary lymphoid organs—sites for the initiation of adaptive immune responses.

Naive T-cell activation, clonal expansion, and differentiation into effector and memory T cells.

General properties of effector T cells and their cytokines.

T cell–mediated cytotoxicity.

An adaptive immune response is initiated when a pathogen overwhelms innate defense mechanisms. As the pathogen replicates and antigen accumulates, sensor cells of the innate immune system become activated to trigger the adaptive immune response. While some infections may be dealt with solely by innate immunity, as discussed in Chapters 2 and 3, host defense against most pathogens, almost by definition, requires recruitment of adaptive immunity; that is, T and B lymphocytes. This is borne out by immunodeficiency syndromes that are associated with failure of particular parts of the adaptive immune response, to be discussed in Chapter 13.

In the next three chapters, we will learn how the adaptive immune response involving antigen-specific T cells and B cells is initiated and deployed. T-cell responses that lead to cellular immunity will be considered first, in this chapter. B-cell responses that lead to antibody-mediated, or humoral, immunity will be considered in Chapter 10. In Chapter 11, we will consider the dynamics of T-cell and B-cell responses in the context of their integration with innate immunity and how this culminates in one of the most important features of adaptive immunity—immunological memory.

Once T cells have completed their primary development in the thymus, they are released into circulation. On reaching a secondary (or peripheral) lymphoid organ—whether a lymph node, the spleen, or mucosal lymphoid tissue—they leave the blood to migrate through the lymphoid tissue in search of their cognate antigen. Circulating T cells that have not yet encountered their specific antigens are known as **naive T cells**. A naive T cell has very limited functional activity, and if it fails to detect its antigen as it migrates through a secondary lymphoid tissue, it soon exits and returns to the circulation with the same limited functionality. If, however, the naive T cell does encounter its antigen—presented as a peptide:MHC complex on the surface of a conventional dendritic cell—it typically becomes activated and is induced to proliferate and differentiate over several days within

that lymphoid tissue to generate many progeny (termed **clonal expansion**) possessing new activities that contribute to removal of the source of antigen. These clonal progeny are called **effector T cells**, and, unlike naive T cells, they perform their acquired functions as soon as they encounter their specific antigen on other cells—generally without requirement for further differentiation. Effector T cells also change their pattern of recirculation, such that many are directed to sites of pathogen entry in nonlymphoid tissues, while others are directed to interact with B cells within the lymphoid tissue to provide 'help' for the production of pathogen-specific antibodies. The initial antigenic response of naive T cells is often referred to as **priming**, and the more general initial antigenic response is referred to as a **primary immune response**, to distinguish it from a subsequent reencounter with the same pathogen in a **secondary (or recall) immune response**.

As we will see, there are several functional classes of effector T cells that can be generated in a primary response, each specialized for the clearance of different types of pathogens. Because of their requirement to recognize peptide antigens presented by MHC molecules, all effector T cells act on other host cells—not on the pathogen itself—to bring about eradication of the pathogen. CD8 T cells recognize pathogen peptides presented by MHC class I molecules, and naive CD8 T cells differentiate into cytotoxic T cells, or **cytotoxic T lymphocytes (CTLs)**, that recognize and kill cells infected by intracellular pathogens such as viruses, which can replicate within host cells. Because MHC class I is expressed on all nucleated cells, CTLs can kill infected cells anywhere in the body. CD4 T cells recognize pathogen peptides presented by MHC class II molecules and have a more flexible repertoire of effector activities. Naive CD4 T cells can differentiate down distinct pathways that generate effector subsets with different immunological functions. The main CD4 effector-cell subsets are T helper 1 ($\mathbf{T_H1}$), $\mathbf{T_H2}$, $\mathbf{T_H17}$, and T follicular helper ($\mathbf{T_{FH}}$), which activate MHC class II–bearing target cells, such as macrophages, mucosal epithelial cells, and B cells, to enhance those cells' activity against the pathogen. Naive CD4 T cells can also differentiate into **regulatory T cells, or $\mathbf{T_{reg}}$** cells, which inhibit the initiation and extent of immune activation. Because the range of host cells that express MHC class II is much more restricted than that of MHC class I, the cellular targets of effector CD4 T cells are also more restricted. The interactions of both CD8 and CD4 effector T cells with target cells is mediated both by direct contact between the T cell and the target cell and by the release of cytokines, which can act locally on target cells or on other cells at a distance to orchestrate the clearance of antigen.

Unlike innate immune cells, which respond to pathogens within minutes to hours, the activation, proliferation, and differentiation of naive T cells into effector T cells takes several days, resulting in a substantial period of delay during which the innate immune system must restrain the pathogen prior to the participation of effector T cells and the antibodies they have helped induce. Once the adaptive immune response is fully developed, the pathogen is typically cleared, resulting in elimination of the antigens that have driven the adaptive response. In the wake of antigen clearance and resolution of the inflammatory response provoked by a pathogen, most of the effector T cells that were generated to combat the infection die off. However, a fraction remains as long-lived **memory T cells**, which can retain effector functions and persist for months to years at substantially higher numbers than their naive clonal precursors to accelerate pathogen clearance should future challenges arise.

In this chapter, we will first consider how the structure of secondary lymphoid tissues enables the interaction of rare clones of circulating T cells with dendritic cells that may bear the antigens they recognize. We will then consider

how naive T cells become activated to differentiate into effector T cells that help other immune cells to clear pathogens. Some of the effector functions of T cells will be considered in this chapter; others will be discussed in the context of T-cell help for B-cell production of antibodies in Chapter 10 and the actions of effector cells to heighten the activation of the innate immune system in Chapter 11.

Development and function of secondary lymphoid organs—sites for the initiation of adaptive immune responses.

As discussed in Chapters 1 and 8, the primary lymphoid organs—the thymus and bone marrow—are the tissue sites for selection of antigenic receptor repertoires of T and B cells, respectively. Adaptive immune responses are initiated in the secondary lymphoid organs—lymph nodes, spleen, and the mucosa-associated lymphoid tissue (MALT), such as the Peyer's patches in the gut. The architecture of these tissues is similar throughout the body and is structured to provide a crossroads for the interaction of rare clonal precursors of recirculating T and B cells with their cognate antigens—whether presented by dendritic cells in the case of T cells or recognized as free antigens in the case of B cells. In view of the rarity of naive T cells that recognize a specific peptide:MHC complex—roughly 100 cells in the entire immune repertoire of approximately 100 million T cells in the mouse (~1 in every million T cells)—and the large area over which an infectious agent can invade, the antigens derived from the pathogen (or in some instances the pathogen itself) must be transported from sites of pathogen entry to secondary lymphoid tissues to facilitate recognition of the antigen by lymphocytes. As we will see, these tissues are structured for the efficient delivery of naive T and B cells and their antigens into a small volume in secondary lymphoid organs to enable the adaptive immune system to overcome the daunting task of effective surveillance of the entire body for pathogens despite the rarity of naive clonal precursors. Moreover, when naive lymphocytes do recognize antigen, the secondary lymphoid tissues serve as the site for rapid clonal expansion as antigen-activated T and B cells divide rapidly and differentiate for several days prior to their release back into the circulation where they can redistribute to sites of infection. Thus, secondary lymphoid tissues are sites of both initiation and amplification of the nascent adaptive response. In this part of the chapter we will first consider the development and structure of secondary lymphoid organs that enable these interactions. We will then discuss how naive T cells are directed to exit the blood and enter secondary lymphoid organs, then exit these tissues to recirculate back to blood. This will be followed by consideration of how dendritic cells pick up antigen and travel to local lymphoid organs, where they can both present antigen to T cells and activate them.

9-1 Secondary lymphoid structures are specialized to facilitate the interaction of circulating T and B lymphocytes with antigen.

The various secondary lymphoid organs are organized roughly along the same lines (see Chapter 1), having distinct areas in which B cells and T cells are concentrated—the B-cell and T-cell zones. They also contain macrophages, dendritic cells, and nonleukocyte stromal cells that are critical to the structural organization and function of these tissues. In the case of the spleen, which is specialized for the capture of antigens that enter the bloodstream,

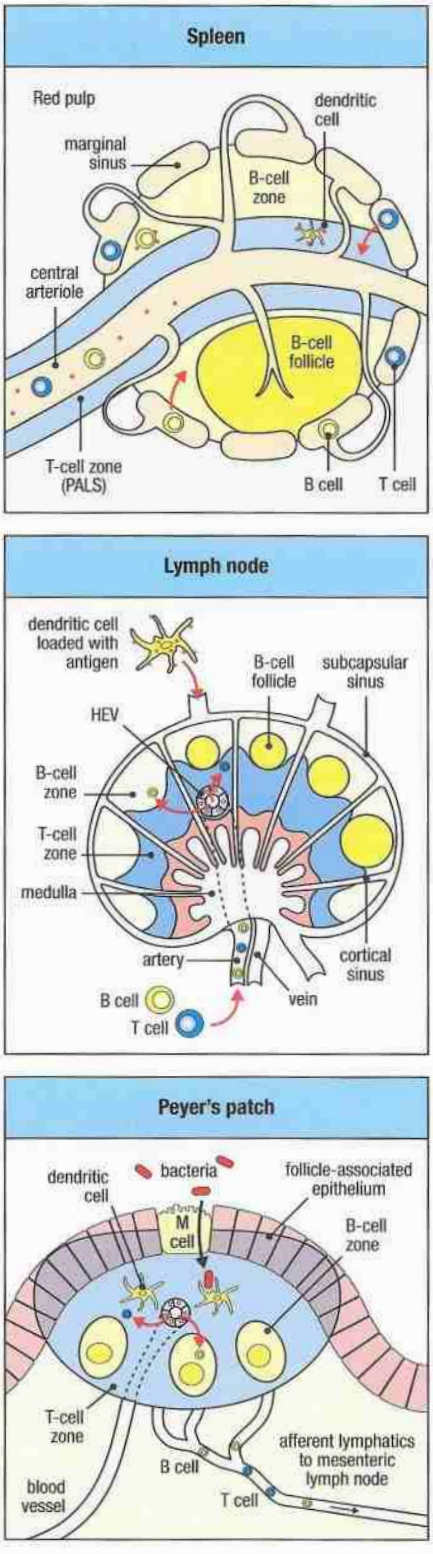

Fig. 9.1 Secondary lymphoid tissues serve as anatomic crossroads for interactions of antigens and lymphocytes. Secondary lymphoid tissues are specialized to facilitate interactions between lymphocytes and antigens. In the spleen (upper panel), antigen (denoted by red dots) is delivered via arterioles that branch from the central arteriole to the marginal sinus, which is the boundary between the white pulp and red pulp. In the marginal sinus, antigen can be taken up by marginal zone B cells, macrophages, or dendritic cells, the last of which can transport antigen into the T-cell zones of the periarteriolar lymphoid sheath, or PALS. T and B cells enter the spleen via the same route as antigen and leave the marginal sinus to travel to either the PALS or the B-cell follicles. In lymph nodes (middle panel), antigen is delivered in lymph either free or as cargo of dendritic cells that have taken up the antigen in the tissues drained by the lymph node. The antigen is conducted via afferent lymphatics to the subcapsular sinus, from which it is delivered to T-cell zones, where T cells can recognize it on the surface of dendritic cells; or, in the case of B cells, it is detected as an intact antigen, often on the surface of macrophages at the border of B-cell follicles. T and B cells enter the lymph node via high endothelial venules (HEVs) in T-cell zones, and then diverge into T-cell and B-cell zones. In the intestines (lower panel), antigens are transported from the lumen via the microfold cells (M cells)—specialized epithelial cells that overlay Peyer's patches and other lymphoid follicles—to dendritic cells that reside immediately beneath the epithelium. Antigen-loaded dendritic cells are then surveyed by T cells in T-cell zones, and if the antigens they bear are not recognized by T cells locally, the dendritic cells can migrate to mesenteric lymph nodes to be further surveyed. As in the lymph nodes, T and B cells enter the Peyer's patches via HEVs in the T-cell zones.

the lymphoid tissue component is called the **white pulp** (Fig. 9.1). The white pulp is demarcated from the **red pulp**—which is specialized for the removal of damaged or senescent red blood cells—by a **marginal sinus**, a vascular network that is formed from branches of a small arterial vessel (the central arteriole) around which the white pulp is organized. Circulating T and B cells are initially delivered to the marginal sinus, which is a highly organized region of cells that is specialized for the capture of blood-borne antigens or intact microbes, such as viruses and bacteria. It is rich in specialized populations of macrophages and dendritic cells and contains a unique population of B cells, the **marginal zone B cells**, which do not recirculate. Pathogens reaching the bloodstream are efficiently trapped in the marginal sinus by dendritic cells and macrophages, which can then deliver pathogen-derived antigen into the white pulp, and by marginal zone B cells, which appear adapted to provide rapid responses to pathogens that enter the marginal zone—particularly the production of IgM antibodies directed against certain pathogens.

From the marginal sinus, incoming T and B cells migrate centrally along marginal zone bridging channels toward the central arteriole, where they bifurcate into T-cell zones that are clustered around the central arteriole—the so-called **periarteriolar lymphoid sheath (PALS)**—and B-cell zones, or follicles, that are located more peripherally between the PALS and the marginal sinus. Some follicles may contain **germinal centers**, in which B cells involved in an adaptive immune response are proliferating and undergoing somatic hypermutation (see Section 1-16 and Chapter 8). The antigen-driven production of germinal centers will be described in detail when we consider B-cell responses in Chapter 10.

Other types of cells are found within the B-cell and T-cell areas and are important for the structural and functional organization of secondary lymphoid organs. In the spleen, T-cell zones and the marginal zone bridging channels contain a network of **fibroblast reticular cells (FRCs)**, which are stromal cells that produce an extracellular scaffold of reticular fibers connecting the marginal sinus to the PALS and produce chemokines that attract T cells to enter from the marginal sinus. This network serves as a 'highway system' along which T cells migrate as they move from the marginal sinus into the PALS. A similar network is present in lymph nodes and will be discussed in more detail in Section 9-4.

The B-cell zone contains a network of **follicular dendritic cells (FDCs)**, which are concentrated mainly in the area of the follicle most distant from the central arteriole. Despite their name, FDCs are not of bone-marrow origin. Instead, they resemble FRCs and are specialized stromal cells that are limited to

B-cell zones, where they produce the chemokine CXCL13, which acts on the chemokine receptor CXCR5 on B cells to attract them to B-cell follicles. FDCs form a network through which B cells move into and within B-cell follicles. FDCs are also specialized for the capture of antigen in the form of immune complexes—complexes of antigen, antibody, and complement. The immune complexes are not internalized but remain intact on the surface of the FDC for prolonged periods of time, where the antigen can be recognized by B cells to drive germinal center responses, to be discussed in Chapter 10.

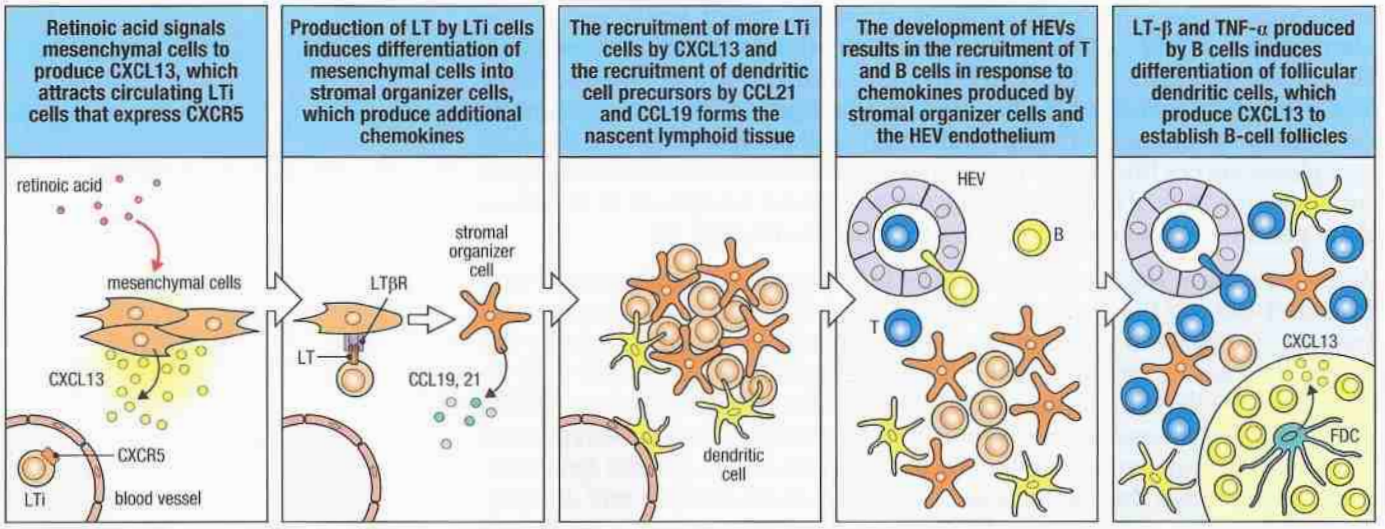
As in the spleen, the T cells and B cells in lymph nodes are organized into discrete T-cell and B-cell areas (see Fig. 9.1). B-cell follicles in the lymph nodes have a structure and composition similar to those of B-cell follicles in the spleen and are located just under the outer capsule of the lymph node in the cortex. T-cell zones surround the follicles in the paracortical areas. Unlike the spleen, lymph nodes have connections to both the blood system and the lymphatic system. Lymph conducted to lymph nodes by afferent lymphatic vessels enters into the **subcapsular sinus**, into which antigen and antigen-bearing dendritic cells are initially delivered from the tissues. T and B cells enter the lymph node via small blood vessels called **high endothelial venules (HEVs)**, which are found in T-cell zones and are so named because of their unusually thick endothelial-cell lining that is specialized for the recruitment of circulating lymphocytes into lymph nodes and mucosal lymphoid tissues.

The **mucosa-associated lymphoid tissue (MALT)** is associated with the body's mucosal epithelial surfaces, which provide physical barriers against infection. **Peyer's patches** are one example and are lymph node–like structures interspersed at intervals just beneath the gut epithelium in the distal portion of the small intestine, where they sample antigens from the intestinal lumen. Like the spleen and lymph nodes, these structures are organized into B-cell follicles and T-cell zones (see Fig. 9.1). The epithelium overlying them contains specialized **M cells** that are adapted to channel antigens and pathogens directly from the gut lumen to the underlying lymphoid tissue (see Section 1-17 and Chapter 12). Peyer's patches and similar tissue present in other mucosal tissues (for example, tonsils) provide specialized sites where B cells become preferentially committed to the synthesis of IgA. These lymphoid tissues will be discussed in more detail in the context of the mucosal immune system in Chapter 12.

9-2 The development of secondary lymphoid tissues is initiated by lymphoid tissue inducer cells and cytokines of the tumor necrosis factor family.

Before considering how secondary lymphoid organs contribute to adaptive immunity, we will briefly look at how these organs develop in the first place. Lymphatic vessels are formed during embryonic development from endothelial cells that originate from blood vessels. Some endothelial cells in the early venous system begin to express Prox1, a member of the homeobox family of transcription factors. These cells bud from veins, migrate away, and reassociate to form a parallel network of lymphatic vessels. Mice lacking Prox1 have normal arteries and veins but fail to form a lymphatic system, showing this factor to be critical to development of the lymphatic endothelium.

At sites destined to become lymphoid organs, **retinoic acid**, a signaling molecule derived from vitamin A that is probably produced by local nerve endings, stimulates mesenchymal cells to produce the chemokine **CXCL13**, which acts to recruit circulating hematopoietic cells called **lymphoid tissue inducer (LTi)** cells that express the receptor for CXCL13, **CXCR5**. LTi cells are a subtype of type 3 innate lymphoid cells (ILC3 cells; see Section 3-23) that initiate the formation of lymph nodes and Peyer's patches by producing TNF family proteins known as **lymphotoxins (LTs)**. LTs activate differentiation of the mesenchymal cells into **stromal organizer cells**, which are precursors of fibroblast



Retinoic acid signals mesenchymal cells to produce CXCL13, which attracts circulating LTi cells that express CXCR5
Production of LT by LTi cells induces differentiation of mesenchymal cells into stromal organizer cells, which produce additional chemokines
The recruitment of more LTi cells by CXCL13 and the recruitment of dendritic cell precursors by CCL21 and CCL19 forms the nascent lymphoid tissue
The development of HEVs results in the recruitment of T and B cells in response to chemokines produced by stromal organizer cells and the HEV endothelium
LT-β and TNF-α produced by B cells induces differentiation of follicular dendritic cells, which produce CXCL13 to establish B-cell follicles

Fig. 9.2 The development of secondary lymphoid organs is orchestrated by the interplay of lymphoid tissue inducer (LTi) cells and stromal cells. During embryonic development, LTi cells arise in the fetal liver and are recruited to sites of future lymphoid organs by CXCL13, which is produced by mesenchymal cells under the influence of retinoic acid and binds CXCR5 expressed on the circulating LTi cells (first panel). The source of retinoic acid is not clear, but it appears to be produced by nerves, at least in some sites. Once recruited from the blood into the tissue, LTi cells express lymphotoxin (LT), which acts on LT-β receptors expressed on mesenchymal cells to induce their differentiation into stromal organizer cells (second panel). The cellular organization of developing lymphoid organs is initiated when, in addition to the further recruitment of LTi cells by CXCL13, stromal organizer cells begin to secrete the chemokines CCL21 and CCL19, which recruit dendritic-cell precursors that express CCR7, the receptor for CCL21 and CCL19 (third panel). Stromal organizer cells also stimulate the development of high endothelial venules (HEVs), which also produce CCL21 and facilitate the recruitment of CCR7-expressing B cells and T cells immediately after birth (fourth panel). Incoming B cells produce LT-β and TNF-α, both of which are needed to induce the differentiation of follicular dendritic cells (FDCs), which then become the dominant source of CXCL13. The production of CXCL13 drives the organization of B cells into discrete B-cell areas (follicles) around the FDCs and contributes to the further recruitment of B cells from the circulation into the lymph node (fifth panel). LTβR, LT-β receptor.

reticular cells (FRCs) and follicular dendritic cells (FDCs) that induce the development of high endothelial venules (HEVs) and produce new chemokines (**CCL21** and **CCL19**) that recruit additional LTi cells as well as dendritic-cell precursors and lymphocytes to these sites (Fig. 9.2). Completion of lymphoid tissue development follows the recruitment of B cells, which provide both LTs and TNF-α required for the differentiation of FDCs, which in turn promote the development of B-cell follicles (Fig. 9.3). The normal development of the white pulp of the spleen also depends on lymphotoxins and TNF-α.

ANIMATION 9.1

A critical signal for the differentiation of stromal organizer cells in all developing secondary lymphoid tissues, including lymph nodes, the splenic white pulp, and Peyer's patches, is delivered to mesenchymal cells by the LT-β receptor (see Fig. 9.3). Although this receptor can bind two different ligands—a membrane-bound heterotrimer consisting of one soluble molecule of LT-α that is anchored by two membrane-bound molecules of LT-β (that is, LT-$\alpha_1\beta_2$) and LIGHT—for most lymphoid tissues LT-$\alpha_1\beta_2$ is nonredundant. Accordingly, mice deficient for LT-β receptor, LT-α, or LT-β fail to develop most lymph nodes. An exception is the lymph nodes that drain mucosal tissues—cervical and mesenteric lymph nodes, and possibly lumbar and sacral lymph nodes (see Chapter 12), development of which is absent in both LT-β receptor–deficient mice and LT-α–deficient mice, but not LT-β–deficient mice, suggesting that an alternative ligand for LT-β receptor (possibly LIGHT) can compensate in the face of LT-β deficiency. In addition to lymphotoxins, TNF-α is required for the normal development of lymphoid tissues because of its co-requirement for the development of FDCs that are required to organize B-cell zones; FDCs are lacking in mice deficient for either TNF-α or its receptor TNFR-I (see Fig. 9.3). These mice do have lymph nodes and Peyer's patches, because they express LTs, but these structures lack FDCs and thus B-cell follicles.

		Effects seen in receptor- or ligand-knockout mice				
Receptor	**Ligands**	**Spleen**	**Peripheral lymph node**	**Mesenteric lymph node**	**Peyer's patch**	**Follicular dendritic cells**
LT-β receptor	LT-$\alpha_1\beta_2$ LIGHT	Distorted architecture No marginal zones	Absent in LT-β receptor and LT-β KO Present in LIGHT KO	Absent in LT-β receptor KO Present in LT-β KO	Absent	Absent
TNFR-I	TNF-α LT-α_3	Distorted architecture	Absent in LT-α KO Present in TNF-α and TNFR-I KO	Absent in LT-α KO Present in TNF-α and TNFR-I KO	Absent in LT-α KO Reduced in TNF-α and TNFR-I KO	Absent

Fig. 9.3 The role of TNF family members in the development of secondary lymphoid organs. The role of TNF family members in the development of secondary lymphoid organs has been deduced mainly from the study of knockout (KO) mice deficient in certain TNF family receptors or their ligands. The defects are organized here with respect to the two main receptors, TNFR-I and the LT-β receptor, and selected members of their ligands, TNF-α and the lymphotoxins (LTs). Note that each of these receptors can bind multiple ligands, but the loss of distinct ligands can lead to different phenotypes, as indicated in the figure. This is due to the ability of the different ligands to bind different sets of receptors (not shown). The LT-α protein chain contributes to two distinct ligands, the LT-α_3 trimer and the LT-$\alpha_1\beta_2$ heterotrimer, each of which acts through a distinct receptor. In general, signaling through the LT-β receptor is required for lymph-node and follicular dendritic cell (FDC) development and for normal splenic architecture, whereas signaling through TNFR-I is also required for FDCs and normal splenic architecture but not for lymph-node development.

Because LT-β is also required for FDC development, mice deficient for LT-β or the LT-β receptor lack normal FDCs in the spleen and any residual lymph nodes. Administration of the appropriate LT to adult mice deficient in these molecules does not restore development of lymph nodes or Peyer's patches, indicating that there are critical developmental periods during which these cytokines act to induce the development of these lymphoid tissues.

9-3 T-cell entry into lymphoid tissues occurs across specialized small blood vessels and is mediated by the sequential actions of adhesion molecules and chemokine receptors.

Circulating T and B cells enter developing and mature secondary lymphoid tissues from the blood by a common route but are then directed into their respective compartments under the control of distinct chemokines that are produced by stromal cells resident in the T- and B-cell zones. Entry of all lymphocytes into lymph nodes and mucosal lymphoid tissues from blood occurs across high endothelial venules (HEVs), through cell–cell interactions that are not antigen-specific but are governed by cell-adhesion molecules. The spleen is the exception, as entry into the white pulp is via the marginal sinus, not HEVs (see Fig. 9.1). Here we will discuss lymphocyte entry of T cells into lymph nodes and mucosal lymphoid tissues. The dynamics of B-cell trafficking will be discussed further in Chapter 10.

The process of T-cell entry into lymphoid tissues from blood is highly efficient and is orchestrated in a manner similar to the recruitment of circulating leukocytes to inflamed tissues (see Section 3-19 and Fig. 3.30): initial tethering and rolling along the endothelial surface of HEVs via selectin–addressin interactions; activation of integrins by chemokines that decorate the endothelial-cell surface; firm adhesion of the T cell to the endothelial surface; and transmigration, or diapedesis, across the endothelial layer into the paracortical areas, or T-cell zones (Fig. 9.4).

Leukocyte Adhesion Deficiency

The selectins are important for guiding lymphocytes to particular tissues, a phenomenon known as **homing**. In the case of naive T cells, this process is mediated by **L-selectin (CD62L)**, which serves as an important marker for these cells and others that circulate through T-cell zones of

Fig. 9.4 Lymphocytes in circulation in blood enter lymph nodes by crossing the walls of high endothelial venules in stages that involve the activity of adhesion molecules, chemokines, and chemokine receptors. T cells and B cells enter lymph nodes via sequential interactions with specialized endothelium of high endothelial venules (HEVs). Shown here is entry of a naive T cell. The first step is the binding of L-selectin on the T cell to sulfated carbohydrates (sulfated sialyl-Lewis^X) of GlyCAM-1 and CD34, vascular addressins that are expressed on the endothelium of the HEV. This induces rolling of the T cell on endothelial-cell surfaces. Chemokines produced by fibroblast reticular cells (FRCs) in the T-cell zones of the lymphoid tissue (CCL21 and CCL19) or by the endothelial cells themselves (CCL21) are bound to a proteoglycan matrix on the HEV surface and are recognized by chemokine receptors on the rolling T cell, leading to activation of LFA-1. This induces both increased affinity of LFA-1 and its clustering on the T-cell surface to increase overall avidity, causing the T cell to bind tightly to ICAM-1 and arrest on the endothelial cell, which is followed by migration across the endothelium between adjacent endothelial cells, or diapedesis. As in the case of neutrophil migration (see Fig. 3.30), matrix metalloproteinases on the lymphocyte surface (not shown) enable the lymphocyte to penetrate the basement membrane under the endothelium so it can crawl into the surrounding T-cell zone in the paracortex of the lymph node along the chemokine gradient.

secondary lymphoid organs (Fig. 9.5). As we will discuss later, L-selectin is also expressed by regulatory T cells, as well as a subset of memory T cells such that they retain a recirculatory pattern similar to that of naive T cells. The exit of naive lymphocytes from the blood is initiated by weak attachment to the wall of the HEV that results in the rolling of the cell along the endothelial surface (see Fig. 9.4). Selectins are cell-surface molecules with a common core structure and are distinguished by the presence of different lectin-like domains in their extracellular portion. The lectin domains bind particular sugar groups, and each selectin binds to a specific cell-surface carbohydrate structure. L-selectin binds to the carbohydrate moiety—sulfated sialyl-Lewis^X—of mucin-like molecules called vascular addressins, which are expressed on the surface of the endothelial cells of the specialized venules in lymphoid organs. Two of these addressins, CD34 and GlyCAM-1 (see Fig. 9.5, upper left panel), are expressed on high endothelial venules in lymph nodes. A third addressin, mucosal addressin cell-adhesion molecule-1 (**MadCAM-1**), is expressed on endothelium in mucosae and the marginal sinus of the spleen and guides lymphocyte entry into mucosal lymphoid tissue, such as the Peyer's patches in the gut, and the white pulp of the spleen (see Fig. 9.5, upper right panel).

Through the process of rolling on the luminal surface of the HEV endothelium, the T cell is able to survey the surface of endothelial cells for chemokines that attract them into T-cell zones of lymphoid tissues (see Fig. 9.4). The chemokines CCL19, produced by FRCs, and CCL21, produced by both FRCs and HEV cells, are unique in directing migration into T-cell zones. Both chemokines are ligands for the chemokine receptor **CCR7**, which is expressed by naive T cells; mice that lack CCR7 do not form normal T-cell zones and have impaired primary immune responses. Like L-selectin, CCR7 is also expressed by regulatory T cells and a subset of memory T cells that recirculate through T-cell zones of secondary lymphoid organs. As with leukocyte migration to other tissue sites (see Section 3-18), recognition of chemokines on the endothelial surface of the HEV by CCR7 induces signaling that activates the integrin **LFA-1** (see Section 3-2 and Fig. 7.25), increasing affinity for its two ligands, ICAM-2 and ICAM-1 (Fig. 9.5 and Fig. 9.6). At homeostasis, ICAM-1 is expressed only on endothelial cells of the HEV in secondary lymphoid tissues, whereas ICAM-2 is constitutively expressed on all endothelial cells. The organization of LFA-1 molecules in the lymphocyte membrane is also altered by chemokine stimulation, such that they become

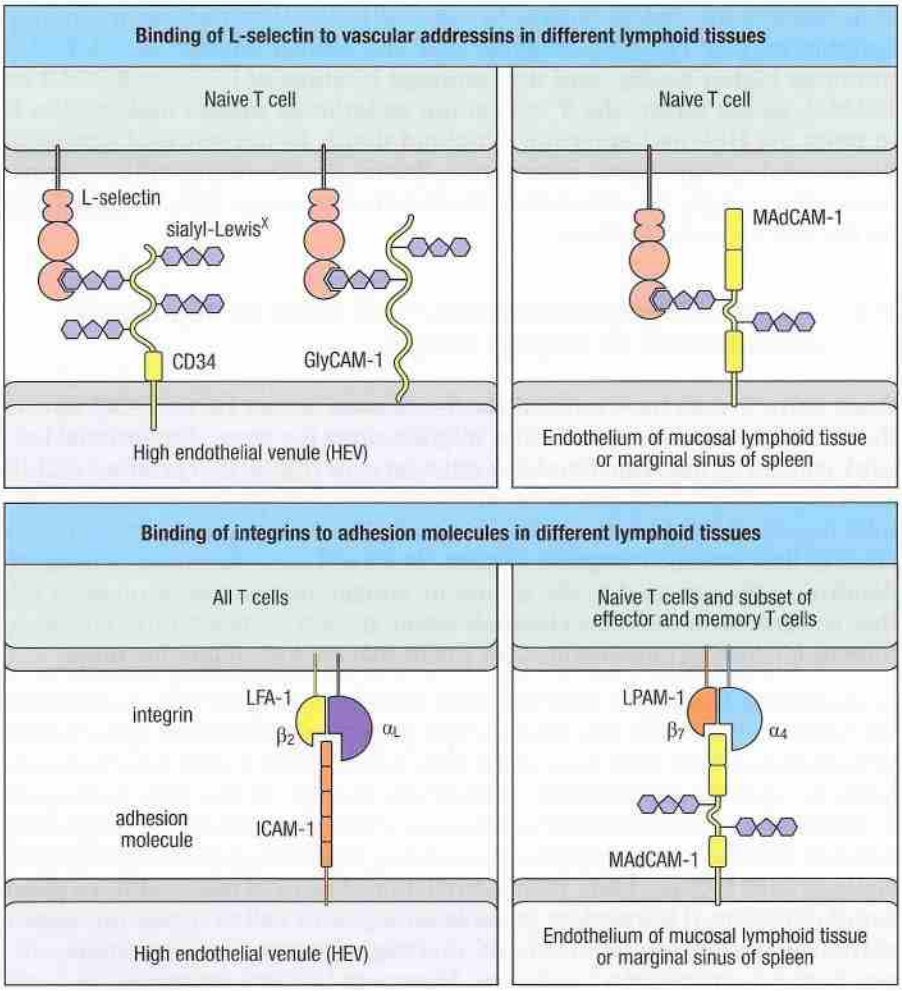

Fig. 9.5 Different selectins and integrins are used by lymphocytes to enter different lymphoid tissues. L-selectin is expressed on naive T cells and recognizes carbohydrate motifs. Its binds to sulfated sialyl-Lewis^X moieties on the vascular addressins CD34 and GlyCAM-1, which are expressed on the luminal surface of HEV endothelial cells (top left panel). CD34 is expressed in appropriately glycosylated form only on HEV cells, although it is found in other forms on other endothelial cells; GlyCAM-1 is expressed only on HEV cells. The addressin MAdCAM-1 is expressed on mucosal endothelium and guides lymphocytes to mucosal lymphoid tissue (top right panel). The configuration shown represents mouse MAdCAM-1, which contains an IgA-like domain closest to the cell membrane; human MAdCAM-1 has an elongated mucin-like domain and lacks the IgA-like domain. Integrins are heterodimeric proteins containing a β chain, which defines the class of integrin, and an α chain, which defines the different integrins within a class. The α chain is larger than the β chain and contains binding sites for divalent cations that may be important in signaling. LFA-1 (integrin $\alpha_L\beta_2$) is expressed on all leukocytes (bottom left panel). It binds ICAMs and is important in cell migration into lymph nodes. Integrin $\alpha_4\beta_7$ (also known as lymphocyte Peyer's patch adhesion molecule, or LPAM-1) is expressed by a subset of naive T cells and contributes to lymphocyte entry into mucosal lymphoid tissues and the white pulp of the spleen by supporting adhesive interactions with the vascular addressin MAdCAM-1 (bottom right panel).

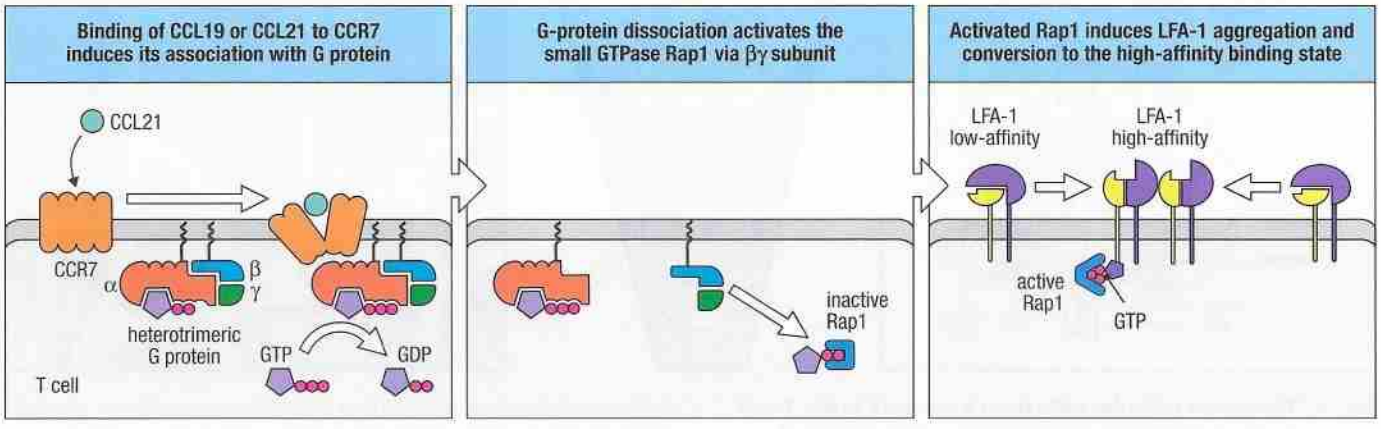

Fig. 9.6 Activation of LFA-1 by chemokine signaling on naive T cells occurs via G-protein signaling. As a naive T cell rolls on HEV endothelium, CCR7 expressed on the T cell detects the chemokines CCL21 and CCL19 that are bound to proteoglycans on the surface of endothelial cells. Binding of CCL21 or CCL19 by CCR7 induces its association with the G-protein complex (left panel), inducing exchange of GDP for GTP and leading to its dissociation into the G_α and $G_\beta G_\gamma$ subunits, the latter of which leads to activation of the small GTPase Rap1 (middle panel). GTP-bound Rap1 leads to a conformational change in LFA-1, inducing its transition from a low-affinity state to a high-affinity state and its clustering on the T-cell surface (right panel), which combine to greatly increase the avidity of LFA-1 for the ICAM ligands that are displayed on the HEV surface.

concentrated into microclusters in areas of cell–cell contact on the rolling lymphocyte (see Fig. 9.6). Together with the affinity change in LFA-1, this produces higher avidity, and thus stronger binding, of LFA-1 to ICAM-1 or ICAM-2, which arrests the T cell on the endothelial surface and enables it to cross the HEV and enter the lymphoid tissue. In the mucosal lymphoid tissues and spleen, some naive and effector T cells use another integrin heterodimer, $\alpha_4\beta_7$, for adhesion to MadCAM-1 and arrest of the rolling T cell on the vascular endothelium.

9-4 T cells are highly motile within T-cell zones as they survey dendritic cells for cognate antigen.

Once naive T cells have entered the T-cell zone across HEVs, CCR7 directs their continued locomotion as they migrate along the three-dimensional network created by the same fibroblast reticular cells (FRCs) that produce CCL19 and CCL21 (Fig. 9.7). These chemokines bind to proteoglycans in the extracellular matrix of channels formed and lined by FRCs, through which the T cells crawl as they search for cognate antigen. As we will see in Section 9-6, because dendritic cells activated in the tissues by antigen uptake also express CCR7, they co-localize to the same channels within the FRC network in T-cell zones, thereby facilitating interactions with T cells that are transmigrating there.

Compared to T cells, the dendritic cells (DCs) that migrate into T-cell zones are relatively immobile. Yet, because they project long dendrites, they provide tremendous surface area for contact with T cells as the T cells scan their surfaces for specific peptide:MHC complexes. In view of the high motility of T cells (about two cell diameters per minute), their high density within the FRC network, and the extensive projections of DCs, it is estimated that a given T cell contacts ~100 DCs per hour. With a dwell time of up to 24 hours within a given lymphoid tissue, it is therefore possible for a given T cell to survey thousands of DCs per day—essentially every DC that might bear the T cell's cognate antigen during its transit of a T-cell zone. Moreover, by some estimates the T-cell

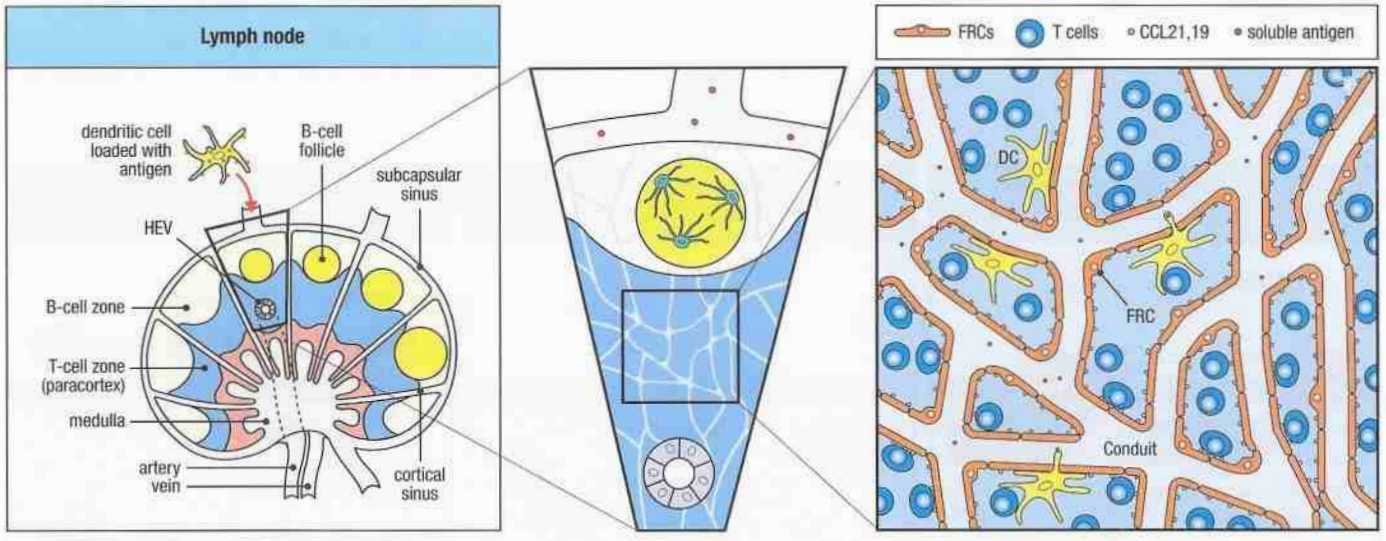

Fig. 9.7 Fibroblast reticular cells form a network in the T-cell zones of lymphoid tissues that facilitates interactions of naive T cells and dendritic cells. Fibroblast reticular cells (FRCs) within the T-cell zones of secondary lymphoid organs produce an extracellular matrix containing reticulin and collagen fibrils that form a meshwork, referred to as lymphoid conduits, that is invested by a continuous layer of FRCs. The conduits extend from the floor of the subcapsular sinus throughout the paracortex of lymph nodes and serve as a scaffold for the network of FRCs as well as a conduction system to deliver free antigens that enter the lymph node via afferent lymphatics to dendritic cells in T-cell zones. The surfaces of the sinusoid-like spaces created by the FRC networks are decorated with CCL21 and CCL19 produced by the FRCs and serve as a 'highway system' along which CCR7-bearing T cells navigate in search of cognate antigen on dendritic cells, which are also attracted to these sites by the same chemokines. A similar network (not shown) is formed by follicular dendritic cells (FDCs) in B-cell follicles and is decorated with the B-cell chemoattractant, CXCL13.

After differentiating into effector cells, T cells exit from the lymph node via the cortical sinuses

Fig. 9.8 Naive T cells encounter antigen during their recirculation through secondary lymphoid organs. Naive T cells recirculate through secondary lymphoid organs, such as a lymph node (shown here), entering from the arterial blood via the specialized vascular endothelium of high endothelial venules (HEVs). Entry into the lymph node is regulated by chemokines (not shown) that direct the T cells' migration through the HEV wall and into the paracortical areas, where the T cells encounter mature dendritic cells (top panel). Those T cells shown in green do not encounter their specific antigen; they receive a survival signal through their interaction with self peptide:self MHC complexes and IL-7, and leave the lymph node through the lymphatics to return to the circulation (second panel). T cells shown in blue encounter their specific antigen on the surface of mature dendritic cells; they lose their ability to exit from the node and become activated to proliferate and to differentiate into effector T cells (third panel). After several days, these antigen-specific effector T cells regain the expression of receptors needed to exit from the node, leave via the efferent lymphatics, and enter the circulation in greatly increased numbers (bottom panel).

receptor can be activated by recognition of just a single antigenic peptide:MHC complex. In view of their high rates of recirculation to, and concentration in, T-cell zones along with incoming dendritic cells, and the high efficiency with which T cells can scan DCs for their cognate peptide:MHC complex, each T cell has a high probability of encountering antigen derived from a pathogen that has set up an infection anywhere in the body.

If naive T cells do not encounter their specific antigen during their transit through a T-cell zone, they exit from the lymphoid organ and reenter the bloodstream, where they continue to recirculate—returning to the blood via the efferent lymphatics in the case of lymph nodes or MALT or directly back to blood in the spleen, which has no lymphatics (Fig. 9.8; see also Fig. 9.1). If, however, a naive T cell recognizes its specific antigen on the surface of an activated dendritic cell, its locomotion is arrested, and it is retained much longer in the T-cell zone where it proliferates for several days, undergoing a remarkable number of cell divisions that gives rise to effector T cells and memory cells of identical antigenic specificity that vastly outnumber their naive precursors, as we will discuss further in Section 9-9. At the end of this period, most effector T cells exit the lymphoid organ and reenter the bloodstream, through which they migrate to the sites of infection to coordinate pathogen clearance with innate immune cells (see Chapter 11), whereas others interact with B cells and migrate instead to B-cell zones, where they participate in the germinal center response to support antibody production (see Chapter 10).

As indicated above, the efficiency with which T cells screen antigen-presenting cells in lymph nodes is very high, as can be seen by the rapid trapping of antigen-specific T cells in a single lymph node containing antigen; within 48 hours of antigen delivery, nearly all antigen-specific T cells in the body can be trapped in the lymph node draining a site of infection (Fig. 9.9). In addition to the high efficiency of T-cell surveillance of the T-cell zone for antigen, local inflammation that accompanies pathogen penetration of innate defenses stimulates a marked increase in the influx, and a decrease in efflux, of lymphocytes into and out of the involved lymph node. This is the basis for local lymph node swelling that typically accompanies infection. Such efficiency is crucial for the initiation of an adaptive immune response, as only one naive T cell out of ~10^6, or ~100 of each clonal precursor per animal (in mice), is likely to be specific for a particular antigenic epitope, and adaptive immunity depends on the activation, differentiation, and expansion of these rare cells to adequately deal with an infection.

9-5 The exit of T cells from T-cell zones of lymphoid tissues is controlled by a chemotactic lipid.

T cells exit from a lymph node via the cortical sinuses, which lead into the medullary sinus and then the efferent lymphatic vessel. The egress of T cells from secondary lymphoid organs involves the phospholipid molecule

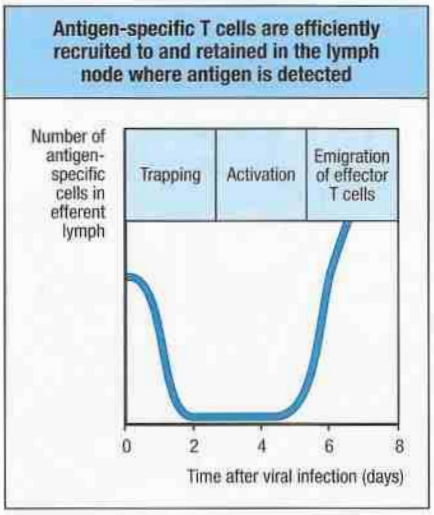

Fig. 9.9 Trapping and activation of antigen-specific naive T cells in lymphoid tissue. Naive T cells entering the lymph node from the blood encounter antigen-presenting dendritic cells in T-cell zones. T cells that recognize their specific antigen bind stably to the dendritic cells and are activated through their T-cell receptors, resulting in their retention within the lymph node as they develop into effector T cells. By 3–6 days after their activation and differentiation, activated effector T cells begin leaving the lymph node in large numbers via the efferent lymphatics. Lymphocyte recirculation and recognition are so effective that all the naive T cells in the peripheral circulation specific for a particular antigen can be trapped by that antigen in one node within 2 days.

sphingosine 1-phosphate (S1P) (Fig. 9.10). S1P has chemotactic activity and signaling properties similar to those of chemokines, in that the receptors for S1P are G protein–coupled receptors (GPCRs). S1P is constitutively produced by endothelial cells lining lymphatic vessels and the cortical and medullary sinuses of lymph nodes and is actively degraded by an enzyme, S1P lyase, that is produced in the lymphoid tissue. A concentration gradient of S1P is therefore established between the T-cell zones and the lymph.

Naive T cells recently arrived from the blood express low levels of the S1P receptor, **S1PR1**, due to its internalization and down-regulation by S1P present in blood. During the hours required for reexpression of the receptor, naive T cells are able to migrate within T-cell zones without sensing the S1P gradient. The up-regulation of S1PR1 by naive T cells that fail to recognize antigen activates their migration to the cortical and medullary sinuses and out the efferent lymphatic vessel, ultimately returning them to the blood via the thoracic duct (see Section 1–16).

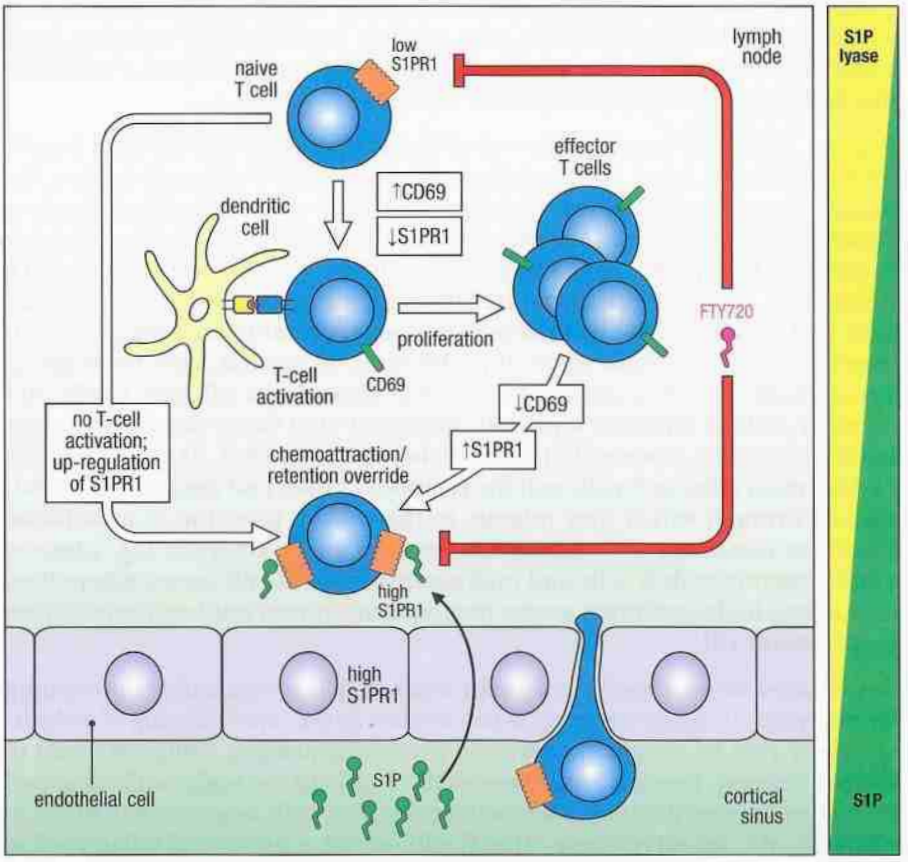

Fig. 9.10 The egress of lymphocytes from lymphoid tissue is mediated by a sphingosine 1-phosphate gradient. The level of sphingosine 1-phosphate (S1P) within lymphoid tissue is low compared with that in blood and lymph, due to the production by stromal cells within T-cell zones of the enzyme S1P lyase, which degrades S1P. This creates an S1P gradient (indicated by shading), such that S1P levels are low in T-cell zones and high in cortical sinuses and efferent lymphatics. The sphingosine 1-phosphate receptor 1 (S1PR1), which is expressed by naive T cells, is present at low levels on the surface of naive T cells that have recently entered T-cell zones, because the high levels of S1P in blood down-regulate the receptor. In the absence of antigen recognition, S1PR1 surface expression on the naive T-cell surface increases, allowing the cell to sense the S1P gradient, which directs its egress from the T-cell zones into a cortical sinus and thus into the efferent lymphatic vessel. T cells activated by an antigen-expressing dendritic cell up-regulate CD69, which acts to internalize S1PR1 expression and cause retention in the T-cell zone. Antigen-activated T cells eventually reexpress S1PR1 as CD69 expression decreases and egress from the lymph node along the S1P gradient. FTY720, an immunomodulatory molecule that cannot be inactivated by S1P lyase, inhibits T-cell egression by down-modulating expression of S1PR1 by ligand-induced internalization within the lymph node. FTY720 may also activate S1PR1-mediated closure of egress ports on the sinusoidal endothelium by enhancing junctional contacts (not shown).

T cells activated by antigen in lymphoid organs undergo more sustained down-regulation of S1PR1 that persists for several days, during clonal expansion and effector T-cell differentiation. This is due to actions of **CD69**, a surface protein induced within a few hours of T-cell receptor signaling that acts to internalize S1PR1. During this period, activated T cells cannot respond to the S1P gradient and do not exit the lymphoid organ. After several days of proliferation and effector T-cell differentiation, as T-cell activation wanes, CD69 expression decreases and S1PR1 reappears on the surface of effector T cells, allowing the effector T cells to migrate out of the lymphoid tissue in response to the S1P gradient.

ANIMATION 9.3

Regulation of the exit of both naive and effector lymphocytes from secondary lymphoid organs by S1P is the basis for a new kind of potential immunosuppressive drug, FTY720 (fingolimod). FTY720 inhibits immune responses by preventing lymphocytes from returning to the circulation, thereby sequestering them in lymphoid tissues and causing rapid onset of lymphopenia (a lack of lymphocytes in the blood). *In vivo*, FTY720 becomes phosphorylated and mimics S1P and acts as an agonist for S1P receptors. Phosphorylated FTY720 is not degraded by S1P lyase and therefore causes chronic inactivation and down-regulation of S1P receptors, leading to trapping of T cells in secondary lymphoid organs. FTY720 may also inhibit lymphocyte exit by effects on lymphatic endothelial cells that increase tight junction formation and close exit portals normally used by T cells.

9-6 Activation of conventional dendritic cells stimulates their maturation and migration to T-cell zones to induce naive T-cell activation.

Dendritic cells (DCs) are central players that bridge innate and adaptive immunity; DCs are sentinel cells that sense pathogens as part of the innate immune system and activate naive T-cell responses to initiate adaptive immunity. Like DCs, macrophages and B cells express MHC class II molecules and can process and present antigen to T cells—hence they are referred to collectively as 'professional' antigen-presenting cells (APCs) (Fig. 9.11).

	Dendritic cells	Macrophages	B cells

Fig. 9.11 The properties of the various antigen-presenting cells (APCs). Dendritic cells, macrophages, and B cells are the main cell types involved in the presentation of foreign antigens to T cells. These cells vary in their means of antigen uptake, MHC class II expression, co-stimulator expression, the type of antigen they present effectively, their locations in the body, and their surface adhesion molecules (not shown). Antigen presentation by dendritic cells is primarily involved in activating naive T cells for expansion and differentiation. Macrophages present antigen primarily to receive help from effector and memory T cells in the form of cytokines or surface molecules that enhance their killing of phagocytosed microbes, whereas B cells present antigen to TFH cells to recruit their help for germinal center responses that produce class-switched, high-affinity antibodies. The degree of activity for each of the indicated functions is indicated on an arbitrary scale from '–' (no activity) to '++++' (highest activity).

Fig. 9.12 Conventional dendritic cells in nonlymphoid tissues undergo sequential steps of antigen uptake, migration, and maturation to deliver antigens to T cells in lymphoid tissues. See text for details.

However, DCs appear to be unique in their activation of naive T cells. The delivery of antigen from a site of infection to lymphoid tissue is actively aided by the innate immune response. Following the sensing of a breach of innate barrier defenses by a pathogen, antigen is delivered to secondary lymphoid tissues by two mechanisms: as free antigen carried via draining lymph or by blood; or as cell-associated antigen, carried primarily by DCs that have taken up antigen in tissue sites. One effect of innate immunity is an inflammatory reaction that increases the rate of entry of blood plasma into an infected tissue and thus increases the drainage of extracellular fluid into the lymph, taking with it free, or soluble, antigen that is carried to lymphoid tissues. Even more important for initiation of the adaptive response is the activation of dendritic cells that have taken up particulate and soluble antigens at the site of infection (Fig. 9.12).

Although there are two major classes of dendritic cells—**conventional (or classical) dendritic cells (cDCs)** and **plasmacytoid dendritic cells (pDCs)** (Fig. 9.13; see also Section 3-1)—the principal antigen-presenting cells tasked with naive T-cell activation are conventional dendritic cells. The major function of cDCs is to ingest and degrade protein antigens and present them as peptides bound to MHC class I or MHC class II molecules (see Chapter 6). There are two major subsets of conventional dendritic cells, **cDC1** and **cDC2**, which are specialized for the presentation of antigens derived from different classes of pathogen, as will be discussed in detail in the next section. Both subsets of cDCs are most abundant in nonlymphoid tissues, particularly at barrier tissue sites, such as the intestines, lung, and skin, where they are strategically positioned in close contact with surface epithelia through which most pathogens enter. They are also present in solid organs such as the heart and kidneys. Conventional dendritic cells that reside in these sites at steady state are often referred to as **nonlymphoid tissue (NLT)-resident (or migratory) cDCs**; because naive T cells do not circulate to nonlymphoid tissues, these cDCs must migrate to T-cell zones to activate them. Conventional dendritic cells also populate secondary lymphoid organs, where they can handle antigens that are delivered directly to the lymphoid tissue, whether introduced across the epithelial barrier to mucosa-associated lymphoid tissue, via the lymph to

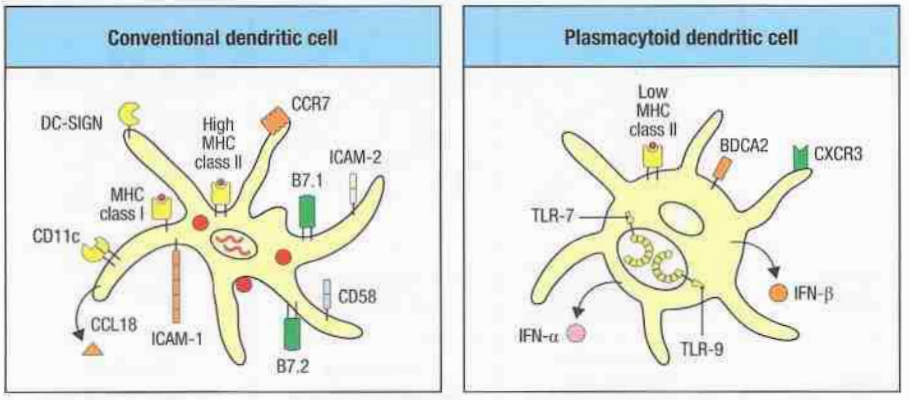

Fig. 9.13 Conventional and plasmacytoid dendritic cells have different roles in the immune response. Mature conventional dendritic cells (left panel) are primarily concerned with the activation of naive T cells. There are several subsets of conventional dendritic cells, but these all process antigen efficiently, and when they are mature they express MHC proteins and co-stimulatory molecules for priming naive T cells. Immature dendritic cells lack many of the cell-surface molecules shown here but have numerous surface receptors that recognize pathogen molecules, including most of the Toll-like receptors (TLRs) and receptors that facilitate antigen uptake. Plasmacytoid dendritic cells (right panel) are sentinels primarily for viral infections and secrete large amounts of type I interferons. This category of dendritic cell is thought to play a minimal role in priming naive T cells, but they express the intracellular receptors TLR-7 and TLR-9 for sensing viral infections.

lymph nodes, or via the bloodstream to the spleen. These **lymphoid tissue (LT)-resident cDCs** are also able to receive antigen from migratory cDCs in some settings.

In accord with their primacy as APCs for naive T-cell activation, all cDCs are highly active at the uptake and processing of antigen, both by receptor-mediated phagocytosis and by macropinocytosis (see Sections 3-1 and 6-1). However, cDCs at all tissue sites express only low levels of co-stimulatory molecules at steady state and are often referred to as **immature cDCs**, reflecting their inability to activate naive T cells. It is only after their recognition of microbial-associated molecular patterns or damage-associated molecular patterns (MAMPs or DAMPs) that immature cDCs are activated to become **mature cDCs** and express the high levels of co-stimulatory molecules required to activate naive T cells (Fig. 9.13 and Fig. 9.14). DC maturation can be enhanced, but not replaced, by stimulation with inflammatory cytokines, such as TNF and IL-1. Activated cDCs alter their integrin and

Dendritic cells in lymphoid tissues

Fig. 9.14 Dendritic cells in different stages of activation and migration. The panels show fluorescence micrographs of dendritic cells stained for MHC class II molecules in green and for a lysosomal protein in red. Unactivated dendritic cells (top panel) have many long processes, or dendrites, from which the cells get their name. The cell bodies are difficult to distinguish in this low-power image, but the cells contain many endocytic vesicles that stain both for MHC class II molecules and for the lysosomal protein; when these two colors overlap they give rise to a yellow fluorescence, as shown here. Activated dendritic cells leave the tissues to migrate through the lymphatics to secondary lymphoid tissues. During this migration their morphology changes. The dendritic cells stop phagocytosing antigen, and staining for the lysosomal protein is beginning to be distinct from that for MHC class II molecules (center panel). The dendritic cell now has many folds of membrane, which gave these cells their original name of 'veil' cells. Finally, in the lymph nodes, dendritic cells express high levels of peptide:MHC complexes and co-stimulatory molecules and are very good at stimulating naive CD4 and naive CD8 T cells. At this stage, the activated dendritic cells do not phagocytose, and the red staining of the lysosomal protein is quite distinct from the green-stained MHC class II molecules displayed at high density on many dendritic processes (bottom panel).

chemokine receptor expression to enable them to leave their initial tissue of residence to traffic to T-cell zones of secondary lymphoid tissues. A remarkable diversity of receptors expressed by immature DCs underlies their recognition of a broad range of extracellular and intracellular signals that induce their activation and maturation and help to define distinct functions of cDC subsets (see Sections 3-1 and 6-5).

Between them, immature cDC1 and cDC2 cells express all members of the TLR family except for TLR-8, which is functionally redundant with TLR-7 (see Fig. 3.10). Thus, cDCs can be activated effectively by any TLR ligand and, therefore, by nearly any pathogen. In addition to TLRs, several other pattern-recognition receptors (PRRs) that are used by dendritic cells to take up pathogens also provide maturation signals. This includes an array of members of the C-type lectin family of receptors, which recognize a diversity of carbohydrates on microbes to facilitate their uptake. Examples include the lectin **DC-SIGN**, which binds mannose and fucose residues present on a wide range of pathogens; DEC 205; and **Dectin-1**, which recognizes β-(1,3)–linked glucans found in fungal cell walls (see Section 3-1). Other receptors that enhance pathogen binding, such as receptors for complement or phagocytic receptors such as the mannose receptor, may also contribute to dendritic-cell activation, in addition to augmenting phagocytosis. Other extracellular antigens are taken up nonspecifically by the process of **macropinocytosis**, in which large volumes of surrounding fluid are engulfed. In this way, microbes that have evolved strategies to escape recognition by phagocytic receptors, such as bacteria with thick polysaccharide capsules, can be ingested. The versatility in pathways for antigen uptake enables dendritic cells to present antigens from virtually any type of microbe, including fungi, parasites, viruses, and bacteria (Fig. 9.15).

A critical result of PRR and inflammatory cytokine signaling is significant alteration in the chemokine receptors and integrins expressed by dendritic cells that induces their mobilization from sites of antigen capture to T-cell zones—whether within the lymphoid tissue in which they reside in

	Routes of antigen processing and presentation by dendritic cells				
	Receptor-mediated phagocytosis	Macropinocytosis	Viral infection	Cross-presentation after phagocytic or macropinocytic uptake	Transfer from incoming dendritic cell to resident dendritic cell

Type of naive T cell activated	CD4 T cells	CD4 T cells	CD8 T cells	CD8 T cells	CD8 T cells, CD4 T cellls

Fig. 9.15 The different routes by which dendritic cells can take up, process, and present protein antigens. Uptake of antigens into the endocytic system, either by receptor-mediated phagocytosis or by macropinocytosis, is considered the major route for delivering peptides to MHC class II molecules for presentation to CD4 T cells (first two panels). Production of antigens in the cytosol, for example, as a result of viral infection, is thought to be the major route for delivering peptides to MHC class I molecules for presentation to CD8 T cells (third panel). It is possible, however, for exogenous antigens taken into the endocytic pathway to be delivered into the cytosol for eventual delivery to MHC class I molecules for presentation to CD8 T cells, a process called cross-presentation (fourth panel). Finally, antigens can be transmitted from one APC to another, whether for presentation to CD8 or CD4 T cells (fifth panel).

the case of LT-resident cDCs or within a draining lymph node in the case of migratory cDCs. PRR signaling induces expression of CCR7, which is required for activated cDCs to sense and migrate along gradients of CCL19 and CCL21—the same chemokines used by naive T cells to home to T-cell zones. CCL19 and CCL21 immobilized on the lymphatic endothelium allow migratory cDCs to enter the afferent lymphatics and navigate through the lymphatics to T-cell zones. Whereas T cells must cross the wall of high endothelial venules to leave the blood and reach the T-cell zones, dendritic cells entering via the afferent lymphatics migrate into T-cell zones via the floor of the subcapsular sinus. In addition to the *de novo* expression of CCR7, activated cDCs must down-modulate their expression of chemokine receptors that act to retain them in their tissue of residence. Although details of how this occurs are not fully understood, desensitization of these receptors by enhanced local expression of the chemokines they bind may play a role.

Signaling through CCR7 not only induces the migration of cDCs into T-cell zones, but, together with other activating signals such as type I interferons, TNF, and IL-1, it may also contribute to their enhanced antigen-presenting function (see Fig. 9.13). By the time activated dendritic cells arrive within T-cell zones, they are no longer able to engulf antigens by phagocytosis or macropinocytosis. They also express high levels of the two main co-stimulatory molecules: the structurally related transmembrane glycoproteins B7.1 (CD80) and B7.2 (CD86), which deliver co-stimulatory signals by interacting with CD28 expressed on naive T cells (see Section 7-22). Moreover, as discussed in Section 6-9, activated cDCs enhance the surface expression of pathogenic peptide:MHC class II complexes by increasing the longevity of newly loaded MHC class II molecules coincident with activation-induced down-regulation of MARCH-1 E3 ligase, which otherwise promotes the internalization and degradation of surface peptide:MHC class II complexes (see Section 6-9). DC activation also shuts off the transcriptional regulator CIITA, thereby preventing new expression of MHC class II molecules. In combination, these actions enable mature cDCs to present peptide:MHC class II complexes loaded at the time of pathogen uptake for very extended periods of time. Loss of the MARCH-1 E3 ligase similarly extends the life span of surface-expressed CD86 (B7.2). Activated dendritic cells also secrete the chemokine CCL19 and express high levels of adhesion molecules, which may enhance their recruitment of, and binding to, naive T cells. Together, these properties of mature cDCs markedly increase the opportunity for pathogen-derived antigens to be recognized by incoming naive T cells.

Despite their enhanced presentation of pathogen-derived peptide antigens, activated dendritic cells also present self peptides. Although the presence of self-peptide:MHC complexes could present a problem for the maintenance of self-tolerance, several mechanisms normally prevent these self peptides from inducing an immune response. First, the T-cell receptor repertoire has largely been purged of receptors that recognize self peptides during thymic development (see Chapter 8), so that T-cell responses against most ubiquitous self antigens are avoided. This is referred to as **central tolerance**. In addition, dendritic cells in the lymphoid tissues that have not been activated by infection will bear self-peptide:MHC complexes on their surface, derived from the breakdown of their own proteins and tissue proteins present in the extracellular fluid. Because these cells do not express the appropriate co-stimulatory molecules, however, they do not have the same capacity to activate naive T cells as do activated dendritic cells. Although the details remain unclear, the presentation of self peptides by LT-resident, immature dendritic cells may induce an alternative program of activation in naive T cells that favors immune regulation and T-cell deletion rather than immune activation (see also Section 9-17).

The induction of co-stimulatory activity in antigen-presenting cells by common microbial constituents is believed to allow the immune system to distinguish antigens borne by infectious agents from antigens associated with innocuous proteins, including self proteins. Indeed, many foreign proteins do not induce an immune response when injected on their own because they fail to induce co-stimulatory activity in antigen-presenting cells. When such protein antigens are mixed with bacteria, however, they become immunogenic, because the bacteria induce the essential co-stimulatory activity in cells that ingest the protein. Bacteria or bacterial components used in this way are known as **adjuvants** (see Appendix I, Section A-1). We will see in Chapter 15 how self proteins mixed with bacterial adjuvants can induce autoimmune disease, illustrating the crucial importance of the regulation of co-stimulatory activity in the discrimination of self from nonself.

9-7 Subsets of conventional dendritic cells are specialized for different modes of antigen presentation.

Conventional dendritic cells are composed of two major subsets—cDC1 and cDC2—that are present in all tissues and share the same general properties discussed in the past section. However, cDC1 and cDC2 cells have distinct ontogeny and distinct roles for priming different types of naive T cells in response to different types of pathogens, hence the subdivision (Fig. 9.16). Although specifics of the functions of cDC subsets are still being defined, it is now apparent that cDC1 cells are specialized for the activation of naive CD8 T cells, which recognize intracellular pathogens that introduce antigens into the cytosol and are processed and loaded onto MHC class I molecules. cDC1 cells are primarily responsible for **cross-priming**; that is, the activation of naive CD8 T cells by **cross-presentation** (see Section 9-13; see also Sections 6-1 and 6-5). For this reason, they are also critical for antitumor immune surveillance, to be discussed further in Chapter 16.

	Conventional DC subset	
Feature	**cDC1**	**cDC2**
Common surface markers	CD11c MHC class II	CD11c MHC class II
Unique surface markers	XCR1 BDCA-3 CLEC9A	CD11b BDCA-1 Dectin-1
Nonlymphoid tissues (migratory DCs)	CD103 CD24	CD11b CD24 SIRPα CD103*
Lymphoid tissues (LT-resident DCs)	CD8αα CD24	CD4 SIRPα
Key transcription factors	BATF3 IRF8	Notch2 IRF4
TLRs	TLR-3+, various	TLR-3-, various
Cytokines produced	IL-12	IL-23, IL-6, TGF-β
Major functions	Antigen presentation to naive CD8 T cells Cross-presentation	Antigen presentation to naive CD4 T cells
Pathogens	Intracellular	Extracellular

Fig. 9.16 Phenotypic and functional features of type 1 and type 2 conventional dendritic cells. This chart highlights the characteristics of conventional dendritic cell 1 (cDC1) and conventional dendritic cell 2 (cDC2). *CD103 is expressed by a subset of cDC2 cells.

In contrast to cDC1 cells, cDC2 cells appear to be specialized for the presentation of extracellular pathogens whose antigens are delivered via vesicular compartments to be loaded onto MHC class II, and thus activate naive CD4 T cells. However, while details are unclear, some CD4 T cells—particularly those that respond to some intracellular pathogens—may receive their activating signals not on cDC2 cells but on cDC1 cells (see Section 9-13). Both subsets encompass migratory and LT-resident cDCs; both cDC1 and cDC2 cells are arrayed at nearly all of the portals of antigen entry in the body, whether in nonlymphoid or lymphoid tissues. Although there are some differences in the cell-surface markers that distinguish them across species, these subsets appear to be analogous in mice and humans.

While all cDCs express the α integrin **CD11c**, as well as MHC class II and **CD24**, the cDC1 subset is defined by the unique expression of the chemokine receptor **XCR1**, the ligand for which is **XCL1** (lymphotactin), which is produced by activated CD8 T cells and NK cells (see Fig. 9.16). Other cDC1-specific markers include CLEC9A, a member of the C-type lectin receptor family that facilitates uptake of necrotic cells (see Section 6-5), and blood dendritic cell antigen 3 (BDCA-3), the function of which is unclear. cDC1s are also distinguished from cDC2s by their expression of **TLR-3**, the endosomal TLR that recognizes double-stranded RNA (dsRNA). Because dsRNA is an intermediate in the replication of many viruses—including those with DNA or single-stranded RNA (ssRNA) genomes—TLR-3 is an important sensor for products of viral replication in host cells that are damaged by viral infection or killed by cytolytic cells; that is, PAMPs that are linked to pathogens best handled by cross-presentation to CD8 T cells. Type 1 cDCs are also the principal producers of IL-12, which, as we will discuss later, is important for the differentiation of both CD8 T cells and the T_H1 subset of CD4 T cells. cDC1 cells can be further divided by the expression of **CD8αα** and **CD103** (the latter being the α_E component of $\alpha_E\beta_7$ integrin), which generally distinguish cDC1 cells resident in lymphoid tissues and nonlymphoid tissues, respectively.

Cells of the cDC2 subset are the most numerous in secondary lymphoid tissues and are defined by expression of the integrin component **CD11b**, which is also expressed on some macrophages, and BDCA-1. In contrast to cDC1 cells, cDC2 cells lack expression of TLR-3 and produce less IL-12, but appear to be the principal producers of IL-23 and IL-6, which are important for the induction of T_H17 responses, as we will discuss. Type 2 cDCs also appear to be dominant in the induction of T_H2 and T_{FH} cells, albeit by undefined mechanisms. Markers for discriminating LT-resident and migratory cDC2 cells that are comparable to CD8αα and CD103 for cDC1 cells have yet to be defined. Although differences in methods of antigen uptake, phagolysosomal processing, and relative expression of MHC class I and MHC class II have been considered, the mechanistic basis for the subdivision of labor between cDC1 and cDC2 cells remains to be completely defined.

Not all cell-bound antigen delivered to lymphoid tissues arrives via migratory cDCs. Although migratory cDCs are typically the dominant source, antigens taken up by **monocyte-derived DCs (MoDCs)** may also contribute in the response to some pathogens. As their name implies, MoDCs are derived from circulating monocytes that are recruited into inflamed tissues, where they take up antigen that is then delivered to T-cell zones of lymphoid tissues. Although they are poor stimulators of naive T cells, MoDCs are able to transfer antigens to LT-resident cDCs, which in turn activate naive T cells. Moreover, in some cases, such as infections with herpes simplex or influenza viruses, the dendritic cells that migrate to the lymph nodes from peripheral tissues may not be the same cells that finally present antigen to naive T cells. In a herpes simplex infection, for example, dendritic cells residing in the dermis of skin capture antigen and transport it to the draining lymph nodes. There, some antigen is transferred to

antigen transfer
resident dendritic cell

Fig. 9.17 Langerhans cells take up antigen in the skin and migrate to the regional lymph nodes, where they can transfer antigen to cDC1 cells to prime CD8 T cells or directly prime CD4 T cells. Langerhans cells (LCs; yellow) are a type of nonlymphoid tissue–resident macrophage with dendritic morphology that resides in the epidermis of the skin. LCs ingest antigen in various ways, including uptake from infected keratinocytes, which are the principal epithelial cells that make up the epidermis (not shown; first panel). After antigen uptake locally, LCs then migrate to the lymph nodes (second panel). There they can transfer their antigen to cDC1 cells (orange; third panel), which, in turn, prime naive CD8 cells, or they can prime CD4 T cells directly (fourth panel).

CD8αα-positive, LT-resident cDCs, which in turn activate naive CD8 T cells. This type of transfer means that antigens from viruses that rapidly kill the dendritic cells they infect can still be presented by uninfected dendritic cells that have been activated via their TLRs to take up the dying dendritic cells and cross-present this material. This may also provide a mechanism to amplify antigen presentation by allowing multiple LT-resident cDCs to present antigen carried by a single migratory DC.

Finally, in rare microenvironments, cDCs are absent. Perhaps the best example is the epidermis of the skin, which normally lacks both cDC1 and cDC2 cells. Here, the initiation of CD8 T-cell responses is dependent on a specialized tissue-resident macrophage, the **Langerhans cell**, for initial uptake and transport of antigen to draining lymph nodes, where it can be transferred to CD8αα-positive, LT-resident cDC1 cells (Fig. 9.17). Thus, cross-presentation by LT-resident cDC1 cells is critical for the responses to many antigens imported by Langerhans cells, which are themselves less efficient at CD8 T-cell priming. In contrast, Langerhans cells appear to be the principal APCs for initiation of some CD4 T-cell responses, particularly those of T_H17 cells (see Section 12-24).

Summary.

An adaptive immune response is generated when naive T cells contact activated antigen-presenting cells in the secondary lymphoid organs. These tissues have a specialized architecture that facilitates efficient interaction between circulating lymphocytes and their target antigens. The formation and organization of the secondary lymphoid organs are controlled by proteins of the TNF family and their receptors (TNFRs). Lymphoid tissue inducer (LTi) cells expressing

lymphotoxin-$\alpha_1 b_2$ (LT-$\alpha_1\beta_2$) interact with stromal cells expressing the LT-β receptor in the developing embryo to induce chemokine production, which in turn initiates formation of the lymph nodes and Peyer's patches. Similar interactions between lymphotoxin-expressing B cells and TNFR-I–expressing follicular dendritic cells (FDCs) establish the normal architecture of the spleen and lymph nodes. B and T cells are partitioned into distinct areas within lymphoid tissue by specific chemokines.

To ensure that rare antigen-specific T cells survey the body effectively for pathogen-bearing antigen-presenting cells, T cells continually recirculate through T-cell zones of all secondary lymphoid organs where they are brought into contact with antigen-presenting cells from many different tissue sites. The migration of naive T cells into lymphoid organs is guided by the chemokine receptor CCR7, which binds CCL19 or CCL21 produced by stromal cells in the T-cell zones of secondary lymphoid tissues and displayed on the specialized endothelium of high endothelial venules (HEVs). L-selectin expressed by naive T cells initiates their rolling along the specialized surfaces of HEVs, where contact with these chemokines induces a switch in the integrin LFA-1 expressed by T cells to a configuration with affinity for the ICAM-1 expressed on the HEV endothelium. This initiates strong adhesion, diapedesis, and migration of the T cells into the T-cell zone. There, naive T cells meet antigen-bearing dendritic cells, of which there are two main populations: type 1 and type 2 conventional dendritic cells (cDC1 and cDC2). Conventional dendritic cells continually survey nonlymphoid tissues for invading pathogens and are the dendritic cells responsible for activating naive T cells. Contact with pathogens delivers signals to dendritic cells via TLRs and other pattern-recognition receptors (PRRs) that accelerate antigen processing and the production of foreign-peptide:self-MHC complexes. TLR signaling also induces expression of CCR7 by dendritic cells, which directs their migration to T-cell zones of secondary lymphoid organs, where they encounter and activate naive T cells.

Naive T-cell activation, clonal expansion, and differentiation into effector and memory T cells.

As we learned in the previous section, the perpetual recirculation of naive T cells from blood to T-cell zones of secondary lymphoid tissues and back to blood is contingent on absence of activation by cognate antigen. For an individual T cell, this pattern of recirculation can persist for years. Because the migration of a T cell to any particular secondary lymphoid tissue is random, and because a single naive T cell can survey about one lymph organ per day, even a clonal population of 100 naive T cells can theoretically survey up to 100 different lymphoid tissues per day. Thus, despite the fact that the diversity of antigen receptors on naive T cells is great and the number of cells in any clonal population is small, the chances that any given T cell within the repertoire will engage its antigen after infection is high. Still, for a clonal population to eradicate an invading pathogen, which in the case of viruses or bacteria can involve an inoculum of thousands to millions of microorganisms that can rapidly amplify their numbers exponentially, T cells must expand their own numbers and functional capabilities to succeed in defending the host.

We now consider the generation of effector and memory T cells from naive T cells. The activation and differentiation of naive T cells, often called priming, is distinct from the later responses of effector T cells to antigen on their target cells and from the responses of memory T cells to subsequent encounters with the same antigen. Priming of naive CD8 T cells by antigen presented on cDC1 cells

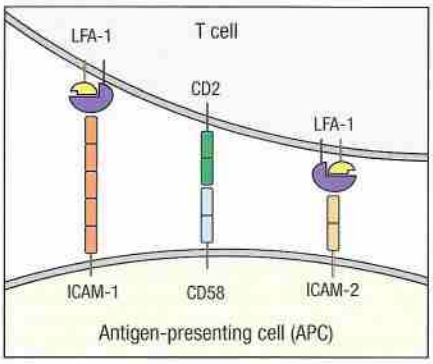

Fig. 9.18 Adhesion molecules involved in APC–T-cell interactions. Adhesion molecules of the immunoglobulin superfamily bind to adhesion molecules of various types, including integrins (LFA-1 and VLA-4) and other immunoglobulin superfamily members [the CD2–CD58 (LFA-2–LFA-3) interaction] to mediate cell–cell contact between APCs and T cells.

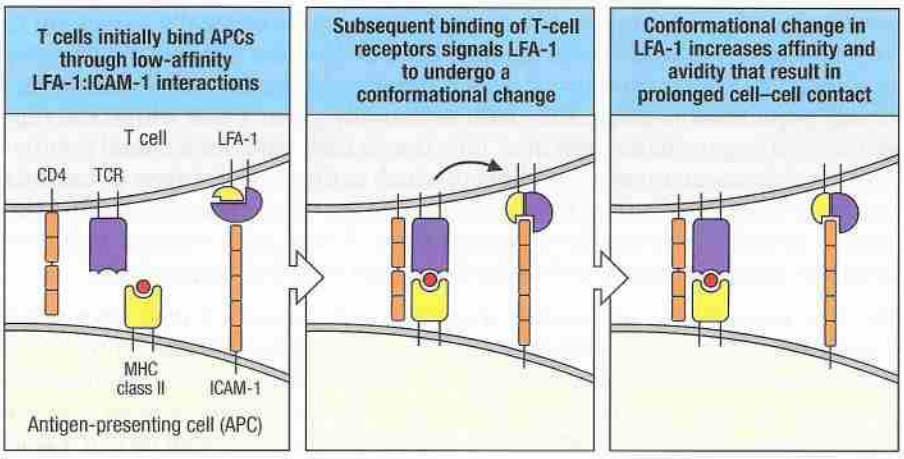
generates cytotoxic T cells capable of directly killing pathogen-infected cells. Naive CD4 T cells activated by antigen presented on cDC2 cells—and in some cases, cDC1 cells—develop into a diverse array of effector cell types depending on the nature of the signals they receive during priming. CD4 effector activity can also include cytotoxicity, but more frequently it involves the secretion of a set of cytokines that direct target cells toward a more pathogen-specific response.

As we will learn, the activation of naive T cells is contingent on at least three signals. The primary signal is T-cell receptor (TCR) recognition of antigenic peptide:MHC on the surface of activated conventional dendritic cells. Activation of the naive T cell also requires co-recognition of co-stimulatory molecules displayed by the same cDC, often referred to as the second signal. Finally, cytokines that control differentiation into different types of effector cells, the so-called third signal, are often delivered to the activated naive T cell by the antigen-presenting DC itself, but they may also be produced by other innate immune cells. All these events are set in motion by earlier signals that arise from the initial detection of the pathogens by the innate immune system and the delivery of antigen to regional lymphoid tissues. The result is a tremendous increase in the number of pathogen-specific T cells—termed clonal expansion—and their acquisition, via effector-cell differentiation, of enhanced functional properties tailored for the eradication of the pathogen that incited their response.

9-8 Conventional dendritic cells deliver multiple signals for the activation of naive T cells.

ANIMATION 9.4

As naive T cells migrate through FRC channels in the T-cell zones of lymphoid tissues, they bind transiently to each dendritic cell they encounter. Binding is mediated by interactions between LFA-1 or CD2 on the T cell and ICAM-1/ICAM-2 or CD58, respectively, on the dendritic cell (Fig. 9.18). The transient binding provides time for a T cell to scan the large number of MHC molecules displayed on the surface of cDCs for its cognate peptide. Most encounters of naive T cells with DCs do not, however, result in the recognition of an antigen, and the T cell must disengage the DC so that it can continue its migration. How naive T cells disengage from their antigen-negative targets is not known, although evidence suggests that, at least in the case of CD4 T cells, binding to MHC class II molecules without engagement of the T-cell receptor provides a signal for the cell to detach. In those rare cases in which a naive T-cell's TCR recognizes its peptide:MHC ligand, signaling through the T-cell receptor induces a conformational change in LFA-1 that greatly increases its affinity for ICAM-1 and ICAM-2 (see Section 7-19)—like that induced by signaling through CCR7 as the naive T cell enters the lymphoid tissue across HEVs (see Section 9-3). The change in LFA-1 stabilizes the association between the antigen-specific T cell and the antigen-presenting cell (Fig. 9.19). The association can persist



T cells initially bind APCs through low-affinity LFA-1:ICAM-1 interactions
Subsequent binding of T-cell receptors signals LFA-1 to undergo a conformational change
Conformational change in LFA-1 increases affinity and avidity that result in prolonged cell–cell contact

Antigen-presenting cell (APC)

Fig. 9.19 Transient adhesive interactions between T cells and antigen-presenting cells are stabilized by specific antigen recognition. When a T cell binds to its specific ligand on an antigen-presenting cell, intracellular signaling through the T-cell receptor (TCR) induces a conformational change in LFA-1 that causes it to bind with higher affinity to ICAMs on the antigen-presenting cell. Not shown, but also contributory, is activation-induced clustering of LFA-1 molecules on the T cell that increases binding avidity for ICAM on the APC. The T cell shown here is a CD4 T cell.

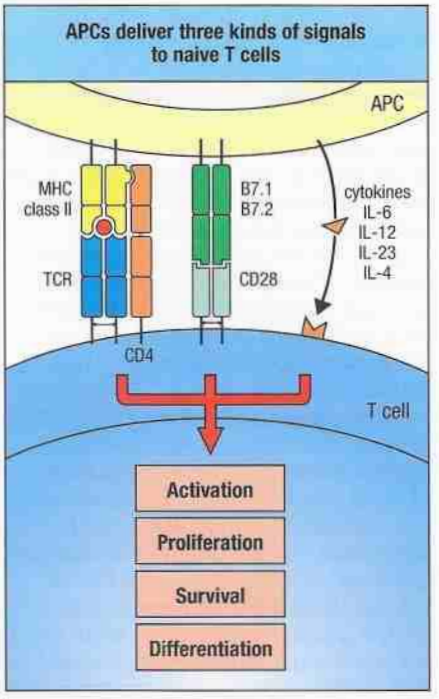

Fig. 9.20 Three kinds of signals are involved in the activation of naive T cells by antigen-presenting cells. Binding of the foreign-peptide:self-MHC complex by the T-cell receptor and, in this example, a CD4 co-receptor transmits a signal to the T cell that antigen has been encountered. Effective activation of naive T cells requires a second signal, the co-stimulatory signal, to be delivered by the same antigen-presenting cell (APC). CD28 on the T cell encounters B7 molecules on the antigen-presenting cell and delivers the second signal, whose net effect is the increased proliferation and survival of the T cell that has received the first (TCR) signal. For CD4 T cells in particular, different pathways of differentiation produce subsets of effector T cells that carry out different effector responses, depending on the nature of a third signal delivered by the antigen-presenting cell. Cytokines commonly, but not exclusively, represent the third signal involved in directing this differentiation.

for several days, during which time the naive T cell proliferates, and its progeny, which can also adhere to the same DC, differentiate into effector T cells.

At least three types of signals are produced by the activating cDC over the time the T cell engages it (Fig. 9.20). The first is generated from the interaction of a specific peptide:MHC complex with the T-cell receptor. Engagement of the T-cell receptor with its specific peptide antigen is essential for activating a naive T cell and engages several key signaling pathways (see Chapter 7). However, even if the co-receptor—CD4 or CD8—is also ligated, this does not, on its own, activate a naive T cell to proliferate and differentiate into effector T cells. Expansion and differentiation of naive T cells involve at least two additional signals: co-stimulatory signals that promote the activation and expansion of the T cells, and cytokines that direct T-cell differentiation into one of the different subsets of effector T cells. Additional signals, such as Notch ligands, can contribute to the effector differentiation of naive T cells, although these signals appear to be of less importance than those of lineage-specifying cytokines (discussed in Section 9-14).

As discussed in Section 7-22, the co-stimulatory molecules required for initial T-cell activation are the B7 family molecules, **B7.1** (CD80) and **B7.2** (CD86). These homodimeric members of the immunoglobulin superfamily are found exclusively on APCs and, in the case of naive T cells are co-expressed by the same cDC on which activating peptide:MHC complexes are engaged. The receptor for B7 molecules on the T cell is **CD28**, a member of the immunoglobulin superfamily (see Section 7-22). Signaling through CD28 that is induced by B7 molecules enhances activation of PLC-γ and other signals transduced through the TCR that are required for activation of transcription factors and PI 3-kinase, which initiate the processes of T-cell division and differentiation (see Section 7-22); targeted deficiency of B7 molecules or experimental blockade of the binding of B7 molecules to CD28 inhibits naive T-cell activation.

ANIMATION 9.5

9-9 T-cell activation induces metabolic changes that prepare the T cell for rapid clonal expansion and differentiation.

Naive T cells have condensed chromatin and little cytoplasm and are generally arrested in the G0 stage of the cell cycle (Fig. 9.21); that is, at any given time most are not progressing through the cell cycle—they have low metabolic activity and synthesize little RNA or protein. Their primary fuel is glucose, which is converted by glycolysis to pyruvate that feeds the TCA cycle in mitochondria, where **oxidative phosphorylation (OXPHOS)** efficiently generates ATP. Within hours of activation, signals generated by antigen recognition induce the cells to undergo a metabolic shift to accommodate an increased demand for macromolecular biosynthesis and energy production in preparation for entry into the cell cycle (Fig. 9.22). The resultant increase in cell size and change in morphology that accompanies the cell's preparation for cell division is referred to as **blast transformation** (see Fig. 9.21).

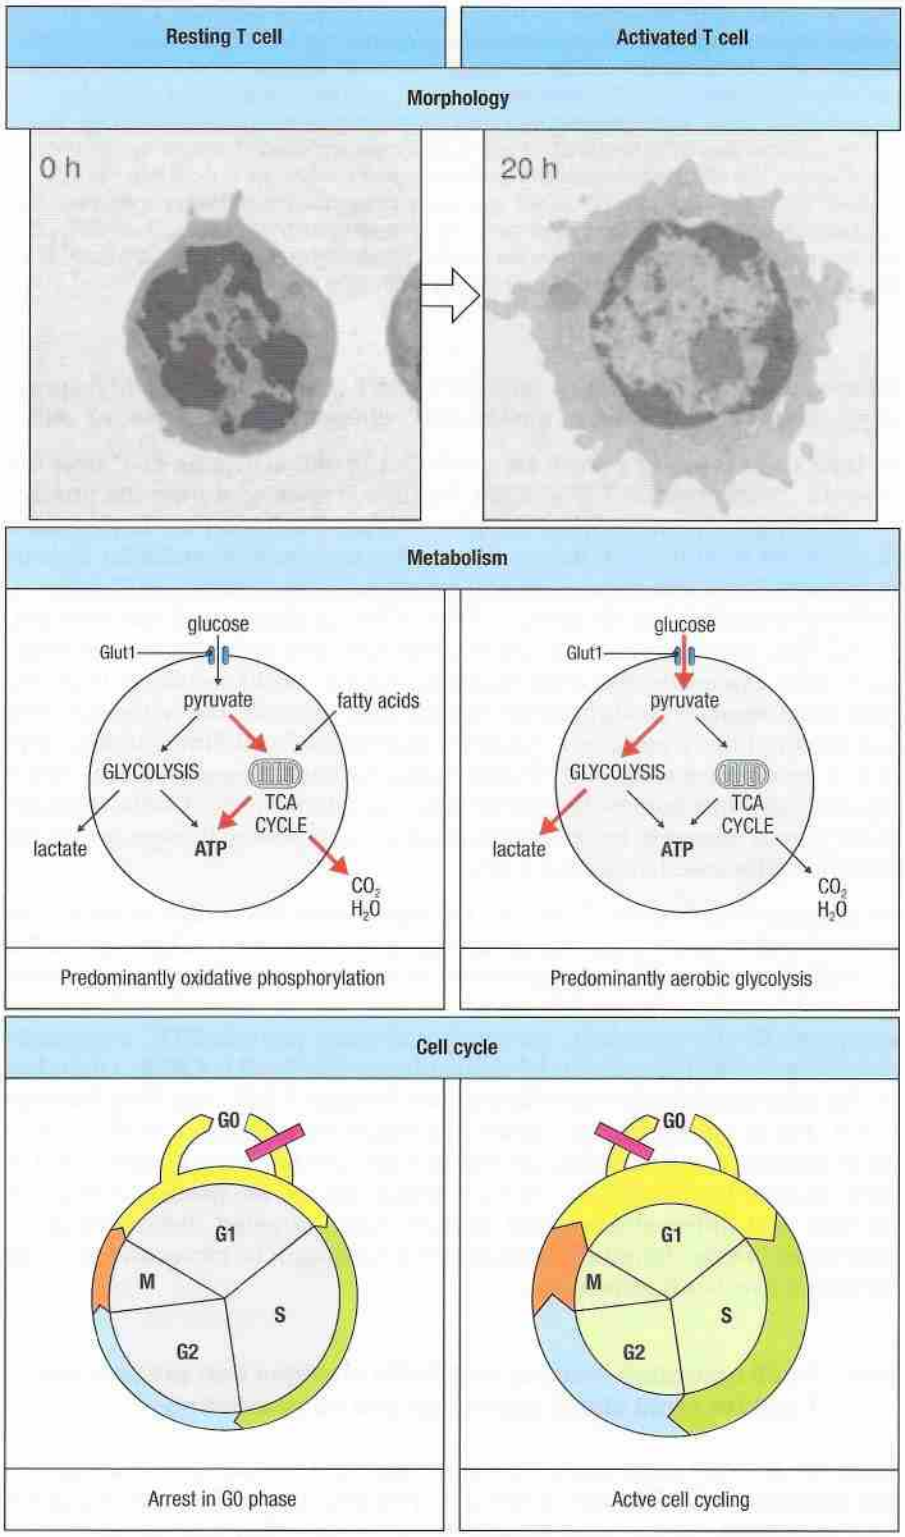

Fig. 9.21 Antigen-induced activation of naive T cells initiates changes in morphology, metabolic activity, and progression into the cell cycle. In the initial minutes to hours after TCR recognition of antigen on a cDC, signals emanating from the TCR and CD28 activate transcription factors such as NFAT, AP-1, and NFκB that induce the transcription of genes whose products are required for retention of the activated T cell within the lymphoid tissue (for example, CD69) and for its proliferation and differentiation into an effector T cell (for example, IL-2 and IL-2Rα). Activation of Akt–mTOR signaling shifts the energy metabolism of the T cell to ramp up aerobic glycolysis to increase macromolecule synthesis in preparation for rapid cell growth (blast transformation; upper panels and middle panels) prior to cell division. The activated T cell leaves the quiescent, G0 phase and enters the cell cycle (lower panels), first transitioning to the first gap phase (G1), during which the cell grows larger and copies organelles. This is followed by the synthesis phase, or S phase, during which the genome is duplicated. A second gap phase follows (G2), during which the cell grows further, increasing the synthesis of macromolecules and organelles prior to mitosis (M), where the cell divides and apportions a complete genome to each of the two daughter cells generated. Antigen-activated T cells typically begin to divide the first of many cell divisions within 2–3 days, initiating the process of clonal expansion that rapidly increases the number of clonal progeny that can participate in the adaptive immune response.

Beginning 24–48 hours after activation, the T cell begins to divide and undergoes remarkably rapid cell division to produce large numbers of progeny (clonal expansion) as it differentiates (Fig. 9.23). Activation of Akt downstream of TCR and CD28 signaling stimulates the mTOR pathway to increase the activated T cell's metabolic and biosynthetic capabilities as it transitions from G0 to G1 and enters the cell cycle. Activation of Akt–mTOR signaling stimulates **aerobic glycolysis** and increases the uptake of glucose to fuel this pathway—while also increasing the OXPHOS pathway to meet energy demands. Although

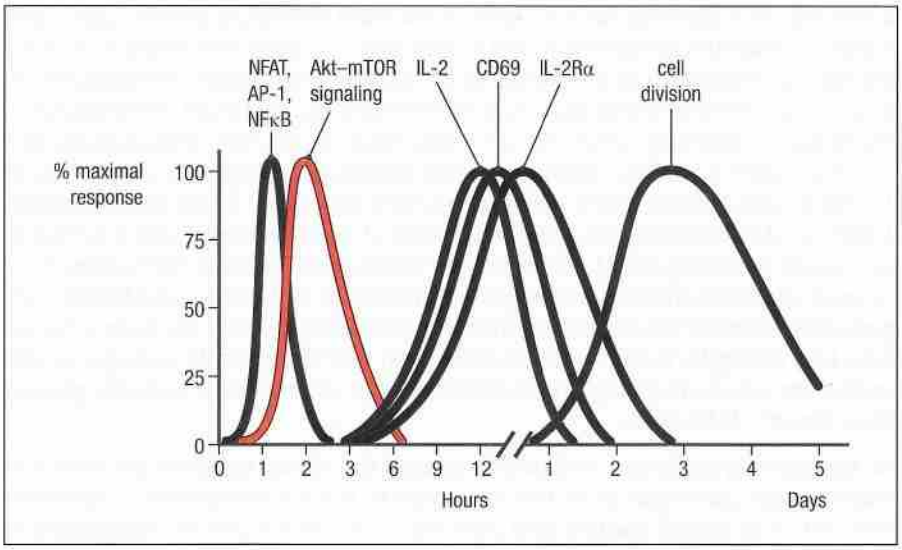

Fig. 9.22 Naive T-cell activation induced by TCR- and CD28-mediated signaling leads to sequential waves of signaling protein activation, gene expression, and cell-cycle progression that lead to rapid cell division and clonal expansion. Shown is a time-course of signaling that leads to new gene expression and entry into the cell cycle that occurs minutes to days after T-cell activation. A number of key transcription factors, including NFAT, AP-1, and NFκB, rapidly undergo changes in expression and/or post-translational modifications by signaling kinases upon activation by TCR and CD28 signaling. These factors then bind regulatory elements in many genes to activate their expression, including the genes encoding IL-2, CD69, and IL-2Rα. Activation of the Akt–mTOR signaling cascade induces metabolic changes in the activated T cell to prepare it for transition from G0 to G1 as it enters the cell cycle.

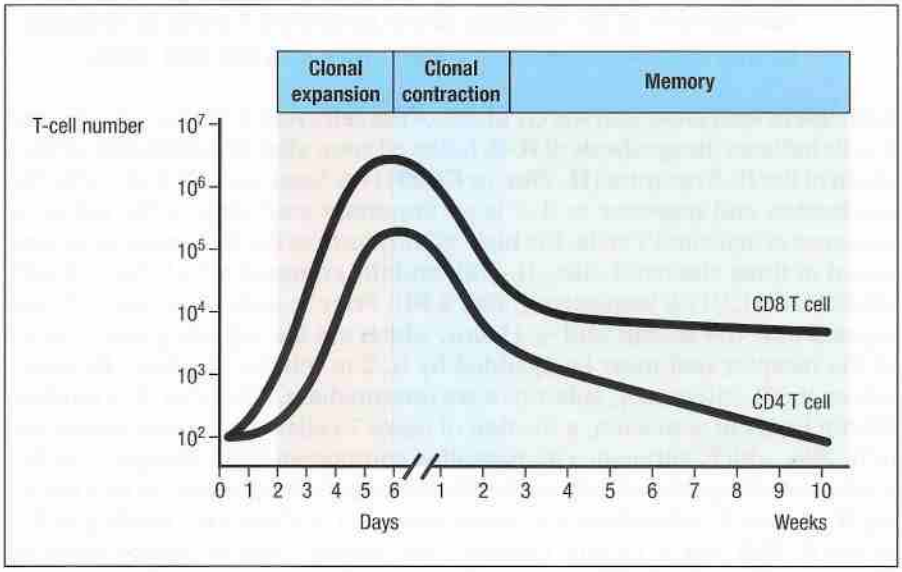

Fig. 9.23 The initial T-cell response to antigen results in rapid clonal expansion that is followed by clonal contraction as the immune response wanes. Because naive T cells of a given antigenic specificity are present in such low numbers (for most clones in mice, approximately 100 cells), they must undergo a remarkable amplification in cell numbers after initial activation in order to adequately cope with an infection. Naive T cells begin to enter the cell cycle within ~48 hours after activation and begin dividing very rapidly. In the case of CD4 T cells, clonal expansion can lead to an ~1000-fold increase in number compared to the initial clone size. For CD8 T cells, clonal expansion can increase the starting T-cell number as much as ~50,000-fold. After antigen clearance, the large majority of clonal progeny produced undergo programmed cell death to reduce the clonal pool size as homeostasis is restored—a process referred to as clonal contraction. The increased number of clonal members that persist long-term after clonal contraction are termed memory T cells.

a less efficient pathway for ATP generation than OXPHOS, aerobic glycolysis supports anabolic metabolism that is required for rapid cell division, including the up-regulation of a number of biosynthetic pathways—mitochondrial biogenesis, protein synthesis, nucleotide synthesis, and lipid biosynthesis—while also repressing catabolic activities, such as protein degradation. The resultant shift in cellular energetics and metabolism supports the ability of T cells to divide once every 4–6 hours, which can result in an approximately 1,000- to 10,000-fold increase in the number of clonal progeny over a period of several days (see Fig. 9.23). Because CD8 T cells exercise their effector function through direct interaction with their targets (target-cell killing) and CD4 T cells generally exercise their function through activation of other immune effector cells (for example, B cells and granulocytes) that themselves undergo proliferative increases, the magnitude of CD8 clonal expansion is typically greater than that of CD4 T cells.

As the inciting pathogen is cleared, most of the clonal progeny generated to eradicate the pathogen must be eliminated to restore homeostasis, a process referred to as **clonal contraction** (see Fig. 9.23), which will be considered in detail in Chapter 11. Nevertheless, the number of clonal progeny that survive clonal contraction and are retained as memory T cells exceeds that of the number of clonal precursors, such that their number is typically increased at least 1–2 orders of magnitude. Memory T cells have enhanced responsiveness to recall challenges with antigen and, like naive T cells, can persist for years without requirement for recognition of their cognate antigen. The persistence of memory T cells is accompanied by a shift in their metabolism back to a maintenance program and a G0 ground state. We will discuss the properties of memory T cells further in Chapter 11.

9-10 The rapid expression of interleukin-2 and the high-affinity component of its receptor allow activated T cells to respond to this cytokine coincident with entry into the cell cycle.

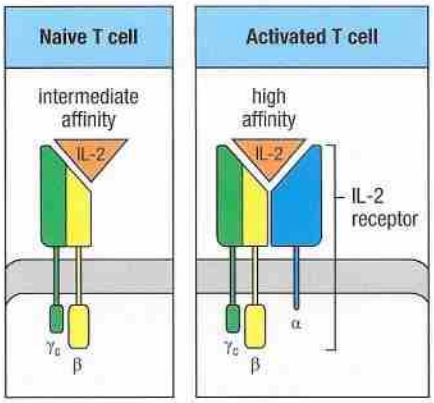

Fig. 9.24 High-affinity IL-2 receptors are three-chain structures that are present only on activated T cells. On resting T cells, the IL-2 receptor β chain (IL-2Rβ; CD122) and common γ chain (γ_c; CD132) are expressed constitutively. They bind IL-2 with intermediate affinity. Activation of T cells induces the synthesis of the IL-2 receptor α chain (IL-2Rα; CD25), which captures IL-2 and presents it to the IL-2Rβ and γ_c chains to form the high-affinity heterotrimeric receptor that signals into the T cell. The IL-2Rβ and γ_c chains show similarities in amino acid sequence to that of cell-surface receptors for other growth hormones that regulate cell growth and differentiation.

Coincident with entry into the G1 phase of the cell cycle, a fraction of activated T cells initiates the synthesis of **IL-2**, followed soon after by expression of the α chain of the IL-2 receptor (**IL-2Rα**, or **CD25**) (see Sections 7-21 and 7-22). The production and response to IL-2 is an important early step in the antigenic response of activated T cells. The high-affinity form of the IL-2 receptor is composed of three chains: IL-2Rα, IL-2Rβ, and the common γ (γ_c) chain (CD25, CD122, and CD132, respectively; Fig. 9.24). Prior to activation, naive T cells express only the IL-2Rβ and γ_c chains, which are the signaling components of the receptor that must be liganded by IL-2 to initiate signaling. By themselves, the IL-2Rβ and γ_c subunits have intermediate affinity for IL-2 binding. Within hours of activation, a fraction of naive T cells up-regulates expression of IL-2Rα, which, although a nonsignaling component of the receptor, confers a substantially greater affinity of the trimeric receptor by capturing and tethering IL-2 to the T-cell surface in an orientation that facilitates the binding of IL-2 to the IL-2Rβ and γ_c chains, thereby cross-linking them to initiate signaling (Fig. 9.25). Notably, IL-2Rα does not bind the other two chains of the receptor once the quaternary complex with IL-2 is formed. Rather, the initial binding of IL-2 by IL-2Rα facilitates its 'presentation' of IL-2 to the IL-2Rβ and γ_c subunits to form the signaling complex. Thus, the expression of IL-2Rα allows the T cell to respond to very low concentrations of IL-2.

Unlike naive T cells, regulatory T cells (T_{reg} cells) constitutively and uniformly express IL-2Rα, and thus can rapidly form the high-affinity signaling complex upon binding IL-2 (see Figs. 9.24 and 9.25). As will be discussed later (see Section 9-17), by expressing the high-affinity IL-2 receptor, T_{reg} cells can outcompete T cells that do not express IL-2Rα for binding of the limited quantities of IL-2 that are available early in the response to antigen. In this way, T_{reg}

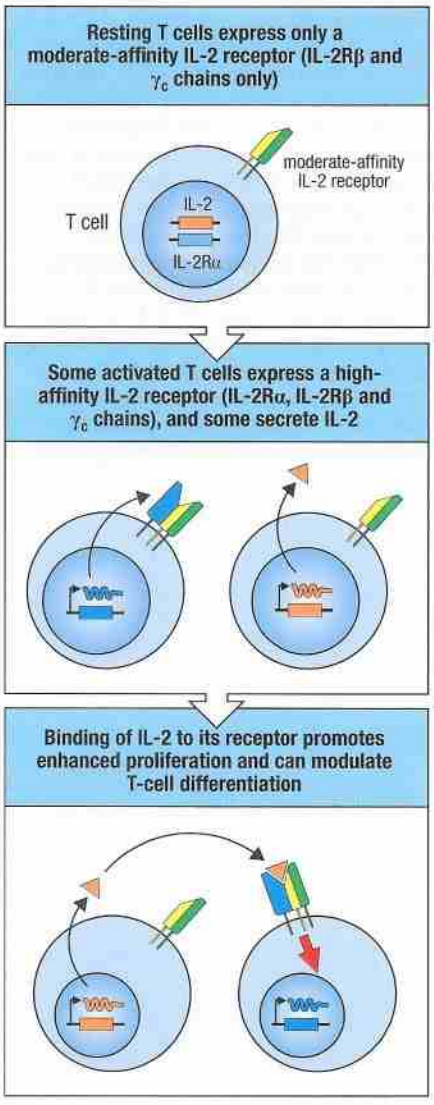
Fig. 9.25 Structural features of the IL-2 receptor. Shown are the structures of the IL-2 receptor in complex with IL-2. In the first panel, the initial complex of IL-2 with IL-2Rα (CD25) is shown. IL-2Rα–bound IL-2 then binds IL-2Rβ and γ_c to form the signaling trimeric IL-2 receptor (second panel, front and lateral views). Note that while IL-2Rα contacts IL-2, it does not contact the IL-2Rβ and γ_c chains in the quaternary complex, whereas IL-2 contacts both the IL-2Rβ and γ_c chains to bring them into close apposition to induce signaling.

cells act as a 'sink' for IL-2 to limit its availability to other cells. However, once activated, naive T cells up-regulate IL-2Rα to effectively compete with T_{reg} cells for binding of IL-2. The binding of IL-2 by these developing T cells triggers signaling that supports their activation and differentiation and may also enhance their proliferation and survival (Fig. 9.26).

On the basis of *in vitro* studies, IL-2 was long thought to be required for the proliferation of naive T cells. However, *in vivo* studies indicate that while IL-2 can augment T-cell proliferation and survival, other functions of IL-2 might be more important. Thus, as we will learn, while IL-2 favors the development of some subsets of effector T cells after initial activation—and is essential for the maintenance of regulatory T cells, which cannot produce their own IL-2—it also represses the development of other subsets of CD4 T cells despite their robust clonal expansion after antigenic priming. This suggests IL-2 is dispensable for the proliferation of at least some developing T cells. Indeed, mice deficient for IL-2 or IL-2Rα receptor develop uncontrolled T-cell proliferation and multiorgan autoimmunity because of the absence of regulatory T cells, indicating an indispensable role for IL-2 in T_{reg} cell maintenance but not for the clonal expansion of at least some non-T_{reg} cells. As will be discussed further in Section 9-15, this points to a complex and important role for IL-2 in regulating the developmental fate of effector T cells early in their differentiation and suggests other roles for IL-2 in the adaptive immune response.

9-11 Additional co-stimulatory and inhibitory receptors are engaged after initial T-cell activation to control clonal expansion and contraction.

Once a naive T cell has been activated, it expresses additional surface molecules that act either to amplify and sustain clonal expansion or to restrain it. These molecules include receptors that belong to both the CD28 and the TNF receptor families. Here we consider those family members that facilitate or impede the initial clonal expansion of T cells after priming; members of the CD28 and the TNF receptor families that play other important roles in the interactions between APCs and T cells will be considered in later sections.



Resting T cells express only a moderate-affinity IL-2 receptor (IL-2Rβ and γc chains only)
T cell
IL-2
IL-2Rα

Some activated T cells express a high-affinity IL-2 receptor (IL-2Rα, IL-2Rβ and γc chains), and some secrete IL-2
Binding of IL-2 to its receptor promotes enhanced proliferation and can modulate T-cell differentiation

Fig. 9.26 Activated T cells either secrete or respond to IL-2. Unlike effector T cells, which can produce a diversity of cytokines depending on the mature effector phenotype, naive T cells primarily produce IL-2 when activated by antigen. However, secretion of IL-2 or expression of the high-affinity component of its receptor, IL-2Rα, typically appears to be differentially induced on activated T cells. Thus, IL-2 produced by one T cell binds to the high-affinity IL-2 receptor of a different T cell, so-called paracrine signaling, which induces enhanced T-cell growth and altered differentiation of the cell receiving the IL-2 signal.

⊕

Fig. 9.27 CTLA-4 is an inhibitory receptor for B7 molecules. Naive T cells express CD28, which delivers a co-stimulatory signal on binding B7 molecules (see Fig. 9.20), thereby driving the survival and expansion of the T cells. Activated T cells express increased levels of CTLA-4 (CD152), which attenuate TCR signaling through three mechanisms. First, because CTLA-4 has a higher affinity than CD28 for B7 molecules and can simultaneously bind two B7 molecules (compared to only one for CD28), it outcompetes CD28 for B7 binding (left panel). CTLA-4 can also remove B7 molecules from the dendritic-cell surface, thereby depleting the co-stimulatory function of the DC (middle panel). Finally, CTLA-4 may deliver negative signals that repress the activating signals generated through the TCR (right panel). Thus, expression of CTLA-4 by the activated T cell serves to attenuate the proliferative phase of the T-cell response.

In addition to CD28, B7 molecules can be engaged by **CTLA-4** (CD152), which, although related in sequence to CD28, acts to restrain, rather than promote, T-cell activation and clonal expansion (Fig. 9.27; see also Section 7-25). Unlike CD28, which binds a single B7 homodimer, CTLA-4 can bind a pair of B7 homodimers and has an affinity for B7 that is about 20 times higher than that of CD28. It is clear that one mechanism by which CTLA-4 inhibits T-cell activation is by outcompeting CD28 for interaction with B7 molecules expressed by antigen-presenting cells. Moreover, it has been shown that CTLA-4 can physically remove B7 molecules from the surface of activated APCs, effectively stripping them of their co-stimulatory capability. Finally, although CTLA-4 does not contain an immunoreceptor tyrosine-based inhibition motif (ITIM), some data indicate that it can also generate negative signals that repress T-cell activation.

Unlike CD28, which is constitutively expressed by naive T cells, surface expression of CTLA-4 is induced only after activation of naive T cells, making activated T cells less sensitive than naive T cells to stimulation by the antigen-presenting cell and also restricting IL-2 production. Thus, binding of CTLA-4 to B7 molecules plays a central role in limiting the response of activated T cells to antigen and B7. This has been confirmed in mice with a disrupted CTLA-4 gene; such mice develop a fatal disorder characterized by a massive overgrowth of lymphocytes. As will be discussed in Section 9-17, unlike naive T cells, regulatory T cells constitutively express CTLA-4 on the cell surface, where it acts to limit the co-stimulatory activity of APCs that bear antigens recognized by the T_{reg} cell TCR.

Programmed death protein-1 (PD-1) is another member of the CD28 family that acts to restrain T-cell responses after their initiation, albeit by a different mechanism. PD-1 is induced by TCR signaling on nearly all activated T cells and recognizes one of two ligands: PD-L1, which is expressed by many cell types, and PD-L2, which is expressed on APCs at sites of inflammation. Unlike CTLA-4, the cytoplasmic domain of PD-1 does contain an ITIM, which acts to repress signaling through CD28 (see Section 7-26). Antibodies that block PD-1 or CTLA-4 signaling, so-called **checkpoint inhibitors**, are the basis for immunotherapies that are now employed for treatment of certain malignancies that impair the antitumor function of T cells, to be discussed in greater detail in Chapter 16.

Several members of the TNF and TNFR families (for example, OX40L and OX40) can deliver co-stimulatory signals that sustain T-cell survival and may

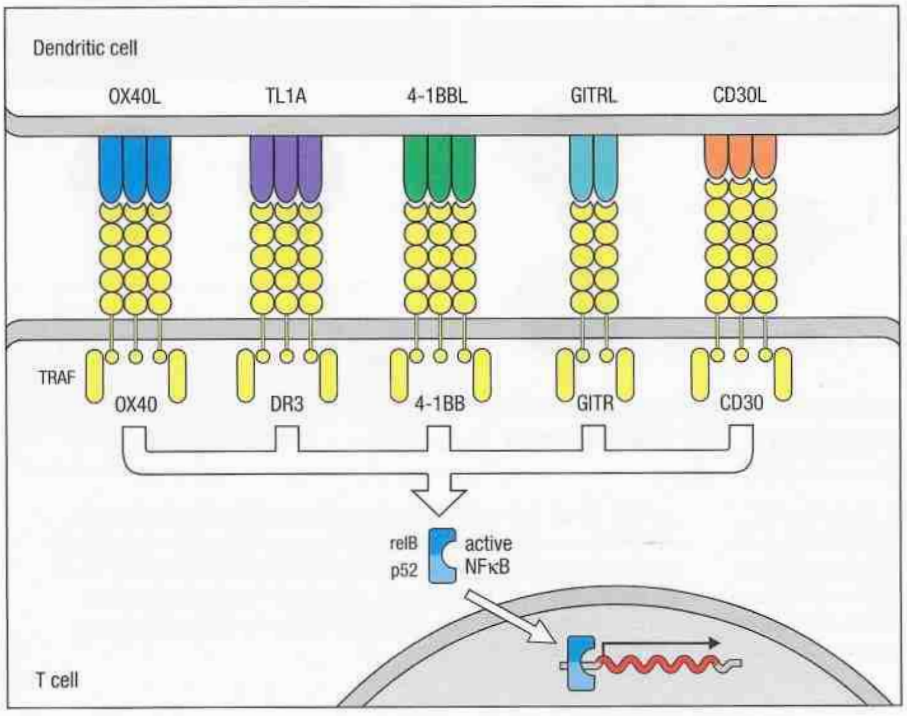

Fig. 9.28 Multiple members of the TNF–TNFR superfamily can activate the non-canonical NFκB pathway to enhance and sustain T-cell responses. See text for details.

amplify clonal expansion after the initial priming event (Fig. 9.28). These pathways all seem to function by activating NFκB through a TRAF-dependent, non-canonical NFκB pathway (see Section 7-24), although other signaling pathways (for example, PI 3-kinase–Akt) appear to be activated by at least some of the family members. While much remains to be learned about the orchestration of this family of co-stimulators and their functions, signals activating these pathways appear to be preferentially delivered by monocyte-derived DCs (MoDCs) rather than cDCs, and may act at sites of T-cell activation in lymphoid tissues as well as in nonlymphoid tissues to which recently activated T cells are recruited. Thus, the actions of these co-stimulators take place with delayed kinetics relative to initial priming by cDCs and are induced by a different APC.

Another TNF family ligand, CD40L, which is expressed on the surface of the T cell soon after initial activation, signals via its CD40 receptor on cDCs and other APCs to up-regulate expression of B7 molecules, thereby providing an amplifying feed-forward signal loop that enhances T-cell clonal expansion. The role of the CD40–CD40L pair in amplifying a T-cell response is demonstrated in mice lacking CD40L; when these mice are immunized, the clonal expansion of responding T cells is curtailed at an early stage. As we will see in subsequent sections in this chapter and the next, CD40L also plays critical roles in activating naive B cells and in signaling cDCs and macrophages to enhance their expression of cytokines, such as IL-12. Thus, deleterious mutations of *CD40L* in humans cause a form of severe immunodeficiency (see Chapter 13).

CD40 Ligand Deficiency

9-12 Proliferating T cells differentiate into effector T cells that are programmed for altered tissue homing and loss of a requirement for co-stimulation to act.

During the period of rapid cell division that follows their activation, naive T cells differentiate into effector T cells that acquire the ability to produce a range of effector molecules required for specialized helper or cytotoxic functions when they reencounter antigen. Effector T cells undergo additional changes that distinguish them from naive T cells. One of the most important is in their activation requirements: once a T cell has differentiated into an effector cell,

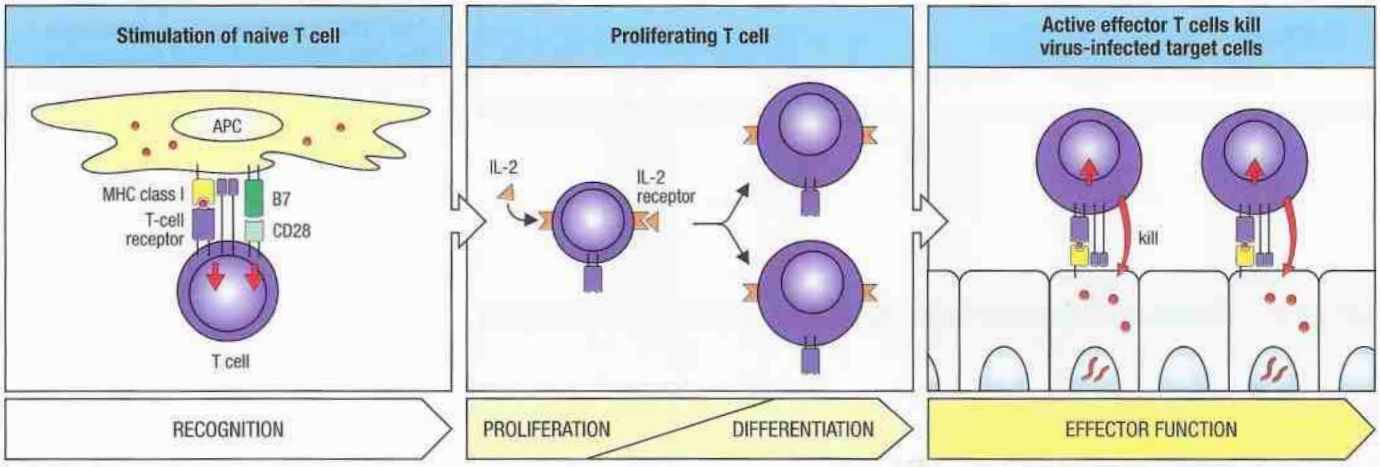

Fig. 9.29 Effector T cells can respond to their target cells without co-stimulation. Naive T cells that recognize antigen on the surface of an antigen-presenting cell and receive the required signals (left panel) become activated and can secrete and respond to IL-2. IL-2 signaling enhances clonal expansion and contributes to the differentiation of the T cells to effector-cell status (central panel). Once the cells have differentiated into effector T cells, encounters with target cells bearing specific antigen can trigger their effector actions without the need for co-stimulation. Thus, as illustrated here (right panel), cytotoxic T cells can kill any virus-infected target cell, including those that do not express co-stimulatory molecules.

an encounter with its specific antigen results in an immune attack without the need for co-stimulation. This distinction is particularly easy to understand for cytotoxic CD8 T cells, which must be able to act on any cell infected with a virus, whether or not the infected cell can express co-stimulatory molecules (Fig. 9.29). However, this feature is also important for the effector function of CD4 cells, as effector CD4 T cells must be able to activate B cells and macrophages that have taken up antigen irrespective of whether or not those cells initially express co-stimulatory molecules.

Changes are also seen in the cell-adhesion molecules and receptors expressed by effector T cells. As we will discuss in more detail in Chapter 11, effector T cells lose cell-surface L-selectin and therefore cease to recirculate through lymph nodes. Instead, they express glycans that serve as ligands for P- and E-selectins (for example, **P-selectin glycoprotein ligand-1,** or **PSGL-1**), which are up-regulated on inflamed vascular endothelial cells and allow effector T cells to roll on the blood vessels at sites of inflammation. They also express higher levels of LFA-1 and CD2 than do naive T cells, as well as the integrin **$\alpha_4\beta_1$ (VLA-4)**, which allows them to bind to vascular endothelium bearing the adhesion molecule **VCAM-1**, which is also expressed on the inflamed endothelium. As we will see, effector T cells that develop in mucosal tissues or the lymph nodes draining them are also induced to express the $\alpha_4\beta_7$ integrin heterodimer, which acts as a 'homing receptor' for the mucosal addressin, MadCAM-1. This altered deployment of cell-adhesion molecules and receptors by effector T cells allows them to exit the bloodstream and enter sites of infection, where they orchestrate the local immune responses. These changes in the T-cell surface are summarized in Fig. 9.30 and will be discussed further in Chapter 11.

9-13 CD8 T cells can be activated in different ways to become cytotoxic effector cells.

Naive T cells fall into two broad classes, one of which expresses the co-receptor CD8 on its surface, and the other expresses the co-receptor CD4. The CD8 co-receptor recognizes MHC class I molecules, hence CD8 T cells are MHC class I–restricted for recognition of their cognate antigen. Naive CD8 T cells typically differentiate into cytotoxic T cells (often called cytotoxic

	Cell-surface molecules

Naive	+	++	++	+	+	–	+	+	+/–	–	–	+
Effector	+	–	–	++	–	+	++	–	++/–	+	+	++

Fig. 9.30 Activation of T cells changes the expression of several cell-surface molecules. The example here is a CD4 T cell. Resting naive T cells express L-selectin, through which they home to lymph nodes, but express relatively low levels of other adhesion molecules such as CD2, LFA-1, and $\alpha_4\beta_7$. Upon activation, expression of L-selectin ceases and, instead, expression of ligands for P- and E-selectins is induced (for example, PSGL-1), which allow the activated T cells to roll on P- and E-selectins expressed on endothelium at sites of inflammation. Increased amounts of the integrin LFA-1 are also produced, which is activated to bind its ligands, ICAM-1 and ICAM-2. A newly expressed integrin called VLA-4, which allows T cells to arrest on inflamed vascular endothelium, ensures that activated T cells can enter nonlymphoid tissues at sites where they are likely to encounter infection. On T cells activated in mucosal lymphoid tissues, there is up-regulation of $\alpha_4\beta_7$ integrin, which similarly serves to direct these cells to nonlymphoid mucosal sites where they reencounter antigen. Activated T cells also have on their surface a higher density of the adhesion molecule CD2, increasing the avidity of their interaction with potential target cells, as well as a higher density of the adhesion molecule CD44. Alternative splicing of the RNA transcript of the CD45 gene induced by antigenic activation causes a change in the isoform of CD45 that is expressed on human T cells: naive T cells preferentially express the CD45RA isoform, while effector and memory T cells express the CD45RO isoform. In mice, there is a similar change from high expression of the CD45RB isoform on naive T cells to low expression of CD45RB in previously activated T cells (not shown). CD45RO associates with the T-cell receptor and CD4 more efficiently to make previously activated T cells more sensitive to stimulation by low concentrations of peptide:MHC complexes. Finally, the sphingosine 1-phosphate receptor 1 (S1PR1) is expressed by naive T cells, allowing cells that do not become activated to egress from lymphoid tissues (see Fig. 9.10). Down-regulation of S1PR1 for several days after activation prevents T-cell egress during the period of proliferation and differentiation. After several days, it is expressed again, allowing effector cells to exit from the lymphoid tissues.

T lymphocytes, or CTLs), which are specialized for killing target cells bearing their cognate antigen (Fig. 9.31). CTLs are important in defense against intracellular pathogens, especially viruses and some intracellular bacteria. Effector CD8 T cells are also central to antitumor immunity. Because all nucleated cells in the body express MHC class I molecules and can process cytosolic antigens to load them, essentially any cell in the body can be targeted for killing by CTLs.

Naive CD8 T cells recognize peptide antigens processed and loaded onto MHC class I of cDC1 cells from two cytosolic sources: antigens of pathogens that can infect the cytosol of cDC1 cells directly and those derived via cross-presentation. Like other cells, dendritic cells are directly susceptible to infection by some viruses, which enter the cytoplasm by binding to cell-surface molecules that act as entry receptors. Viral proteins synthesized in the cytoplasm of dendritic cells are processed in the proteasome and presented on the cell surface as peptides loaded onto MHC class I molecules after transport into the endoplasmic reticulum, as in any other type of virus-infected cell (see Chapter 6). Similarly, bacteria that have evolved mechanisms to escape the phagosome after uptake by phagocytes, such as *Listeria monocytogenes*, shed antigens in the cytosol that can be loaded onto MHC class I molecules and recognized by CD8 T cells.

Uptake of extracellular virus particles or virus-infected cells into the endocytic pathway by macropinocytosis or phagocytosis can also result in the presentation of viral peptides on MHC class I molecules. This phenomenon, known as

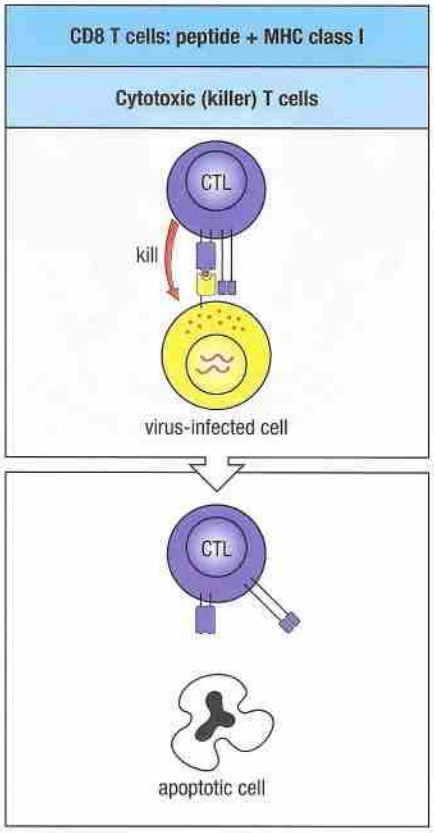

Fig. 9.31 Cytotoxic CD8 T cells are specialized to kill cells infected with intracellular pathogens. Cytotoxic CD8 T cells (cytotoxic T lymphocytes; CTLs) kill target cells that display at their cell surface the peptide fragments of cytosolic pathogens (most notably viruses) that are bound to MHC class I molecules.

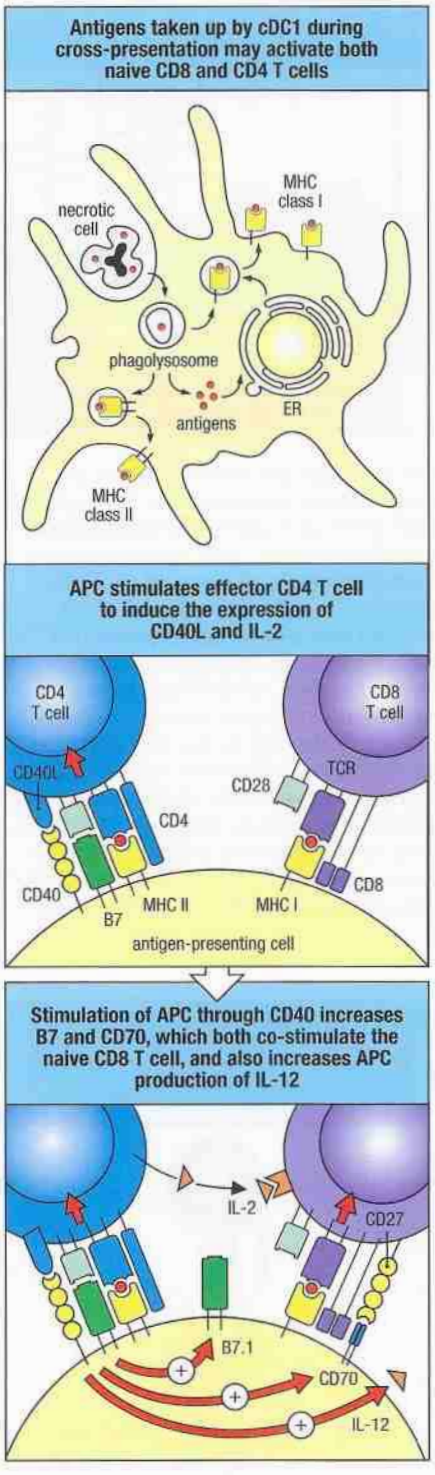

Fig. 9.32 CD8 T-cell responses can be enhanced by CD4 T cells. CD8 T cells that recognize antigen on weakly co-stimulatory cells may become activated only in the presence of CD4 T cells interacting with the same antigen-presenting cell (APC). CD40 ligand (CD40L) expressed by the activated CD4 T cells can signal via CD40 on the dendritic cell to up-regulate its expression of B7 molecules to enhance CD8 activation and may also induce increased levels of other co-stimulatory activity on the dendritic cell (for example, CD70, which is recognized by CD27 expressed by the CD8 T cell), a process known as licensing of the dendritic cell. CD40 signaling also can enhance DC expression of IL-12, which enhances differentiation of CD8 T cells. Finally, the CD4 T cell may also produce abundant IL-2, which helps drive CD8 T-cell proliferation and differentiation.

cross-presentation, is an alternative to the usual cytosolic pathway for MHC class I antigen processing (see Section 6-5 and Section 9-7). In this case, viral antigens that enter dendritic cells via endocytic or phagocytic vesicles may be diverted to the cytosol for proteasomal degradation and transferred to the endoplasmic reticulum for loading onto MHC class I molecules. The result is that viruses that do not directly infect dendritic cells can nevertheless stimulate the activation of naive CD8 T cells. Cross-presentation is typically mediated by cDC1 cells, which are specialized for stimulating T-cell responses to intracellular pathogens and are the principal APC for CD8 T-cell priming (see Section 6-5 and Section 9-7). Any viral infection can therefore lead to the generation of cytotoxic effector CD8 T cells, whether or not the virus can directly infect dendritic cells.

In addition to priming CD8 T cells, some antigens taken up in the process of cross-presentation can be presented by MHC class II molecules on type 1 cDCs to co-activate naive CD4 T cells. CD4 T cells that recognize antigens presented by the same cDC1 cell may amplify the activation of naive CD8 T cells by further activating the antigen-presenting cell, so-called **licensing** of the dendritic cell, by directly recruiting CD4 T-cell help (Fig. 9.32). The production by the CD4 T cell of CD40L can induce the cDC1 cell to express heightened levels of B7 and CD70, which bind CD28 and CD27, respectively, on the CD8 T cell to amplify its response. Naive CD4 T cells activated on the same DC as a naive CD8 T cell may also provide IL-2 to the activated CD8 cell, which can enhance CD8 T-cell memory through mechanisms not yet understood. Finally, heightened IL-12 production by antigen-presenting cDC1 cells is also induced by CD40 signaling. In addition to enhancing the differentiation of CTLs, IL-12 may also promote the development of T_H1 cells from the activated CD4 T cell, as we will discuss shortly. Therefore, cooperativity between naive CD8 and CD4 T cells in the context of cross-presentation of antigens derived from intracellular pathogens may induce concomitant CTL and T_H1 responses that later act together in tissue sites of infection, as we will discuss further in Chapter 11.

Although plasmacytoid dendritic cells (pDCs) do not play a direct role in antigen presentation to naive CD8 T cells, like CD4 T cells they also contribute signals to cDC1 cells for CD8 T-cell effector differentiation. This is mediated principally through their abundant production of type I interferons. Specialized for the detection of viral infections by their unique pattern of nucleic acid–sensing TLRs, activated pDCs produce high levels of IFN-α and IFN-β that act on cDC1 cells to increase their production of IL-12. This may also enhance T_H1 responses activated by type 1 cDCs.

9-14 CD4 T cells differentiate into several functionally distinct subsets.

In contrast to CD8 T cells, naive CD4 T cells can differentiate into several types of helper or regulatory T effector cells that orchestrate different immune functions. The main helper subsets are T helper 1 (T_H1), T_H2, T_H17, T follicular helper (T_{FH}), and regulatory T (T_{reg}) cells. The T_H1, T_H2, and T_H17 subsets are elicited by different classes of pathogens and are defined on the basis of the

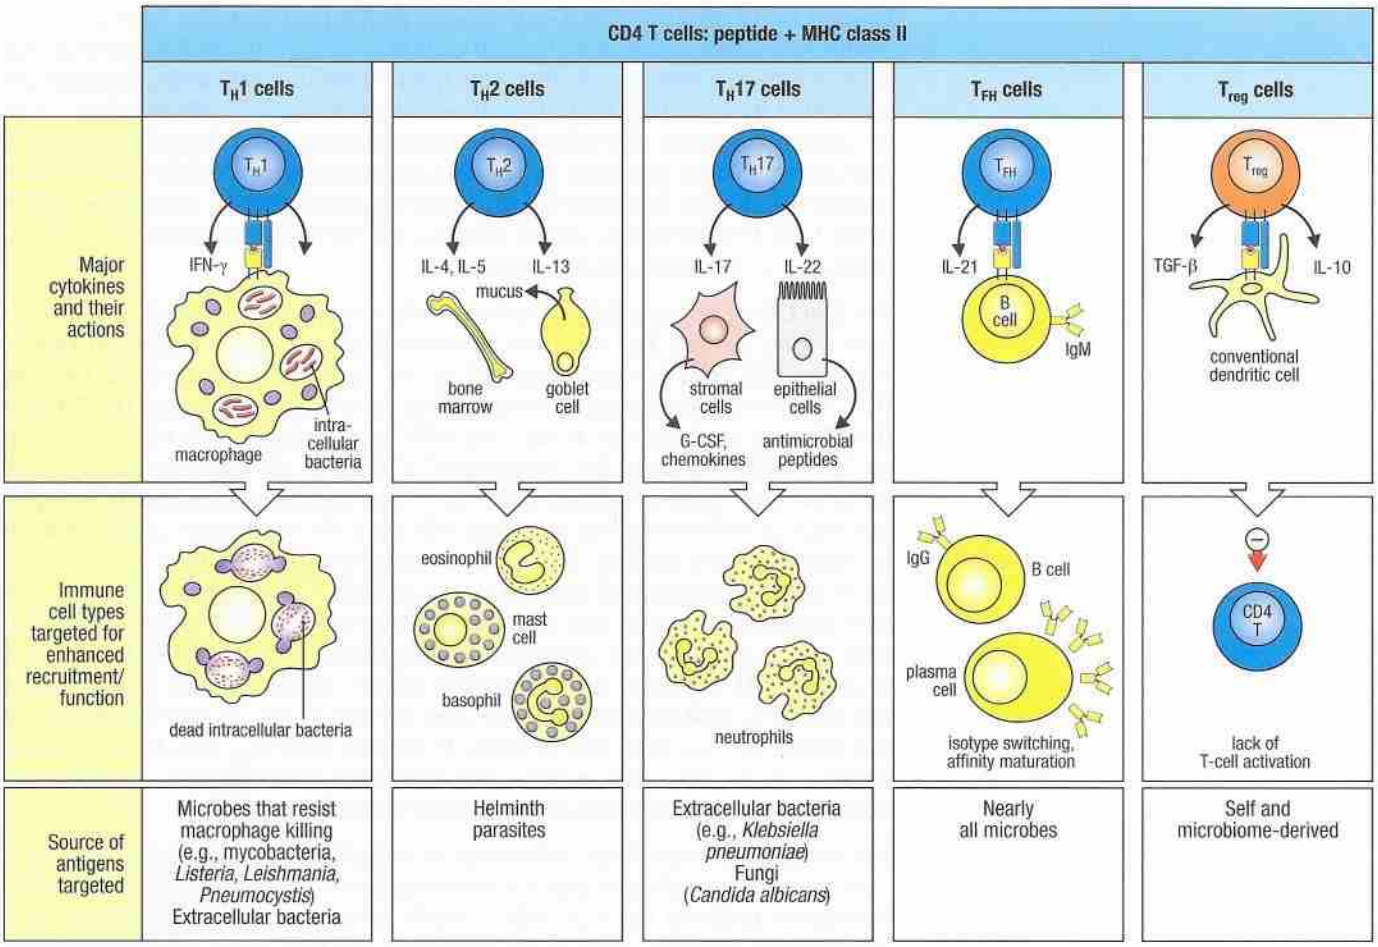

Fig. 9.33 Subsets of effector CD4 T cells are specialized to help different target cells eradicate different classes of pathogens. Unlike CD8 T cells, which act directly on infected target cells to eliminate pathogens, CD4 T cells typically enhance the effector functions of other cells that eradicate pathogens—whether cells of the innate immune system or, in the case of T_{FH} cells, antigen-specific B cells. T_H1 cells (first panels) produce cytokines, such as IFN-γ, which activate macrophages, enabling them to destroy intracellular microorganisms more efficiently. T_H2 cells (second panels) produce cytokines that recruit and activate eosinophils (IL-5) as well as mast cells and basophils (IL-4) and promote enhanced barrier immunity at mucosal surfaces (IL-13) to eradicate helminths. T_H17 cells (third panels) secrete IL-17 family cytokines that induce local epithelial and stromal cells to produce chemokines that recruit neutrophils to sites of infection. T_H17 cells also produce IL-22, which along with IL-17 can activate epithelial cells at barrier sites to enhance barrier integrity and repair, and produce antimicrobial peptides that kill bacteria. T_{FH} cells (fourth panels) form cognate interactions with naive B cells through linked recognition of antigen and traffic to B-cell follicles, where they promote the germinal center response. T_{FH} cells can produce cytokines characteristic of other subsets that participate in type 1, 2, and 3 immune responses to influence isotype class-switching, but they primarily produce IL-21, which is important for optimal production of high-affinity, class-switched antibodies. Regulatory T cells (right panels) generally suppress naive T-cell responses and can produce immune regulatory cytokines, such as IL-10 and TGF-β, which regulate the response of effector T cells directly or via repression of pro-inflammatory cytokines.

different combinations of cytokines that they secrete (Fig. 9.33). These subsets cooperate with different innate effector cells of the myelomonocytic series (granulocytes and monocyte/macrophages) and with innate lymphoid cells (ILCs) to form integrated 'immune modules' specialized for the clearance of the different classes of pathogens (see Fig. 3.36 and also Chapter 11). One of these subsets will typically become predominant as an immune response progresses, especially in persistent infections, autoimmunity, or allergies. As we will discuss further in Chapter 11, the functional features of these T-cell subsets parallel in many ways those of ILCs, which, although lacking antigenic receptors, produce many of the same patterns of effector cytokines or cytotoxins. Alternatively, naive CD4 T cells can differentiate into T_{reg} cells, which respond to self antigens or nonpathogenic microbes that are components of the commensal microbiota that is normally resident at barrier tissues, such as the intestines, as we will discuss in Chapter 12.

Each of these effector CD4 T-cell subsets develops in concert with T_{FH} cells, which help antigen-activated naive B cells to develop into antibody-producing cells of different isotypes. In this way, innate immune cell responses that are controlled by T_H1, T_H2, or T_H17 cells—so-called non-T_{FH} effector cells—will be coordinated with the appropriate antibody isotypes induced by T_{FH} cells that enhance their function. As we shall see in the next section, the developmental bifurcation between T_{FH} and non-T_{FH} effector cells occurs very early in the CD4 T-cell response and is heavily influenced by the principal cytokine produced by activated naive T cells—IL-2.

The first CD4 T helper (T_H) cell subsets to be distinguished were T_H1 and T_H2, hence their names. T_H1 cells are characterized by the production of **IFN-γ**, whereas T_H2 cells are characterized by the production of **IL-4**, **IL-13**, and **IL-5**. T_H17 cells are so named because they produce the cytokines **IL-17A** and **IL-17F**; they also produce **IL-22**. T_{FH} cells develop in concert with T_H1, T_H2, or T_H17 cells and share the production of some of the same cytokines. This influences the class switching of B cells to generate immunoglobulin isotypes that bind to different innate immune effector cells contingent on the array of Fc receptors they display. T_{FH} cells also produce **IL-21**, which is important for B-cell maturation and support of the germinal center response. T_{reg} cells have immunoregulatory function and promote tolerance to, rather than clearance of, the antigens they recognize. They produce **TGF-β** and can be induced to produce **IL-10** upon further antigen-driven differentiation (see Fig. 9.33 and also Fig. 9.34 later in text; see also Section 9-17). As will be discussed in Chapter 12, T_{FH} cells that develop in concert with T_{reg} cells favor the production of mucosal IgA, which reinforces anti-inflammatory responses to nonpathogenic constituents of the healthy microbiome.

T_H1 cells help to eradicate infections by microbes that can survive or replicate within macrophages and are characterized by the production of IFN-γ. Pathogens targeted by T_H1 cells include certain viruses, protozoans, and intracellular bacteria, such as the mycobacteria that cause tuberculosis and leprosy. These bacteria are phagocytosed by macrophages in the usual way, but they can evade the intracellular killing mechanisms described in Chapter 3. If a T_H1 cell recognizes microbial antigens displayed on the surface of an infected macrophage, it will activate the macrophage further by releasing IFN-γ, which enhances the macrophage's microbicidal activity. T_{FH} cells that develop in concert with T_H1 cells can promote B-cell class switching that favors production of opsonizing IgG antibodies, such as IgG2a in mouse and IgG3 in humans. We will describe the macrophage-activating functions of T_H1 cells and the enhancement of the function of other innate effector cells by T_H2 and T_H17 cells in more detail in Chapter 11.

T_H2 cells help to control infections by multicellular parasites, particularly helminths, by promoting responses mediated by eosinophils, basophils, mast cells, as well as mucus-producing cells in mucosal epithelia. T_H2 cells also play an important role in the repair of tissue damage that results from infection. T_{FH} cells that develop in concert with T_H2 cells promote class switching of B cells to produce IgE, the primary role of which is to arm eosinophils, basophils, and mast cells to fight infections by helminths. IgE is also the antibody responsible for allergies and asthma, making T_H2 differentiation and type 2 immune responses of considerable medical interest.

T_H17 cells are typically induced in response to extracellular bacteria and fungi and amplify neutrophilic and monocytic responses that help to clear such pathogens (see Fig. 9.33). In addition to stimulating increased production and recruitment of neutrophils from the bone marrow, the effector cytokines produced by T_H17 cells are important in activating barrier epithelial cells in the gastrointestinal, respiratory, and urogenital tracts and in the skin to produce antimicrobial peptides that resist microbial invasion. T_{FH} cells that develop together with T_H17 cells also promote B-cell class switching to opsonizing IgG2

and IgG3 antibodies, which arm neutrophils and monocytes for enhanced phagocytosis.

As noted earlier, T_{FH} cells contribute to the eradication of most classes of pathogens through their unique role in providing help to B cells to promote germinal center responses—irrespective of the pattern of immune response with which they are associated. Thus, T_{FH} cells are elicited in the context of type 1, type 2, or type 3 immune responses, where they play a central role in the development of distinct patterns of class-switched antibodies. T_{FH} cells are identified primarily by their expression of the chemokine receptor CXCR5 after antigenic priming, which directs their mobilization toward B-cell follicles where CXCL13 is constitutively produced by stromal cells.

Prior to the discovery of T_{FH} cells, a point of controversy had been the role of CD4 T-effector subsets in providing B-cell help. Although historically it was thought B-cell help was a primary function of T_H2 cells, it is now clear that the T_{FH} cell, rather than T_H1, T_H2, or T_H17 cells, is the effector T cell that provides help to B-cells for high-affinity antibody production. Nevertheless, T_{FH} cells develop as a component of type 1, 2, or 3 immune responses and share production of some of the same lineage-defining cytokines as T_H1, T_H2, and T_H17 cells to drive the differentiation of naive B cells to alternative patterns of isotype switching. This explains how, in the course of an infection, B cells can receive help to switch to IgE through the presence of 'T_H2' cytokines or switch to other isotypes such as IgG2a through the presence of 'T_H1' cytokines. We will return to the helper functions of T_{FH} cells in more detail in Chapters 10 and 11.

All the effector T cells described above are involved in activating target cells that bear their antigens to enhance responses that help clear pathogens from the body. Another major branch of CD4 T cells has a different function. These are called regulatory T cells, or T_{reg} cells, because their function is to promote immune tolerance to the antigens they recognize. T_{reg} cells achieve this, at least in part, by preventing or limiting other T cell–driven immune responses, including those that might otherwise cause immune-mediated disease, such as autoimmunity. Two pathways of regulatory T cell development are currently recognized. One occurs during positive selection by self antigens in the thymus and produces natural T_{reg} cells or thymically derived T_{reg} cells (nT_{reg} cells or tT_{reg} cells, respectively; see Section 8-27). The other occurs in T-cell zones of secondary (peripheral) lymphoid organs, where naive CD4 T cells develop into T_{reg} cells under the influence of particular environmental cues, as we discuss in Section 9-17. This group is known as induced or peripheral T_{reg} cells (iT_{reg} or pT_{reg} cells, respectively) to distinguish them from those that develop in the thymus. In addition to self antigens, pT_{reg} cells can be induced in response to microbial antigens derived from microbes that normally live as commensal organisms in different host tissues, such as the gut, respiratory tract, and skin. This will be discussed further in Section 9-17 and in Chapter 12.

9-15 Cytokines play a central role in guiding the differentiation of CD4 T cells down distinct pathways.

Having briefly described the types and functions of CD4 T-cell subsets, we will now consider how they are derived from naive T cells. The fate of the progeny of a naive CD4 T cell is largely defined during the initial priming period and is regulated by signals provided by the local environment, whether by the priming antigen-presenting cell, other innate immune cells that have been activated by a pathogen, or by activated CD4 T cells themselves. As noted previously, the principal determinants of the developmental fate of naive CD4 T cells are the combination and balance of lineage-specifying cytokines, which are integrated with TCR and co-stimulatory signaling during priming. The five main subsets into which naive CD4 T cells may develop—T_H1, T_H2, T_H17, T_{FH},

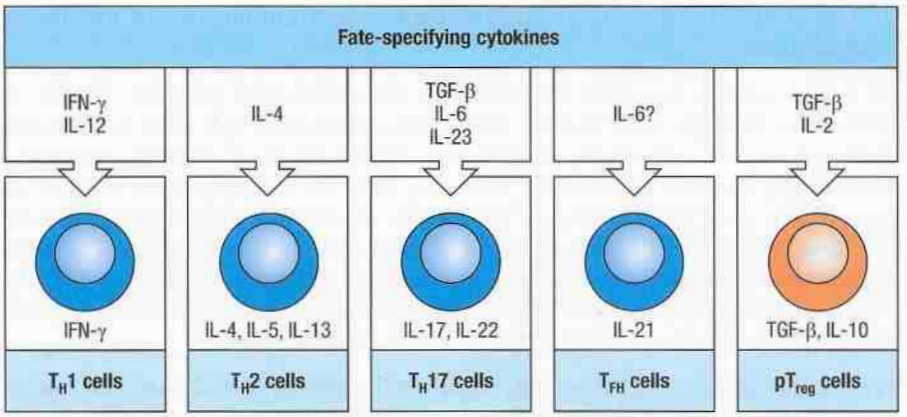

Fig. 9.34 Cytokines are the principal determinants of alternative programs of CD4 T-cell effector differentiation. Antigen-presenting cells, principally dendritic cells, as well as other innate immune cells can provide various cytokines that induce the development of naive CD4 T cells into distinct subsets. The environmental conditions, such as the exposure to various pathogens, determine which cytokines the innate sensor cells will produce. T_H1 cells differentiate in response to sequential IFN-γ and IL-12 signaling, whereas T_H2 cells differentiate in response to IL-4. IL-6 produced by dendritic cells acts with transforming growth factor-β (TGF-β) to induce differentiation of T_H17 cells, which up-regulate expression of the IL-23 receptor and become responsive to IL-23. Mouse T_{FH} cells also require IL-6 for their development, although it does not appear that human T_{FH} cells do, and it is not currently understood what additional signals might induce their differentiation from naive precursors in either species. When pathogens are absent, the presence of TGF-β and IL-2, and the lack of IL-6, favor the development of peripheral T_{reg} (pT_{reg}) cells.

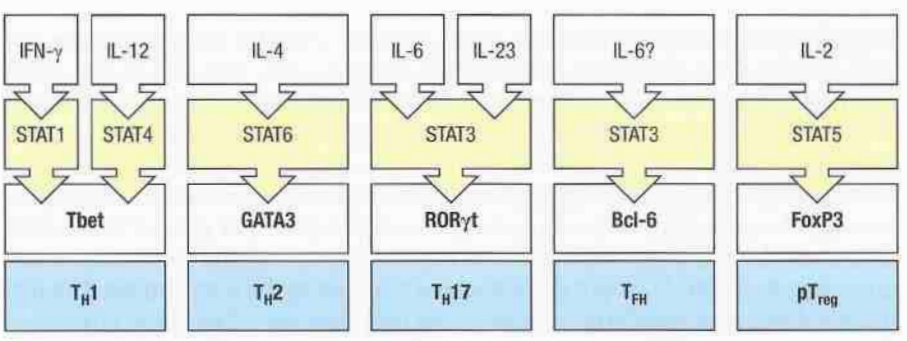
and peripheral regulatory T cells (pT_{reg} cells)—are associated with distinct signals that induce their formation, different transcription factors that drive their differentiation, and unique cytokines and surface markers that define their identity (Fig. 9.34; see also Fig. 9.33).

T_H1 development is induced when there is a predominance of interferons (for example, IFN-γ) and IL-12 during the early stages of naive T-cell activation. As described in Section 3-16, many key cytokines, including the interferons and IL-12, stimulate a JAK-STAT intracellular signaling pathway that results in the activation of specific gene networks. Different members of the JAK and STAT families are activated by different cytokines. Each of the effector pathways is dependent on a distinct pattern of STAT activation downstream of the lineage-specifying cytokines to program a unique transcription factor network that defines the gene-expression profile of mature effector T cells (Fig. 9.35). For T_H1 development, **STAT1** and **STAT4** are critical and are sequentially activated by interferons (type I, IFN-α and IFN-β; or type II, IFN-γ) and IL-12, respectively, which are produced by innate immune cells early during infection. Activated group 1 ILCs, or NK cells, may also be an important source of IFN-γ, whereas activated plasmacytoid DCs produce abundant type I interferons. Finally, T_H1 cells themselves may provide IFN-γ, thus reinforcing the signal for the differentiation of more T_H1 cells through a positive feedback loop. The activation of STAT1 by interferons also induces the expression of another transcription factor, **Tbet**, which switches on the genes for IFN-γ and the inducible component of the IL-12 receptor, IL-12Rβ2 (the other component of the receptor, IL-12Rβ1, is already expressed on naive T cells). These T cells are now committed to becoming T_H1 cells and can be further activated by IL-12 produced by dendritic cells and macrophages to induce STAT4 signaling. STAT4 further up-regulates Tbet expression and completes T_H1 programming. Because of its central role in programming T_H1 development, Tbet is sometimes referred to as a 'master regulator' of T_H1 cell differentiation.

Fig. 9.35 Different members of the STAT family of transcription factors are coupled to cytokine receptors that specify CD4 T-cell subset development. With the exception of TGF-β, which participates in both T_H17 and pT_{reg} development, the cytokines that specify the development of distinct effector cells typically activate different members of the STAT family of transcription factors. T_H1 cell differentiation is dependent on sequential activation of STAT1 and STAT4 by binding of IFN-γ and IL-12 to their respective receptors on antigen-activated naive CD4 T cells. Both of these STAT factors promote the expression of Tbet, which in turn cooperates with STAT1 and STAT4 to program T_H1 differentiation. T_H2 cell differentiation is dependent on STAT6 activation downstream of IL-4 receptor signaling. STAT6 acts to increase GATA3 expression, which cooperates with STAT6 to program T_H2 differentiation. IL-6 activates STAT3, which, in concert with TGF-β, participates in the induction of RORγt expression and T_H17 differentiation. IL-23, which acts later in T_H17 differentiation, also activates STAT3 to sustain and amplify the T_H17 program. The programming of T_{FH} cell differentiation by STAT factors is not fully understood, although STAT3 actions upstream of Bcl-6 expression are essential for T_{FH} development in mice. Activation of STAT5 by IL-2 is important in pT_{reg} differentiation and acts upstream of FoxP3 expression.



T_H2 development requires IL-4. When an antigen-activated naive T cell encounters IL-4, its receptor activates **STAT6**, which promotes expression of the transcription factor **GATA3**. GATA3 is a powerful activator of the genes encoding several cytokines produced by T_H2 cells, such as IL-4 and IL-13. GATA3 also induces its own expression, thereby stabilizing T_H2 differentiation via a cell-intrinsic positive feedback loop. The initial source of IL-4 that triggers a T_H2 response has long been debated. Eosinophils, basophils, and mast cells are each attractive possibilities because they can produce abundant IL-4 when activated by chitin, a polysaccharide present in helminth parasites, as well as in insects and crustaceans, which induces T_H2 responses. In mice treated with chitin, eosinophils and basophils are recruited into tissues and are activated to produce IL-4. In humans, group 2 ILCs can also produce IL-4, suggesting that these cells might contribute to T_H2 differentiation, although this is unproven. Clearly, there are several innate immune cells that might contribute IL-4 for T_H2 development, and the cellular source might differ, contingent on the inciting antigen. Similar to the positive feedback for T_H1 cell development provided by IFN-γ produced by activated T_H1 cells, IL-4 produced by activated T_H2 cells may amplify T_H2 development from naive T-cell precursors.

T_H17 cells arise when the cytokines IL-6 and TGF-β predominate during naive CD4 T-cell activation (see Figs. 9.33 and 9.34). Development of T_H17 cells requires the actions of **STAT3**, which is activated by IL-6 signaling. The signature transcription factor, or master regulator, of T_H17 cell differentiation is **RORγt**, a nuclear hormone receptor that is central to stabilizing the development of T_H17 cells. Developing T_H17 cells express the receptor for the cytokine IL-23, rather than the IL-12 receptor typical of T_H1 cells, and the expansion and further development of T_H17 effector activity seem to require IL-23, similar to the requirement for IL-12 in effective T_H1 responses (see Figs. 9.33 and 9.34). IL-21, which can be produced by T_H17 cells early in their development, has been proposed as an autocrine factor for T_H17 cell development and growth, although mice deficient for IL-21 or its receptor show no obvious impairment in T_H17 responses to infection. Notably, recent studies indicate that ongoing IL-6 signaling is required for the maintenance of T_H17 cells, indicating a nonredundant role for this cytokine both in the induction and maintenance of the T_H17 program. The initial source of IL-6 and TGF-β required for T_H17 cell differentiation appears to be cDC2 cells, although other innate immune cells activated by microbial products can also produce these cytokines. Unlike T_H1 or T_H2 cells, T_H17 cells do not appear to directly induce further T_H17 cell development from naive CD4 T cells via positive feedback, as they do not produce IL-6. However, IL-17 produced by T_H17 cells appears to enhance IL-6 production by innate immune cells and provides an indirect mechanism for reinforcing T_H17 differentiation from naive precursors.

It remains to be determined what cytokine signals—if any—are required for the initial commitment of activated CD4 T cells into T_{FH} cells. Unlike the other helper subsets, the requirements for T_{FH} differentiation are not yet clearly established and may differ between mice and humans. IL-6 seems to be important for T_{FH} development in mice but may be dispensable for development of this subset in humans. However, both species share a requirement for the transcription factor **Bcl-6** for T_{FH} development. Induction of Bcl-6 is required for the expression of CXCR5, the chemokine receptor for CXCL13, which is produced by the follicular dendritic cells and other stromal cells of the B-cell follicle. CXCR5 is essential for T_{FH} localization in follicles and is not expressed by other effector T-cell subsets. T_{FH} cells also express ICOS, the ligand for which (ICOSL) is expressed abundantly by B cells. ICOS, a member of the CD28 family, is crucial for the helper activity of T_{FH} cells, as we will see in Chapter 10. In addition to production of low amounts of cytokines characteristic of the effector T-cell subsets with which they develop in parallel (for example, IFN-γ, IL-4, or IL-17) and which promote different patterns of B-cell class switching,

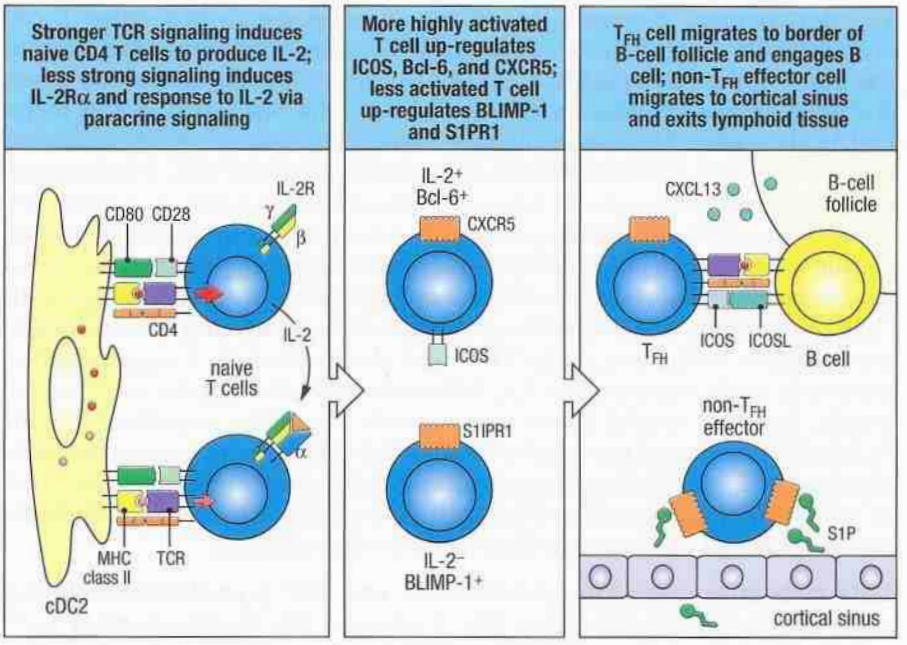


Fig. 9.36 CD4 T cells differentially express IL-2 and IL-2Rα after initial activation contingent on strength of TCR signaling, leading to alternative developmental programming. See text for details.

T_{FH} cells produce high amounts of IL-21, a cytokine that supports the proliferation and differentiation of B cells into antibody-producing plasma cells.

One cytokine that appears to be important in T_{FH} development is IL-2—not by its presence, but rather by its absence (Fig. 9.36). Unlike effector T cells, which produce an array of 'effector' cytokines when reactivated by antigen, naive T cells are limited to production of primarily IL-2 when initially activated—and then by only a fraction of antigen-activated cells. Although still an area of active study, it now appears that differential expression of IL-2 by activated naive CD4 T cells is linked to their developmental fate, such that IL-2 producers preferentially become T_{FH} cells whereas IL-2 nonproducers preferentially become non-T_{FH} effector cells (for example, T_H1, T_H2). This would appear to be counterintuitive, as IL-2 activates STAT5, which induces the expression of the transcription factor **BLIMP-1**, which in turn represses the transcriptional actions of the central T_{FH} transcription factor, Bcl-6. Thus, IL-2 is a potent inhibitor of T_{FH} differentiation, yet cells destined for a T_{FH} fate are the producers of IL-2.

However, because expression of IL-2 and IL-2Rα appear to be reciprocal, the fraction of cells producing IL-2—those fated to develop into T_{FH} cells—are resistant to its signaling, whereas cells that do not express IL-2, but instead express IL-2Rα, become activated by IL-2—despite their lack of its production. This suggests IL-2 signaling in nascent T-cell responses is primarily paracrine, not autocrine. The basis for this is likely related to the directional secretion of some cytokines, as we will discuss in Section 9-18. Thus, IL-2 and IL-2Rα appear to be differentially expressed by activated T cells fated to become T_{FH} and non-T_{FH} effectors, respectively. The outlier would appear to be T_H17 cells, the development of which, like T_{FH} cells, is also inhibited by IL-2. How divergence of T_{FH} and T_H17 development occurs despite their shared repression by IL-2 is currently unknown. Also, mechanisms that control the differential expression of IL-2 and IL-2Rα following activation of naive T cells are not yet understood. However, the strength of TCR and CD28 co-signaling appears to be contributory: stronger activation favors IL-2 expression and T_{FH} cell development, whereas weaker activation favors IL-2Rα expression and non-T_{FH} cell development.

Peripheral regulatory T (pT_{reg}) cells differ from thymic regulatory T (tT_{reg}) cells in that they develop upon antigen recognition in secondary lymphoid tissues,

not the thymus. However, like tT_{reg} cells, pT_{reg} cells are distinguished by expression of the transcription factor **FoxP3**, and they appear to be functionally equivalent to tT_{reg} cells. Peripheral T_{reg} cells develop when naive T cells are activated in the presence of the cytokines TGF-β and IL-2 in the absence of IL-6 and other pro-inflammatory cytokines. Another factor that is critical to pT_{reg} cell development is all-*trans*-retinoic acid (at-RA, or simply RA), a derivative of vitamin A that binds the nuclear retinoic acid receptor (RAR). As we will discuss in Chapter 12, both TGF-β and RA are abundant in the mucosa of the gut, where the antigens derived from commensal microbes stimulate the development of pT_{reg} cells to maintain tolerance to the intestinal microbiome.

Importantly, the shared requirement for TGF-β in the development of pT_{reg} and T_H17 cells is a basis for the overlapping programming of these two subsets, such that the presence or absence of IL-6 and RA is central in determining whether TGF-β co-signaling leads to the development of immunosuppressive pT_{reg} cells or pro-inflammatory T_H17 cells (Fig. 9.37). The generation of IL-6 by innate immune cells, particularly cDC2 cells, is regulated by the detection of pathogen signatures by innate sensor cells. In the absence of pathogens, IL-6 production is low, favoring differentiation of the immunosuppressive pT_{reg} cells and so preventing unwanted immune responses. Both pT_{reg} and tT_{reg} cells can also produce TGF-β, which in certain contexts can act in an inhibitory manner to suppress immune responses and inflammation and may act to support further pT_{reg} differentiation. Both types of T_{reg} cells can also undergo further differentiation to produce the immunoregulatory cytokine IL-10, as we will consider further in Section 9-17, as well as in Chapters 11 and 12.

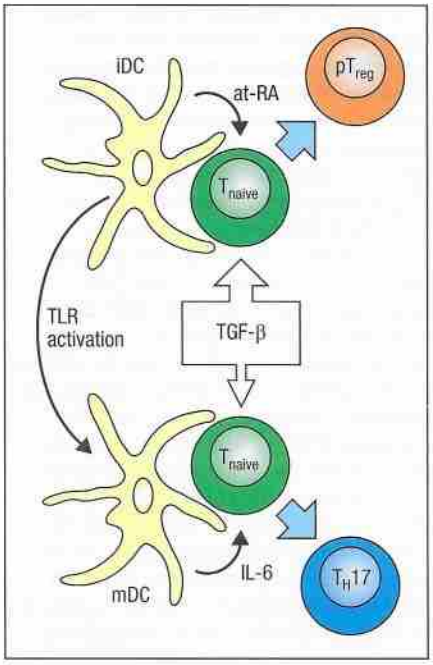

Fig. 9.37 A shared requirement for TGF-β in the differentiation of pT_{reg} and T_H17 cells provides a developmental link that reflects their complementary roles in promoting mutualism with the microbiota. A major site for the deployment of pT_{reg} and T_H17 cells is mucosal tissues, particularly the intestines, where the immune system must cope with an extraordinarily high density of microbial organisms that compose the microbiota. While the microbiota provides its host with important metabolic functions, it also represents a potential threat as some of its constituents are opportunistic pathogens that can cause serious infections if they breach the mucosal barrier. As an adaptation to restrain untoward inflammation directed against the microbiota while retaining the capacity to mount a host-protective immune response should barrier breach occur, the developmental balance between pT_{reg} cells, which suppress inflammatory responses against the microbiota, and T_H17 cells, which promote host-protective inflammatory responses, is determined by the balance between production of the vitamin A metabolite all-*trans*-retinoic acid (at-RA) and production of the pro-inflammatory cytokine IL-6 by mucosal dendritic cells. At homeostasis, antigens derived from the microbiota are presented by a specialized subset of resident dendritic cells that produce high amounts of at-RA, but little IL-6 (so-called immature DC, or iDC). However, when antigens are recognized in the context of TLR-stimulating signals, at-RA production is suppressed in favor of IL-6, resulting in a 'mature' DC (mDC) that favors the development of T_H17 effector cells.

9-16 CD4 T-cell subsets can cross-regulate each other's differentiation through the cytokines they produce.

The various subsets of helper CD4 T cells have quite different immune functions. For the immune response to efficiently control different types of pathogens, it must orchestrate a coordinated effector response that is dominated by one of these subsets. A principal means of achieving this is through the distinct ensemble of cytokines that are produced by the different subsets. Importantly, some of these same cytokines also participate in positive and negative feedback loops that control the differentiation of helper T cells from naive precursors, thereby providing a mechanism to promote one pattern of effector response while suppressing others. For example, TGF-β produced by T_{reg} cells inhibits the development of both T_H1 and T_H2 cells. And both IFN-γ (produced by T_H1 cells) and IL-4 (produced by T_H2 cells) potently inhibit T_H17 development, promoting T_H1 or T_H2 development, respectively (Fig. 9.38). Similarly, there is cross-regulation between T_H1 and T_H2 cells. IL-4 produced by T_H2 cells potently inhibits T_H1 development. Conversely, IFN-γ, a product of T_H1 cells, can inhibit the proliferation of T_H2 cells. As these cytokines are produced only after effector-cell development, their actions would appear to be limited to the later stages of an ongoing primary antigenic response or in a secondary, recall response. In this way, cytokines produced by effector T cells likely reinforce the differentiation of their own kind from naive precursor cells.

The adverse consequences of inappropriate cross-regulation of effector T-cell responses by cytokines have been demonstrated in a number of infectious models in mice. Such studies reinforce the notion that induction of the appropriate effector CD4 T-cell subset is crucial for pathogen clearance and show that subtle differences in CD4 T-cell responses can have a significant impact on the outcome of infection. One example is the murine model of infection by the protozoan parasite *Leishmania major*, which requires a T_H1 response and activation of macrophages for clearance. C57BL/6 mice

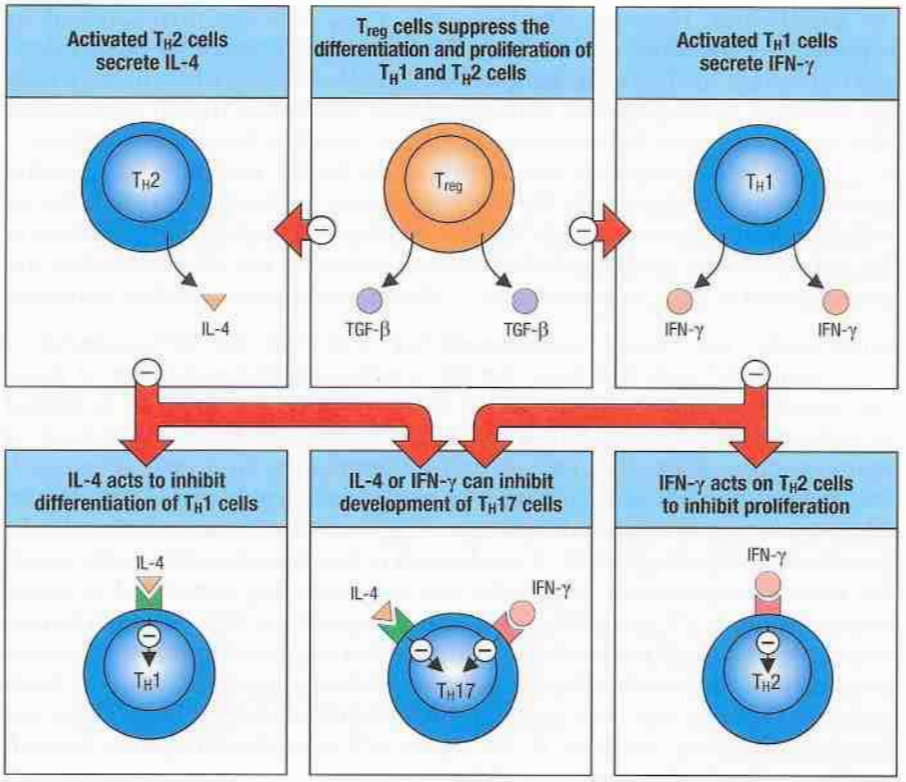

Fig. 9.38 The subsets of CD4 T cells each produce cytokines that can negatively regulate the development or effector activity of other subsets. Under homeostatic conditions, TGF-β produced by T_{reg} cells represses T_H1 and T_H2 responses in order to promote T_{reg} development. Under inflammatory conditions that favor IL-6 production, TGF-β production by T_{reg} cells similarly inhibits the activation of T_H1 or T_H2 responses (upper panels) in order to facilitate the development of T_H17 cells, which otherwise would be potently inhibited by IFN-γ or IL-4. Conversely, if signals are present to induce T_H1 or T_H2 cells, the cytokines IFN-γ or IL-4 produced by them can override the effect of IL-6 and inhibit T_H17 development (lower center panel). IFN-γ produced by T_H1 cells blocks the growth of T_H2 cells (right panels). On the other hand, IL-4 produced by TH2 cells dominantly prevents T_H1 cell development in favor of T_H2 (left panels). Although not shown, all T-cell subsets can produce IL-10 under conditions of chronic antigen stimulation, which inhibits the production of IL-12, IL-4, and IL-23 by dendritic cells and macrophages, thereby suppressing the development and/or maintenance of T_H1, T_H2, and T_H17 cells.

produce T_H1 cells that protect the animal by activating infected macrophages to kill *L. major*. In BALB/c mice infected with *L. major*, however, CD4 T cells fail to differentiate into T_H1 cells; instead, they become T_H2 cells, which are unable to activate macrophages to inhibit *Leishmania* growth. This difference seems to result from a population of memory T cells that are specific for gut-derived antigens but cross-react with an antigen, LACK (*Leishmania* analog of the receptors of activated C kinase), expressed by the *Leishmania* parasite. These memory cells are present in both strains of mice, but for unknown reasons they produce IL-4 in BALB/c mice but not in C57BL/6 mice. In BALB/c mice, the small amount of IL-4 secreted by these memory cells during *Leishmania* infection drives new *Leishmania*-specific CD4 T cells to become T_H2 cells instead of T_H1 cells, leading to failure of pathogen elimination and death. The preferential development of T_H2 rather than T_H1 cells in BALB/c mice can be reversed if IL-4 is blocked early during infection by anti-IL-4 antibody, but this treatment is ineffective if delayed after a week or so of infection, demonstrating the crucial importance of cytokines early in developmental decisions made by naive T cells (Fig. 9.39).

9-17 Regulatory T cells are a subset of CD4 T cells that restrains immune responses to maintain self-tolerance.

Regulatory T cells play a central role in preventing autoreactive immune responses and fall into different groups that are defined by their different developmental origins and functions. Thymic regulatory T (tT_{reg}) cells develop during positive selection in the thymus (see Section 8-27) and are characterized by constitutive expression of IL-2Rα, high levels of L-selectin (CD62L) and CCR7, as well as CTLA-4. As their name implies, peripheral regulatory T (pT_{reg}) cells arise in the periphery from naive CD4 T cells (see Section 9-14) and also express IL-2Rα, CD62L, CCR7, and CTLA-4. Collectively, T_{reg} cells represent about 5–10% of the CD4 T cells in circulation. A hallmark of both thymic and peripheral T_{reg} cells is their expression of the transcription factor FoxP3, which, among other actions, interferes with the interaction between

AP-1 and NFAT at the IL-2 gene promoter, preventing transcriptional activation of the gene and production of IL-2. Accordingly, although T_{reg} cells are highly dependent on IL-2 for their development and survival, they are unable to produce it. They are thus dependent on other immune cells for the IL-2 that sustains them.

Thymic T_{reg} cells develop from potentially self-reactive T cells that express conventional αβ T-cell receptors and are selected in the thymus by high-affinity binding to MHC molecules containing self-peptides (see Section 8-27). They exert their regulatory function after export to secondary lymphoid tissues, where—like naive CD4 and CD8 T cells, so-called conventional T cells—they continually recirculate between blood and T-cell zones, where they survey resident and migratory cDCs for antigen. It is not currently known whether tT_{reg} cells are activated to express their regulatory function in the periphery by the same self antigens that selected them in the thymus or by other self or nonself antigens, but antigen recognition on APCs is required for their actions to inhibit the activation of conventional T cells. The critical role for tT_{reg} cells in maintaining immune tolerance to self antigens is demonstrated in humans and mice that are defective in, or deficient for, FoxP3, which results in fatal multi-organ autoimmunity (described further in Chapter 15). In essence, release of the T_{reg} cell 'brake' on naive T-cell priming by autoantigens releases uncontrolled effector T-cell differentiation that can target self antigens.

Multiple mechanisms appear to contribute to the ability of T_{reg} cells to inhibit the priming of conventional T cells by cDCs, but principal among these are interactions that interfere with the capacity of these antigen-presenting cells to provide activating signals. The expression of high levels of CTLA-4 on the surface of T_{reg} cells is thought to permit them to compete for B7 expressed by antigen-presenting cells, thereby preventing adequate co-stimulation of naive T cells. CTLA-4 is an inhibitory receptor for B7 that has a higher affinity for its ligand than that of its activating family member, CD28, and therefore can outcompete CD28 for their shared ligand. Moreover, it has been shown that CTLA-4 expressed on T_{reg} cells can physically remove B7 molecules from the surface of antigen-presenting cells, thereby depleting them of co-stimulatory activity. Similarly, by constitutively expressing the high-affinity α chain of the IL-2 receptor (IL-2Rα, and lacking the ability to produce IL-2 themselves, T_{reg} cells appear to sequester IL-2 from naive T cells, which lack IL-2Rα expression until activated. Finally, T_{reg} cells can produce TGF-β, which can inhibit the development and function of T_H1 and T_H2 cells.

Other functions of T_{reg} cells are not as well understood but are acquired only after they undergo further differentiation after antigen activation in secondary lymphoid tissues. These T_{reg} cells, called **effector regulatory T (eT_{reg}) cells**, resemble other effector CD4 T cells in that they alter their movement to sites of pathogen entry or inflammation in nonlymphoid tissues, where they act to restrain antigenic responses by T_H1, T_H2, or T_H17 cells (see Chapter 11). A key cytokine produced by eT_{reg} cells is IL-10, which inhibits the expression of MHC molecules and co-stimulatory molecules by antigen-presenting cells as a means of limiting the responses of other effector T cells. IL-10 also inhibits the production of pro-inflammatory cytokines by antigen-presenting cells. For example, IL-10 potently inhibits the production of IL-12 and IL-23 by APCs and thus impairs their ability to promote the differentiation and maintenance of T_H1 and T_H17 cells, respectively.

Although they differentiate in secondary lymphoid tissues after export from the thymus, peripheral T_{reg} cells also express FoxP3 and share most of the phenotypic and functional features of thymic T_{reg} cells. A major function of pT_{reg} cells is the prevention of inflammatory immune responses to antigens of the commensal microbiota, particularly bacteria and fungi that are residents

Fig. 9.39 The development of CD4 T-cell subsets can be manipulated by altering the cytokines acting during the early stages of infection. Elimination of infection with the intracellular protozoan parasite *Leishmania major* requires a T_H1 response, because IFN-γ is needed to activate the macrophages that provide protection. BALB/c mice are normally susceptible to *L. major* because they generate a T_H2 response to the pathogen. This is because they produce IL-4 early during infection, and this induces naive T cells to develop into the T_H2 lineage (see the text). Treatment of BALB/c mice with neutralizing anti-IL-4 antibodies at the beginning of infection inhibits this IL-4 and prevents the diversion of naive T cells toward the T_H2 lineage; these mice develop a protective T_H1 response.

in mucosal tissues and skin, and to dietary antigens to which the host must maintain tolerance. Here, pT_{reg} cells appear to be the dominant source of IL-10, deficiency of which causes inflammatory bowel disease, an immune-mediated disease of the intestines characterized by chronic reactivity against antigens of the intestinal microbiota (see also Section 15-17). As discussed in Section 9-15 and considered in more detail in Chapter 12, the differentiation of pT_{reg} cells in the intestines is favored by the presence of antigen-presenting cells that produce retinoic acid (RA). RA produced by intestinal cDCs acts with TGF-β to induce pT_{reg} cell differentiation while suppressing the differentiation of T_H17 cells (see Fig. 9.37). The antagonistic balance of RA and IL-6 therefore controls the differentiation of pT_{reg} cells and T_H17 cells, respectively, in the intestinal lymphoid tissues.

CD4 T cells that lack FoxP3 expression but produce immunosuppressive cytokines characteristic of T_{reg} cells have also been described. One such population, referred to as **type 1 regulatory (T_R1) cells**, has been defined largely by their production of IL-10 but absence of FoxP3 expression. However, we now recognize that many different cells, including T_H1, T_H2, T_H17, and B cells, can produce IL-10 under certain circumstances, such as during chronic responses to persistent antigen. Therefore, it is uncertain whether T_R1 cells represent a distinct subset of T cells, and if so, whether they have unique functions in immune regulation.

Summary.

The initiation of adaptive immunity is one of the most compelling narratives in immunology. The crucial first step in adaptive immunity is the activation, or priming, of naive antigen-specific T cells by antigen-presenting cells within the lymphoid tissues through which they constantly circulate. The most distinctive feature of antigen-presenting cells is the expression of cell-surface co-stimulatory molecules, of which the B7 molecules are the most important. Naive T cells will respond to antigen only when the antigen-presenting cell presents both a specific antigen to the T-cell receptor and a B7 molecule to CD28 on the T cell. This dual requirement for both receptor ligation and co-stimulation by the same antigen-presenting cell helps to prevent naive T cells from responding to self antigens on tissue cells, which lack co-stimulatory activity.

Activation of naive T cells leads to their proliferation and differentiation into effector T cells, the critical event in most adaptive immune responses. Various combinations of cytokines regulate the type of effector T cell that develops in response to antigen. In turn, the cytokines present during primary T-cell activation are influenced by the innate immune system. Once an expanded clone of T cells acquires effector function, its progeny can act on any target cell that displays antigen on its surface. Effector T cells have a variety of functions. CD8 cytotoxic T cells recognize virus-infected cells and kill them. T_H1 effector cells promote the activation of macrophages to enhance their killing of intracellular pathogens. T_H2 cells promote mucosal barrier immunity against helminth pathogens by amplifying the effector activities of innate effector cells such as eosinophils, basophils, and mast cells, which ultimately eliminate the worms. The elimination of certain types of bacteria and fungi is orchestrated by T_H17 cells, particularly at barrier sites, where they recruit neutrophils to sites of infection and promote the production of antimicrobial peptides by epithelial cells. T_{FH} cells are specialized for interactions with B cells and localization to the B-cell follicle and germinal centers, where they provide help for antibody production and isotype switching. Regulatory CD4 T-cell subsets restrain the immune response by preventing the activation of self-reactive naive T cells by antigen-presenting cells and by producing inhibitory cytokines that limit the effector responses of other T-cell subsets.

General properties of effector T cells and their cytokines.

Once a T cell has been primed and has undergone differentiation in the T-cell zones of a lymphoid tissue, it migrates out of the T-cell zone to perform its function. As we will learn further in Chapter 10, T_{FH} cells act on their B-cell targets without leaving the lymphoid tissue in which they were primed; they migrate to the border between T-cell and B-cell zones, where they are reactivated by an antigen-presenting B cell that has taken up the T cell's cognate antigen via its B-cell receptor (membrane-associated IgM). Most other effector T cells emigrate from their site of activation in lymphoid tissues and enter the blood, either directly if primed by antigen in the spleen or via the efferent lymphatics and thoracic duct if primed in lymph nodes. Because of the cell-surface changes that have occurred during their differentiation, effector T cells can now migrate into tissues, particularly at sites of infection. They are guided to these sites by changes in the adhesion molecules expressed on the endothelium of the local blood vessels as a result of infection, and by local chemotactic factors, as will be discussed further in Chapter 11.

Effector proteins expressed by the T cell, whether cell-associated (for example, CD40L) or secreted (for example, cytokines), are often focused on the target by mechanisms that are activated by antigen recognition. This focusing mechanism is common to all types of effector T cells and is an important mechanism controlling the efficiency and selectivity of immune effector responses, irrespective of the target cell engaged. The initial binding of an effector T cell to its target, like that of a naive T cell to an antigen-presenting cell, is an antigen-nonspecific interaction mediated by LFA-1 and CD2. The levels of LFA-1 and of CD2 are twofold to fourfold higher on effector T cells than on naive T cells, such that effector T cells can bind efficiently to target cells that have less ICAM and CD58, respectively, on their surface than do activated conventional DCs. As for naive T cells that engage cDCs, this interaction is transient unless recognition of antigen on the target cell by the T-cell receptor triggers an increase in the affinity of the T-cell's LFA-1 for its ligands. The T cell then binds more tightly to its target and remains bound long enough to release its effector molecules. Because effector CD4 T cells have to switch on new genes and synthesize new proteins to carry out their effector actions, they must maintain contact with their targets for relatively long periods (hours). Cytotoxic T cells, by contrast, can be observed under the microscope attaching to and dissociating from successive targets relatively rapidly as they kill them, as we shall see later. Killing of the target or some local change in the T cell allows the effector T cell to detach and address new targets.

9-18 An immunological synapse can form between effector T cells and their targets to direct the release of effector molecules.

As we learned in Chapter 7, when binding to cells that express their specific antigenic peptide:self MHC complexes on target cells, the T cell sometimes forms a specialized structure at the site of cell–cell contact that facilitates focused secretion of its effector molecules onto the target; this structure is called the supramolecular activation complex (SMAC), or immune (immunological) synapse (see Section 7-19). Other cell-surface molecules also cluster here. For example, the tight binding of LFA-1 to ICAM-1 induced by ligation of the T-cell receptor creates a molecular seal that surrounds the T-cell receptor and its co-receptor (Fig. 9.40; see also Fig. 7.5). In some cases, the contact surface organizes into two zones: a central zone known as the central supramolecular activation complex (cSMAC) and an outer zone known as the peripheral supramolecular activation complex (pSMAC). The cSMAC contains most of the signaling proteins known to be important in T-cell activation.

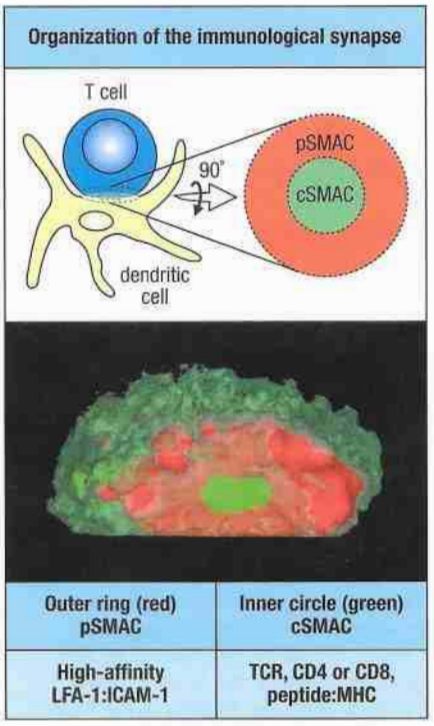

Fig. 9.40 The area of contact between an effector T cell and another cell forms an immunological synapse. Proteins in the contact area between the T cell and the APC form a structure called the immunological synapse, also known as the supramolecular activation complex (SMAC), which is organized into two distinct regions: the outer, or peripheral SMAC (pSMAC), indicated by the red ring; and the inner, or central SMAC (cSMAC), indicated in bright green. The cSMAC is enriched in the T-cell receptor (TCR), CD4 or CD8, and peptide:MHC complexes. The pSMAC is enriched in the integrin LFA-1 and ICAM-1. A confocal fluorescence micrograph of the area of contact between a CD4 T cell and an APC (as viewed through one of the cells) is shown below the schematic.

ANIMATION 9.6

The pSMAC is notable mainly for the presence of the LFA-1 and the cytoskeletal protein talin, which connects LFA-1 to the actin cytoskeleton (see Section 3-18). The immunological synapse is not a static structure, as may be inferred from Fig. 9.40, but is quite dynamic. TCRs move from the periphery into the cSMAC, where they undergo endocytosis through ubiquitin-mediated degradation involving the E3 ligase Cbl (see Section 7-5). Because TCRs are being degraded in the cSMAC, signaling is actually weaker there than in the peripheral contact areas, where microclusters of TCRs are being formed and are highly active (see Section 7-8).

ANIMATION 9.7

Wiscott-Aldrich Syndrome

Clustering of TCRs signals a reorientation of the cytoskeleton that polarizes the effector cell and focuses the release of effector molecules at the site of contact with the target cell. This is illustrated for a cytotoxic T cell in Fig. 9.41. An important intermediary in reorganization of the cytoskeleton downstream of T-cell receptor signaling is the Wiskott–Aldrich syndrome protein (WASp), defects in which result in the inability of T cells to become polarized, among other effects, and cause an immune deficiency syndrome for which the protein is named (see Section 7-19 and Section 13-5). Activation and recruitment of WASp by TCR signaling is mediated by the adaptor protein Vav (see Section 7-19). Polarization starts with the local reorganization of the cortical actin cytoskeleton at the site of contact; this in turn leads to the reorientation of the microtubule-organizing center (MTOC)—the structure from which the microtubule cytoskeleton is produced—and reorientation of the Golgi apparatus, through which most proteins destined for secretion travel. In the cytotoxic T cell, the cytoskeletal reorientation focuses exocytosis of the preformed cytotoxic granules at the site of T-cell contact with its target cell. In CD4 effector T cells, cytoskeletal polarization also focuses the secretion of newly synthesized effector molecules induced by ligation of the T-cell receptor. For example,

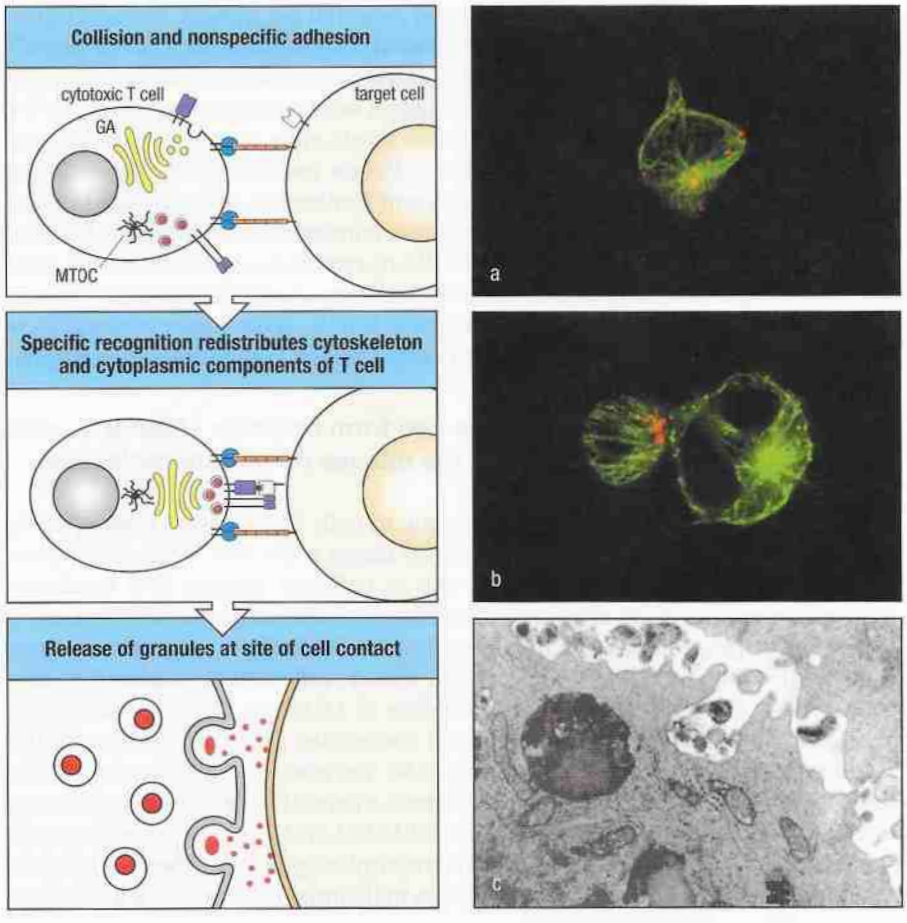

Fig. 9.41 The cellular polarization of T cells during specific antigen recognition allows effector molecules to be focused on the antigen-bearing target cell. The example illustrated here is a CD8 cytotoxic T cell. Cytotoxic T cells contain specialized lysosomes called cytotoxic granules (shown in red in the left panels), which contain cytotoxic proteins. Initial binding to a target cell through adhesion molecules does not have any effect on the location of the cytotoxic granules. Binding of the T-cell receptor causes the T cell to become polarized: reorganization within the cortical actin cytoskeleton at the site of contact aligns the microtubule-organizing center (MTOC), which in turn aligns the secretory apparatus, including the Golgi apparatus (GA), toward the target cell. Proteins stored in cytotoxic granules derived from the Golgi are then directed specifically onto the target cell. The photomicrograph in panel a shows an unbound, isolated cytotoxic T cell. The microtubule cytoskeleton is stained in green and the cytotoxic granules in red. Note how the granules are dispersed throughout the T cell. Panel b depicts a cytotoxic T cell bound to a (larger) target cell. The granules are now clustered in the bound T cell at the site of cell–cell contact. The electron micrograph in panel c shows the release of granules from a cytotoxic T cell.

IFN-γ and IL-4 produced by T_H1 and T_H2 cells, respectively, may be confined and concentrated at the site of contact with the target cell.

Thus, the T-cell receptor controls the delivery of effector molecules to target cells in three ways: it induces tight binding of effector cells to their target cells to create a narrow space in which effector molecules can be concentrated; it focuses delivery of effector molecules at the site of contact by inducing a reorientation of the secretory apparatus of the effector cell; and it triggers the synthesis and/or release of the effector molecules. All these mechanisms contribute to targeting actions of effector molecules onto the cell bearing specific antigen. Effector T-cell activity is thus highly selective for appropriate target cells, even though effector molecules themselves are not antigen-specific.

9-19 The effector functions of T cells are determined by the array of effector molecules they produce, which can act locally or at a distance.

The effector molecules produced by effector T cells fall into two broad classes: cytotoxins, which are stored in specialized cytotoxic granules and released by CD8 cytotoxic T cells, and cytokines or membrane-associated proteins, which are synthesized *de novo* by all effector T cells. Cytotoxins are the principal effector molecules of cytotoxic T cells (discussed later in Section 9-22). Their release must be tightly regulated because they are not specific; they can penetrate the lipid bilayer and trigger apoptosis in any cell. By contrast, effector CD4 T cells act mainly through the production of cytokines and membrane-associated proteins, and their actions are largely restricted to cells bearing MHC class II molecules that express receptors for these proteins. Secreted cytokines and membrane-associated molecules often act in concert to mediate their effects. Although cytokines can act on the secreting T cell itself (autocrine actions), it often directs its effector functions onto other cells (paracrine actions). The main effector molecules produced by CD8 and CD4 effector T cells are summarized in Fig. 9.42; the major effector T-cell cytokines and their effects on different target cells are summarized in Fig. 9.43 (see also a more comprehensive list of cytokines of immunological interest in Appendix III).

In many cases the formation of an immunological synapse ensures the polarized release of cytokines so that they are concentrated at the site of contact with the target cell (see Section 9-18). Moreover, the actions of many cytokines synergize with those of membrane-bound effector molecules. The effect, therefore, is combinatorial, and because the membrane-bound effectors can bind only to receptors on an interacting cell, this is another mechanism by which selective effects of cytokines are focused on the target cell. The effects of some cytokines are further restricted to target cells by tight regulation of their synthesis downstream of TCR signaling: the synthesis of IL-2, IL-4, and IFN-γ, for example, is controlled by mRNA instability, so that their secretion by T cells does not continue after the antigen engagement on the target cell has ended.

In other instances, cytokines have distant effects. For example, IL-3 and GM-CSF are released by T_H1, T_H2, and T_H17 cells and act on bone marrow cells to stimulate increased production of macrophages and granulocytes, which are important innate effector cells in both antibody-mediated and T cell–mediated immunity. IL-17A and IL-17F produced by T_H17 cells act both on barrier epithelium, such as in the intestinal and respiratory tracts, and on stromal cells, activating them to produce G-CSF, which enhances production of neutrophils by the bone marrow. The production by T_H2 cells of IL-5 stimulates bone marrow production of eosinophils. Whether a given cytokine effect is local or more distant is likely to reflect the amounts released, the degree to which this release is focused on the target cell, and the stability of the cytokine *in vivo*.

Fig. 9.42 The different types of effector T-cell subsets produce different effector molecules. CD8 T cells are predominantly killer T cells that recognize peptide:MHC class I complexes. They release perforin (which helps deliver granzymes into the target cell) and granzymes (which are pro-proteases that are activated intracellularly to trigger apoptosis in the target cell), and often also produce the cytokine IFN-γ. They also carry the membrane-bound effector molecule Fas ligand (CD178). When this binds to Fas (CD95) on a target cell, it activates apoptosis in the Fas-bearing cell. The various functional subsets of CD4 T cells recognize peptide:MHC class II complexes. T_H1 cells are specialized to activate macrophages that are infected by or have ingested pathogens; they secrete IFN-γ to activate the infected cell, as well as other effector molecules. They can express membrane-bound CD40 ligand and/or Fas ligand. CD40 ligand triggers activation of the target cell, whereas Fas ligand triggers the death of Fas-bearing targets, and so which molecule is expressed strongly influences T_H1 function. T_H1 cells also produce chemokines (for example, CXCL2) that enhance the recruitment of monocytes to enhance type 1 immune responses. T_H2 cells are specialized for promoting immune responses to the multicellular parasites—helminths. They provide cytokines (IL-4, IL-5, and IL-13) that enhance helminth clearance through their actions to enhance eosinophil, mast cell, basophil, and barrier epithelial cell activities. They can also produce CD40 ligand and chemokines that preferentially recruit innate effector cells that enhance type 2 immune responses, as well as cytokines that promote tissue repair/healing. T_H17 cells produce members of the IL-17 family and IL-22 that both can activate barrier epithelial cell activities and can promote acute inflammation by helping to recruit neutrophils to sites of infection. They also produce CCL20, a chemokine that assists in coordination of type 3 immune responses. T_{FH} cells produce the cytokine IL-21, which is important in helping B cells mature into class-switched antibody-producers, as well as some cytokines that participate in class switching characteristic of type 1, 2, or 3 immune responses (for example, IL-4). Importantly, CD40 ligand expressed by T_{FH} cells is critical to the activation and differentiation of antigen-bearing B cells with which they interact.

9-20 Effector T cells express several TNF family cytokines.

Most effector T cells express members of the TNF family as membrane-associated proteins on the cell surface. These include TNF-α, the lymphotoxins (LTs), Fas ligand (CD178), and CD40 ligand, the last two always being cell-surface associated. TNF-α is made by T cells in soluble and membrane-associated forms and assembles into a homotrimer. Secreted LT-α is a homotrimer, but LT-α can also heterotrimerize with the transmembrane member of this family called LT-β (see Section 9-2). The receptors for TNF-α and LT-α (TNFR-I and TNFR-II) form homotrimers when bound to their ligands. The trimeric structure is characteristic of nearly all members of the TNF family (see Fig. 9.28), and the ligand-induced trimerization of their receptors is critical in initiating signaling.

Fas ligand (FasL) and CD40 ligand (CD40L) bind respectively to the transmembrane proteins Fas (CD95) and CD40 on target cells. Fas contains a 'death' domain in its cytoplasmic tail, and binding of Fas by FasL induces death by apoptosis in the Fas-bearing cell (see Fig. 9.45). Other TNFR family members, including TNFR-I, are also associated with death domains and can also induce apoptosis under some circumstances. Thus, TNF-α and LT-α can induce apoptosis by binding to TNFR-I.

CD40 Ligand Deficiency

CD40L is particularly important for CD4 T-cell effector function; its expression is induced on T_H1, T_H2, T_H17, and T_{FH} cells, and it delivers activating signals to B cells and innate immune cells through CD40. As we have seen, CD40L also plays an important role in licensing type 1 cDCs for heightened

Cytokine	T-cell source	Effects on					Effect of gene knockout
		B cells	T cells	Macrophages	Hematopoietic cells	Other tissue cells	
Interleukin-2 (IL-2)	Naive, T_H1, some CD8	Stimulates growth and J-chain synthesis	Growth and differentiation	–	–	–	↓T-cell responses IBD
Interferon-γ (IFN-γ)	T_H1, T_{FH}, CTL	Differentiation IgG2a synthesis (mouse)	Inhibits T_H2 and T_H17 cell differentiation	Activation, ↑MHC class I and class II	Activates NK cells	Antiviral ↑MHC class I and class II	Susceptible to mycobacteria, some viruses
Lymphotoxin-α (LT-α, TNF-β)	T_H1, some CTL	Inhibits	Kills	Activates, induces NO production	Activates neutrophils	Kills fibroblasts and tumor cells	Absence of lymph nodes Disorganized spleen
Interleukin-4 (IL-4)	T_H2, T_{FH}	Activation, growth IgG1, IgE ↑MHC class II induction	Growth, survival	Promotes marginal zone macrophage activation	↑Growth of mast cells	–	No T_H2
Interleukin-5 (IL-5)	T_H2	Mouse: Differentiation IgA synthesis	–	–	↑Eosinophil growth and differentiation	–	Reduced eosinophilia
Interleukin-13 (IL-13)	T_H2	IgG1, IgE class switch	–	Promotes marginal zone macrophage	–	↑Production of mucus (goblet cell)	Impaired helminth expulsion
Interleukin-17 (IL-17)	T_H17, T_{FH}	Promotes IgG2a, IgG2b, IgG3 (mouse)	–	–	Stimulates neutrophil recruitment	Stimulates fibroblasts and epithelial cells to secrete chemokines	Impaired antibacterial defense
Interleukin-22 (IL-22)	T_H17	–	–	–	–	Stimulates mucosal epithelium and skin to produce antimicrobial peptides	Impaired antibacterial defense
Interleukin-21 (IL-21)	T_{FH}, some T_H1, T_H17, CTL	Stimulates B-cell growth, germinal center formation, IgG class switching	Promotes CTL memory	–	–	–	Deficient antibody responses
Transforming growth factor-β (TGF-β)	T_{reg}, T_{FH}	Inhibits growth IgA switch factor	T_H17 and iT_{reg} differentiation, inhibits T_H1 and T_H2	Inhibits activation	Activates neutrophils	Inhibits/ stimulates cell growth	Death at ~10 weeks
Interleukin-10 (IL-10)	T_{reg}, some T_H1, T_H2, T_H17, CTL	↑MHC class II	Inhibits T_H1	Inhibits cytokine release	Co-stimulates mast cell growth	–	IBD

Tumor necrosis factor-α (TNF-α)	T_H1, T_H17, some T_H2, some CTL	–	–	Activates, induces NO production	–	Activates microvascular endothelium	Susceptibility to Gram + sepsis
Granulocyte–macrophage colony-stimulating factor (GM-CSF)	T_H1, T_H17, some T_H2, some CTL	Differentiation	Inhibits growth?	Activation Differentiation to dendritic cells	↑Production of granulocytes and macrophages (myelopoiesis) and dendritic cells	–	–

Fig. 9.43 The nomenclature and functions of well-defined T-cell cytokines. Each cytokine has multiple activities on different cell types and is typically produced only after T-cell activation by antigen. Major activities of effector cytokines are highlighted in red. The mixture of cytokines secreted by a given cell type produces many effects through what is called a 'cytokine network.' ↑, increase; ↓, decrease; CTL, cytotoxic T lymphocyte; NK cells, natural killer cells; CSF, colony-stimulating factor; Gram +, Gram positive; IBD, inflammatory bowel disease; NO, nitric oxide.

activation of naive CD8 T cells. The cytoplasmic tail of CD40 lacks a death domain; instead, it is linked downstream to proteins called TRAFs (TNF receptor–associated factors). CD40 is involved in the activation of B cells and macrophages; the ligation of CD40 on B cells promotes growth and isotype switching, whereas CD40 ligation on macrophages induces them to secrete higher amounts of pro-inflammatory cytokines (for example, TNF-α) and become receptive to much lower concentrations of IFN-γ. Deficiency in CD40 ligand expression is associated with immunodeficiency, as we will learn in Chapter 13.

Summary.

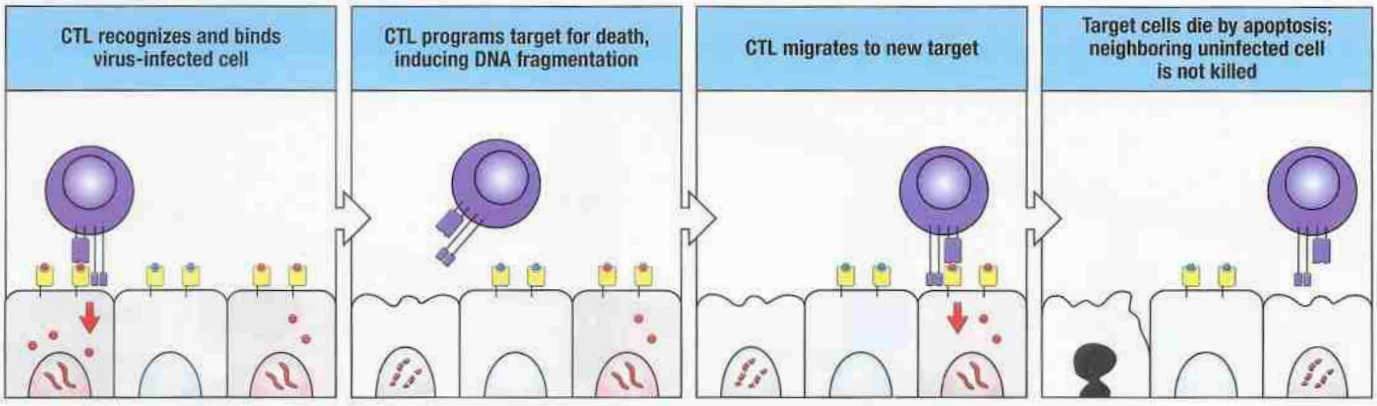
Interactions between effector T cells and their targets are initiated by transient antigen-nonspecific adhesion. T-cell effector functions are elicited only when peptide:MHC complexes on the surface of the target cell are recognized by the receptor on an effector T cell. This recognition event triggers the effector T cell to adhere more strongly to the antigen-bearing target cell and to release its effector molecules directly at the target cell, leading to the activation or death of the target. The immunological consequences of antigen recognition by an effector T cell are determined largely by the set of effector molecules that the T cell produces on binding a specific target cell. CD8 cytotoxic T cells store preformed cytotoxins in specialized cytotoxic granules whose release is tightly focused at the site of contact with the infected target cell, thus killing it without killing any uninfected cells nearby. Cytokines and members of the TNF family of membrane-associated effector proteins are synthesized *de novo* by most effector T cells. Membrane-associated effector molecules can deliver signals only to an interacting cell bearing the appropriate receptor, whereas soluble cytokines can act on cytokine receptors expressed locally on the target cell or on other cells at a distance. The actions of cytokines and membrane-associated effector molecules through their specific receptors, together with the effects of the cytotoxins released by CD8 cells, account for most of the effector functions of T cells.

T cell–mediated cytotoxicity.

All viruses and some bacteria and single-cell protozoans multiply in the cytoplasm of infected cells; indeed, a virus is a highly sophisticated parasite that has no biosynthetic or metabolic apparatus of its own and, in consequence, can replicate only inside cells. Although susceptible to antibody-mediated clearance before they enter cells, once they enter cells these pathogens are not accessible to antibodies and can be eliminated only by the destruction or modification of the infected cells in which they replicate. This role in host defense is largely filled by cytotoxic CD8 T cells, although T_H1 cells may also acquire cytotoxic capacities. The crucial role of cytotoxic T cells in limiting such infections is seen in the increased susceptibility of animals artificially depleted of these T cells or of mice or humans that lack the MHC class I molecules that present antigen to CD8 T cells. The elimination of infected cells without the destruction of healthy tissue requires the cytotoxic mechanisms of CD8 T cells to be both powerful and accurately targeted.

9-21 Cytotoxic T cells induce target cells to undergo programmed cell death via extrinsic or intrinsic pathways of apoptosis.

To deprive intracellular pathogens of their cellular host, cytotoxic T cells target the infected host cells for death. Cytotoxic T cells kill by inducing their targets to



CTL recognizes and binds virus-infected cell
CTL programs target for death, inducing DNA fragmentation
CTL migrates to new target
Target cells die by apoptosis; neighboring uninfected cell is not killed

Fig. 9.44 Cytotoxic CD8 T cells can induce apoptosis in infected target cells while sparing neighboring uninfected cells. Specific recognition of peptide:MHC complexes on an infected target cell by a cytotoxic CD8 T cell (CTL) leads to the death of the target cell by apoptosis. CTLs can recycle to kill multiple targets, so called 'serial killing.' Each killing requires the same series of steps, including receptor binding and the directed release of cytotoxic proteins stored in granules. Although all the cells in a tissue are susceptible to killing by the cytotoxic proteins of CTLs, the polarized release of the cytotoxic granules onto infected cells by specific antigen recognition ensures that neighboring cells are spared.

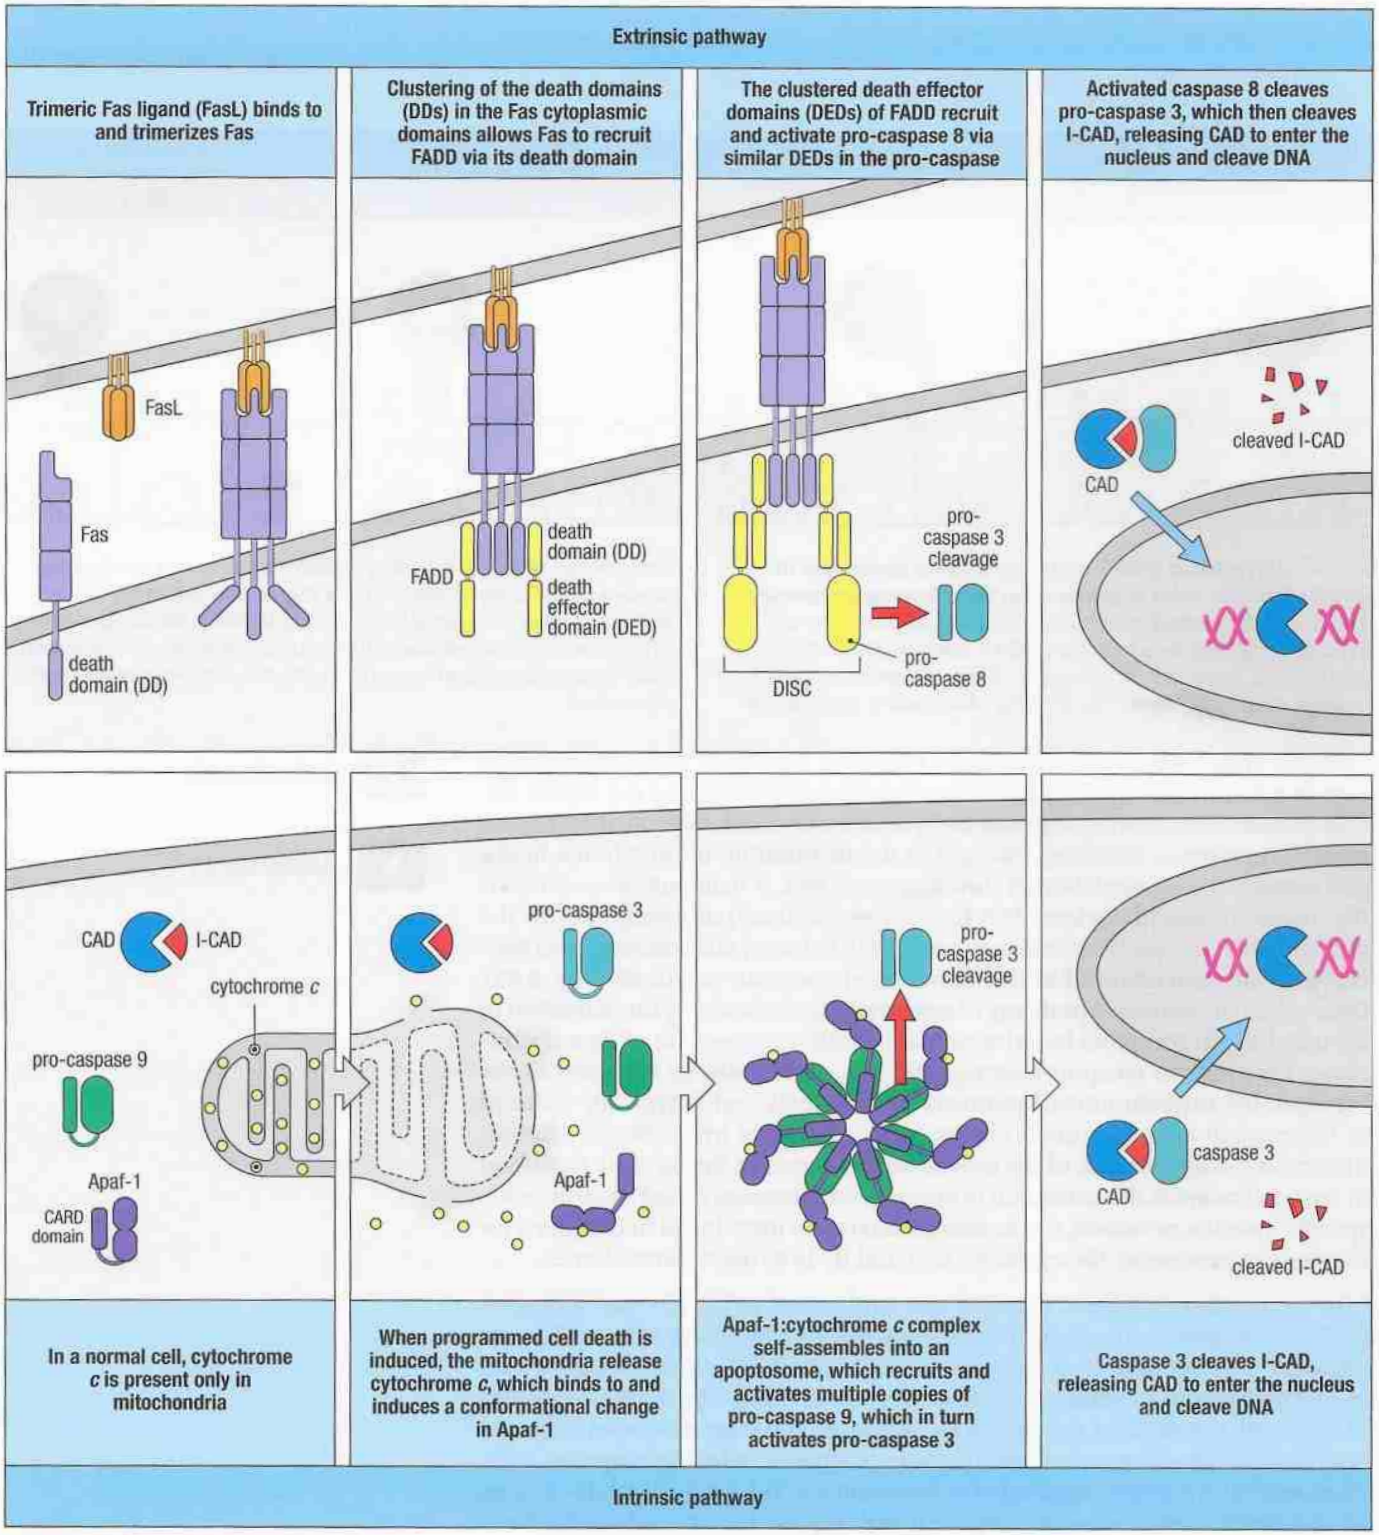
undergo **apoptosis** (Fig. 9.44; see also Fig. 9.31). Apoptosis is a regulated process that is induced either by specific extracellular signals or by the lack of signals required for survival. It proceeds by a series of cellular events that include plasma-membrane blebbing, changes in the distribution of membrane lipids, and enzymatic fragmentation of chromosomal DNA. A hallmark of apoptosis is the fragmentation of nuclear DNA into pieces 200 base pairs long through the activation of nucleases that cleave genomic DNA between nucleosomes. Two general pathways are involved in the induction of apoptotic cell death (Fig. 9.45). One, called the **extrinsic pathway of apoptosis**, is mediated by the activation of so-called death receptors by extracellular ligands. Engagement of ligand stimulates apoptosis in receptor-bearing cells. The other pathway is known as the **intrinsic** (or **mitochondrial) pathway of apoptosis** and is typically induced in response to noxious stimuli (for example, ultraviolet irradiation or chemotherapeutic drugs) or lack of the growth factors required for survival. Common to both pathways is the activation of specialized proteases called aspartic acid–specific cysteine proteases, or caspases, which were introduced in Chapter 3 for their role in processing the cytokines IL-1 and IL-18 to their mature forms.

ANIMATION 9.8

ANIMATION 9.9

Like many other proteases, caspases are synthesized as inactive pro-enzymes, in this case, pro-caspases, in which the catalytic domain is inhibited by an adjacent pro-domain. Pro-caspases are activated by other caspases that cleave the protein to release the inhibitory pro-domain. There are two classes of caspases involved in the apoptotic pathway: **initiator caspases** promote apoptosis by cleaving and activating other caspases; **effector caspases** initiate the cellular changes associated with apoptosis. The extrinsic pathway uses two related initiator caspases, caspase 8 and caspase 10, whereas the intrinsic pathway uses caspase 9. Both pathways use caspases 3, 6, and 7 as effector caspases. The effector caspases cleave a variety of proteins that are critical for cellular integrity and also activate enzymes that promote the death of the cell. For example, they cleave and degrade nuclear proteins that are required for the structural integrity of the nucleus and activate the endonucleases that fragment the chromosomal DNA.

Cytotoxic T cells can induce target-cell death by either the extrinsic or the intrinsic apoptotic pathway. The extrinsic pathway is mediated by expression of FasL and TNF-α or LT-α, receptors for which [Fas (CD95) and TNFR-I, respectively] are expressed by other cells of the immune system, as well as non-immune-system cells. Activation of the extrinsic pathway (or death receptor pathway) leads to the formation of the **death-inducing signaling complex (DISC)** (see Fig. 9.45, upper panel). The first step in Fas-mediated



Extrinsic pathway
Trimeric Fas ligand (FasL) binds to and trimerizes Fas

Caspase 3 cleaves I-CAD, releasing CAD to enter the nucleus and cleave DNA
Intrinsic pathway

Fig. 9.45 Apoptosis of target cells can be induced by the extrinsic or intrinsic pathway. Induction of apoptosis can occur by either the extrinsic pathway (upper panels) or the intrinsic pathway (lower panels). Apoptosis induced by the extrinsic pathway is typically mediated via signaling through one of several 'death' receptors of the TNF receptor superfamily, such as Fas, which contain a so-called death domain (DD) in their cytoplasmic tails. When Fas ligand (FasL) binds Fas, this trimerizes the receptor (upper first panel). The adaptor protein FADD (also known as MORT-1) also contains a death domain and can bind to the clustered death domains of Fas (upper second panel). FADD also contains a domain called a death effector domain (DED), which allows it to recruit pro-caspase 8 (or pro-caspase 10, not shown), which also contains a DED (upper third panel). Clustered pro-caspase 8 cleaves itself to form an active enzyme that is released from the death-inducing signaling complex, or DISC, allowing active caspase 8 to then cleave executioner caspases, such as pro-caspase 3; this results in the activation of enzymes such as I-CAD, which can cleave DNA (upper fourth panel). Induction of apoptosis by the intrinsic pathway (lower panels) is mediated by the mitochondrial release of cytochrome *c*, which induces formation of the apoptosome, which in turn activates pro-caspase 9 to initiate programmed cell death. In normal cells, cytochrome *c* is confined to the mitochondria (lower first panel). However, after stimulation of the intrinsic pathway, there is mitochondrial outer membrane permeabilization (MOMP)—typically induced by activation of members of the Bcl-2 family that can form pore complexes (for example, Bax and Bak; see Fig. 9.46)—allowing cytochrome *c* to leak out into the cytosol (lower second panel), where it is bound by Apaf-1. The conformational change that ensues in Apaf-1 induces self-assembly of the multimeric apoptosome, which recruits pro-caspase 9 (lower third panel). Clustering of pro-caspase 9 by the apoptosome activates it, allowing it to cleave downstream caspases, such as pro-caspase 3, resulting in the activation of proteases and nucleases, such as I-CAD (lower fourth panel).

formation of the DISC is binding of the homotrimeric FasL, which results in the trimerization of Fas. This causes the death domains of Fas to bind to the death domain of FADD (Fas-associated via death domain), an adaptor protein that is recruited to the activated death domains of a number of TNF receptor superfamily members. In addition to its death domain, FADD contains an additional domain called a death effector domain (DED) that can bind to DEDs present in other proteins. When FADD is recruited to Fas, the DED of FADD then recruits the initiator caspase pro-caspase 8 (and/or pro-caspase 10) via interaction with a DED in the pro-caspase. The high local concentration of these caspases in association with activated receptors allows the caspases to cleave themselves, resulting in their activation. Once activated, caspases 8 and 10 are released from the receptor complex and can activate the downstream effector caspases that induce apoptosis. Loss-of-function mutations in Fas leads to the increased survival of lymphocytes and is one cause of the disease **autoimmune lymphoproliferative syndrome (ALPS)**. This disease can also be due to mutations in FasL and in caspase 10.

Because the distribution of these receptors is somewhat restricted, cytotoxic T cells have acquired a more universal mechanism for inducing cell death in antigen-specific targets: the directional release of cytotoxic granules that activate the intrinsic pathway of apoptosis (see Section 9.22). When cytotoxic T cells engage target cells that express cognate antigen, they can induce target-cell death within 5 minutes, although death can take hours to become fully evident (see Fig. 9.44). The rapidity of this response reflects the release of preformed effector molecules that are delivered to the target cell. In addition to killing the host cell, the apoptotic mechanism may also act directly on cytosolic pathogens. For example, the nucleases that are activated in apoptosis to destroy cellular DNA can also degrade viral DNA. This prevents the assembly of virions and the release of infectious virus, which could otherwise infect nearby cells. Other enzymes activated in the course of apoptosis may destroy nonviral cytosolic pathogens. Apoptosis is therefore preferable to necrosis as a means of killing infected cells; in cells dying by necrosis, intact pathogens are released from the dead cell, and these can continue to infect healthy cells or parasitize the macrophages that ingest them.

Apoptosis by the intrinsic pathway is triggered by the release of **cytochrome *c*** from mitochondria, which triggers the activation of caspases. Once released into the cytoplasm, cytochrome *c* binds Apaf-1 (apoptotic protease activating factor-1), stimulating its oligomerization to form the **apoptosome**. The apoptosome then recruits an initiator caspase, pro-caspase 9, aggregation of which promotes its self-cleavage and frees its catalytic domain to activate effector caspases (see Fig. 9.45, lower panel).

The release of cytochrome *c* is controlled by interactions between members of the **Bcl-2 family** of proteins. The Bcl-2 family of proteins is defined by the presence of one or more Bcl-2 homology (BH) domains and can be divided into two general groups: members that promote apoptosis, and members that inhibit apoptosis (**Fig. 9.46**). Pro-apoptotic Bcl-2 family members, such as Bax, Bak, and Bok (referred to as 'executioners'), bind to mitochondrial membranes and can directly cause cytochrome *c* release. How they do this is still not known, but they may form pores in the mitochondrial membranes.

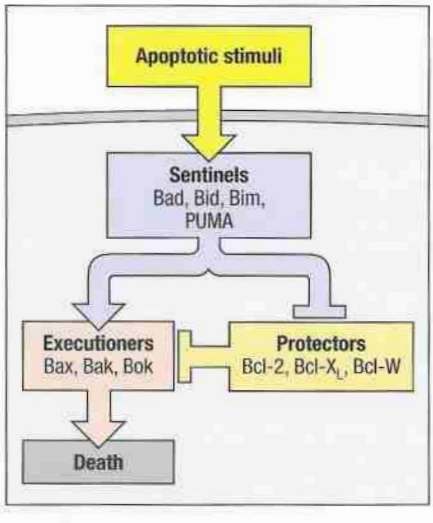

Fig. 9.46 General scheme of intrinsic pathway regulation by the Bcl-2 family of proteins. Extracellular apoptotic stimuli activate a group of pro-apoptotic (sentinel) proteins. Sentinel proteins can function either to block the protection provided by pro-survival, protector proteins or to directly activate pro-apoptotic, executioner proteins. In mammalian cells, apoptosis is mediated by the executioner proteins Bax, Bak, and Bok. In normal cells, these proteins are prevented from acting by the protector proteins (Bcl-2, Bcl-X_L, and Bcl-W). The release of activated executioner proteins causes the release of cytochrome *c* and subsequent cell death, as shown in Fig. 9.45.

Protein in granules of cytotoxic T cells	Actions on target cells

Granzymes	Serine proteases, which activate apoptosis once in the cytoplasm of the target cell
Granulysin	Has antimicrobial actions and can induce apoptosis

Fig. 9.47 Cytotoxic effector proteins released by cytotoxic T cells.

The anti-apoptotic Bcl-2 family members are induced by stimuli that promote cell survival. The best known of the anti-apoptotic proteins is Bcl-2 itself. The gene *Bcl2* was first identified as an oncogene in a B-cell lymphoma, and its overexpression in tumors makes the cells more resistant to apoptotic stimuli and thus more likely to progress to an invasive cancer. Other members of the inhibitory family include Bcl-X_L and Bcl-W. Anti-apoptotic proteins function by binding to the mitochondrial membrane to block the release of cytochrome *c*. The precise mechanism of inhibition is not clear, but they may function by directly blocking the function of the pro-apoptotic family members.

In addition to the executioners, another set of pro-apoptotic Bcl-2 family members, termed 'sentinels,' promotes apoptosis through dual actions: once activated by apoptotic stimuli, these proteins, which include Bad, Bid, Bim, and PUMA, can both block the activity of the anti-apoptotic proteins and act directly to promote the activity of the executioner pro-apoptotic proteins.

9-22 Cytotoxic effector proteins that trigger apoptosis are contained in the granules of cytotoxic CD8 T cells.

The principal mechanism of cytotoxic T-cell action is the calcium-dependent release of specialized cytotoxic granules upon recognition of antigen on the surface of a target cell. Cytotoxic granules are modified lysosomes containing at least three distinct classes of cytotoxic effector proteins that are expressed specifically in cytotoxic T cells: perforin, granzymes, and granulysin (Fig. 9.47). These proteins are stored in cytotoxic granules in an active form, but conditions within the granules prevent their actions until after release. **Perforin** acts by forming pores in, or perforating, the target-cell plasma membrane, which both causes direct damage to the target cell and forms a conduit through which other contents of cytotoxic granules are delivered into the cytosol of the target cell. **Granzymes**, of which there are 5 in humans and 10 in the mouse, activate apoptosis once delivered to the target-cell cytosol via pores formed by perforin. **Granulysin**, which is expressed in humans but not in mice, has antimicrobial activity and, at high concentrations, is also able to induce apoptosis in target cells. Cytotoxic granules also contain the proteoglycan **serglycin**, which acts as a scaffold, forming a complex with perforin and the granzymes. Both perforin and granzymes are required for effective target-cell killing. In cytotoxic cells that lack granzymes, the presence of perforin alone can kill target cells, but large numbers of cytotoxic cells are needed because the killing is very inefficient. In contrast, cytotoxic T cells from mice lacking perforin are unable to kill other cells because of the lack of a mechanism to form pores that deliver granzymes into the target cell.

Granzymes trigger apoptosis in the target cell both by directly activating caspases and by inducing mitochondrial release of cytochrome *c*, which also activates caspases (Fig. 9.48). The two most abundant granzymes are granzymes A and B. Granzyme A triggers cell death by caspase-independent mitochondrial damage, through mechanisms that are not completely understood. Granzyme B, like the caspases, cleaves proteins after aspartic acid residues and directly activates caspase 3, thereby activating a caspase proteolytic cascade, which eventually activates caspase-activated deoxyribonuclease (CAD) by cleaving an inhibitory protein (I-CAD) that binds to and inactivates CAD. This nuclease is believed to be the enzyme that degrades DNA in target cells. Granzyme B also targets mitochondria to activate the intrinsic apoptotic pathway; it cleaves the protein Bid (BH3-interacting domain death agonist protein), either directly or indirectly by activated caspase 3, causing disruption of the mitochondrial outer membrane and the release from the mitochondrial intermembrane space of pro-apoptotic molecules such as cytochrome *c*. As discussed in Section 9-21, cytochrome *c* is central to amplification of the intrinsic apoptotic cascade, as it initiates assembly of the apoptosome with

Fig. 9.48 Perforin, granzymes, and serglycin are released from cytotoxic granules and deliver granzymes into the cytosol of target cells to induce apoptosis. Recognition of its antigen on a virus-infected cell by a cytotoxic CD8 T cell induces the T cell to release the contents of its cytotoxic granules in a directed fashion. Perforin and granzymes, in a complex with the proteoglycan serglycin, are delivered to the membrane of the target cell (top panel). Perforin permeabilizes the target-cell membrane to allow the entry of the granule contents into the cytosol of the target cell, and the introduced granzymes then act on specific intracellular targets such as the proteins Bid and pro-caspase 3 (second panel). Either directly or indirectly, the granzymes cause the cleavage of Bid into truncated Bid (tBid) and the cleavage of pro-caspase 3 into an active caspase (third panel). tBid displaces the protective Bcl-2 family member, Bcl-X_L, from its interaction with the executioner Bcl-2 family member, Bax, resulting in Bax multimerization to form a pore to induce mitochondrial outer membrane permeabilization (MOMP). This results in mitochondrial release of cytochrome *c* into the cytosol, which promotes apoptosis by inducing the formation of the apoptosome that activates pro-caspase 9, which in turn further amplifies caspase 3 activation (see lower panels of Fig. 9.45). Activated caspase 3 targets I-CAD to release caspase-activated deoxyribonuclease (CAD), which fragments the DNA (bottom panel).

Apaf-1, which in turn activates the initiator caspase 9 (see Fig. 9.45, lower panels). Thus, granzyme B acts directly to activate the effector caspase 3 and indirectly to activate the initiator caspase 9.

Cells undergoing programmed cell death are rapidly ingested by phagocytic cells, which recognize a change in the cell membrane: phosphatidylserine, which is normally found only in the inner leaflet of the membrane, replaces phosphatidylcholine as the predominant phospholipid in the outer leaflet. The ingested cell is broken down and completely digested by the phagocyte without the induction of co-stimulatory proteins. Thus, apoptosis is normally an immunologically 'quiet' process; that is, apoptotic cells do not normally contribute to or stimulate immune responses.

9-23 Cytotoxic T cells are selective serial killers of targets expressing a specific antigen.

When cytotoxic T cells are offered a mixture of equal amounts of two target cells, one bearing a specific antigen and the other not, they kill only the target cell bearing the specific antigen. The 'innocent bystander' cells and the cytotoxic T cells themselves are not killed. The cytotoxic T cells are probably not killed because release of the cytotoxic effector molecules is highly polarized via an immune synapse. As we saw in Fig. 9.41, cytotoxic T cells orient their Golgi apparatus and microtubule-organizing center to focus secretion on the point of contact with a target cell (Fig. 9.49). Cytotoxic T cells attached to several different target cells reorient their secretory apparatus toward each cell in turn and kill them one by one, strongly suggesting that the mechanism whereby cytotoxic mediators are released allows attack at only one point of contact at any one time. The narrowly focused action of cytotoxic CD8 T cells allows them to kill single infected cells in a tissue without creating widespread tissue damage (see Fig. 9.44) and is of crucial importance in tissues where cell regeneration does not occur, as with the neurons of the central nervous system, or is very limited, as in the pancreatic islets.

Cytotoxic T cells (cytotoxic T lymphocytes; CTLs) can kill their targets rapidly because during effector differentiation from naive precursors, developing CTLs synthesize and store preformed cytotoxic proteins that are maintained in an inactive state in the cytotoxic granule by serglycin. Reactivation of the CTL by ligation of its T-cell receptor not only stimulates rapid release of preformed cytotoxins but also induces *de novo* synthesis of perforin and granzymes, so that the supply of cytotoxic granules is replenished as serial killing of targets proceeds. This makes it possible for a single CD8 T cell to kill a series of targets in rapid succession.

ANIMATION 9.10

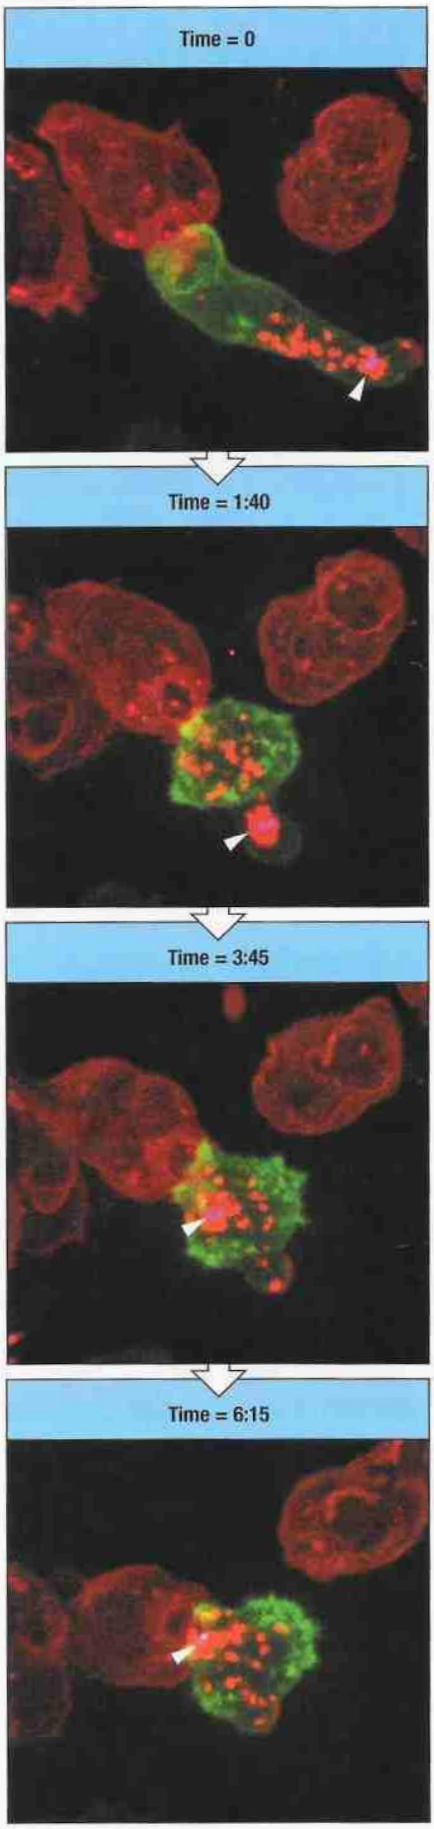

Fig. 9.49 Effector molecules are released from cytotoxic granules of a CTL in a highly polar fashion. The granules and centrosome of cytotoxic T cells (cytotoxic T lymphocytes; CTLs) can be labeled with fluorescent proteins, allowing their movements to be followed by time-lapse microscopy. Here is shown a series of pictures taken during the interaction of a CTL (green cell) with a target cell (red cell), which is eventually killed. In the top panel, at time 0, the CTL has just made contact with a target cell. At this time, the cytotoxic granules of the T cell (red dots) and the centrosome (small blue dots; arrowhead) trail the main body of the T cell and are distant from the point of contact. In the second panel, after 1 minute and 40 seconds have elapsed, the granules and centrosome have begun to move toward the target cell, a move that has nearly been completed in the fourth panel (time 6:15). After the granule contents have been released into the space between the T cell and the target, the target cell will undergo apoptosis (not shown). The T cell will then disengage from the target cell, whereupon it can go on to recognize and kill other targets.

9-24 Cytotoxic T cells also act by releasing cytokines.

Inducing apoptosis in target cells is the main way in which cytotoxic CD8 T cells eliminate infection. However, most cytotoxic CD8 T cells also release the cytokines IFN-γ, TNF-α, and LT-α, which contribute to host defense in other ways. IFN-γ inhibits viral replication directly and induces the increased expression of MHC class I molecules and other proteins that are involved in peptide loading of these newly synthesized MHC class I molecules in infected cells. This increases the chance that infected cells will be recognized as target cells for cytotoxic attack. IFN-γ also activates macrophages, which serve as both innate effector cells and as antigen-presenting cells, and stimulates the production of chemokines (for example, CXCL9, CXCL10, and CXCL11) that recruit additional macrophages and CD8 T cells to sites of infection. Finally, TNF-α and LT-α can induce apoptosis in target cells that express TNFR-I via the extrinsic pathway (see Sections 9-20 and 9-21), providing an alternative mechanism for killing of cells infected with pathogens that have the capability to subvert the perforin/granzyme mode of killing (see Chapter 13). Thus, cytotoxic effector CD8 T cells act in a variety of ways to limit the spread of cytosolic pathogens.

Summary.

Cytotoxic effector CD8 T cells are essential in host defense against many intracellular pathogens, most commonly, viruses. CTLs can kill any cell harboring such pathogens by recognizing foreign peptides that are transported to the cell surface bound to MHC class I molecules. Cytotoxic CD8 T cells perform their killing function by releasing three types of preformed cytotoxic proteins: granzymes, which use multiple mechanisms to induce apoptosis in any type of target cell; perforin, which acts in the delivery of granzymes into the target cell; and granulysin, which has antimicrobial activity and is pro-apoptotic. These properties allow the cytotoxic T cell to attack and destroy virtually any cell infected with a cytosolic pathogen. TNF family molecules, such as Fas and TNF-α, may also induce apoptosis on some target cells that express their receptors. However, this pathway is less important in most infections than that mediated by cytotoxic granules. Cytotoxic CD8 T cells also produce IFN-γ, which inhibits viral replication and is an important inducer of MHC class I molecule expression and macrophage activation. Cytotoxic T cells kill infected targets with remarkable precision, sparing adjacent normal cells. This precision is crucial in minimizing tissue damage while allowing the eradication of infected cells.

Summary to Chapter 9.

An adaptive immune response is initiated when naive T cells encounter specific antigen on the surface of an antigen-presenting cell in T-cell zones

of secondary lymphoid tissues. In most cases, the antigen-presenting cells responsible for activating naive T cells, and inducing their clonal expansion, are conventional dendritic cells that express the co-stimulatory molecules B7.1 and B7.2. Conventional dendritic cells not only reside in lymphoid tissues but also survey the periphery, where they encounter pathogens, take up antigen at sites of infection, become activated through innate recognition, and migrate to local lymphoid tissue. The dendritic cell may become a potent direct activator of naive T cells or it may transfer antigen to dendritic cells resident in secondary lymphoid organs that prime T cells. Plasmacytoid dendritic cells contribute to rapid responses against viruses by producing type I interferons. Activated T cells produce IL-2, which is important in modulating early proliferation and differentiation of T cells; various other signals drive the differentiation of several types of effector T cells, which primarily act by releasing mediators directly onto their target cells. This triggering of effector T cells by peptide:MHC complexes occurs independently of co-stimulation, so that any infected target cell can be activated or destroyed by an effector T cell. Cytotoxic CD8 T cells kill target cells infected with cytosolic pathogens, thus removing sites of pathogen replication. CD4 T cells can become specialized effectors that in turn promote distinct arms of the immune response by targeting different innate and adaptive immune cells for enhanced effector function: macrophages (T_H1); eosinophils, basophils, and mast cells (T_H2); neutrophils (T_H17); or B cells (T_{FH}). Thus, effector T cells control virtually all known effector mechanisms of the adaptive and innate immune responses. In addition, subsets of CD4 regulatory T cells help control and limit immune responses by suppressing T-cell activity.

Discussion Questions

9.1 Secondary lymphoid organs are specialized for the induction of adaptive immune responses. What cells and molecules are important for the development of lymph nodes? Describe the structural features of lymph nodes and the processes of recruitment and migration of T cells through this tissue.

9.2 Dendritic cells that reside in nonlymphoid tissues are key sentinel cells that bridge innate and adaptive immunity. Describe the different types of dendritic cells, their roles in the immune response, and how they become activated to initiate an immune response in lymphoid tissues.

9.3 Activation of a naive T cell requires interaction with a conventional dendritic cell (cDC). Which molecules on T cells are involved in this process, and which molecules do they interact with on the dendritic cell? What consequences would you expect if these molecules were deficient in an individual?

9.4 CD4 T cells can develop into several subsets of effector cells. Describe the known CD4 subsets and define their major immunological functions. Describe the role of dendritic cells and different types of pathogens in generating each subset. What are the key transcription factors that contribute to the development of each CD4 subset? What are the principal cytokines produced by each subset?

9.5 T_{FH} cells are uniquely specialized to provide help to B cells for T-dependent antibody responses. Describe the features of T_{FH} cells that equip them for this function.

9.6 Effector CD8 T cells (CTLs) kill infected targets via cell–cell contact. Describe the process by which CTLs induce target-cell death, including common and unique features of the induction of apoptotic cell death by the extrinsic versus intrinsic pathways. How do CTLs kill infected target cells but spare uninfected neighboring cells?

The Humoral Immune Response 10

Many pathogens multiply in the body's extracellular spaces, and even intracellular pathogens can spread by moving through the extracellular fluids. The extracellular spaces are protected by the adaptive **humoral immune response**, in which antibodies produced by B cells act to destroy extracellular microorganisms and their products and prevent the spread of intracellular infections. As we introduced in Section 1-20, antibodies contribute to immunity in three main ways: **neutralization**, **opsonization**, and **complement activation** (Fig. 10.1). Antibodies can bind to pathogens and prevent their entry into cells and therefore are said to neutralize the pathogen; antibodies may also bind bacterial toxins, preventing their action or ability to enter cells. Recall that there are different forms of antibodies, known as antibody **classes** or **isotypes**, which differ in their constant regions (C regions). Antibodies of some classes can facilitate the uptake of pathogens by phagocytes by binding to certain Fc receptors through their C regions. Other Fc receptors interact with the C regions of other antibody isotypes to mediate different effector functions, such as mast-cell degranulation. Finally, antibodies bound to pathogens can activate proteins of the classical pathway of the complement system, as we described in Chapter 2. This can opsonize the pathogen by placing other complement proteins onto the pathogen's surface, helping to recruit phagocytic cells to the site of infection and activating the membrane-attack complex, which can directly lyse certain microorganisms by forming pores in their membranes. The choice of which effector mechanisms are used is influenced by the heavy-chain isotype of the antibodies produced, which determines their class (see Section 4-6).

In the first part of this chapter, we describe the interactions of naive B cells with antigen and helper T cells that lead to the activation of B cells and antibody production. Some microbial antigens can provoke antibody production without T-cell help, but activation of naive B cells by antigens usually involves help from activated CD4 T cells, especially from T follicular helper (T_{FH}) cells (see Section 9-14). Some activated B cells then differentiate into antibody-secreting **plasma cells** and memory B cells. Most antibody responses undergo a process called affinity maturation, in which antibodies of greater affinity for their target antigen are produced by the somatic hypermutation of antibody variable-region (V-region) genes. We examine the molecular mechanism of somatic hypermutation and its immunological consequences, as well as class switching—a process that generates the different classes of antibodies that confer functional diversity on the antibody response. Both affinity maturation and class switching occur only in B cells and require T-cell help. In the second part of the chapter, we introduce the distributions and functions of various classes of antibody, in particular those secreted into mucosal sites. In the

B-cell activation by antigen and helper T cells.

The distributions and functions of immunoglobulin classes.

The destruction of antibody-coated pathogens via Fc receptors.

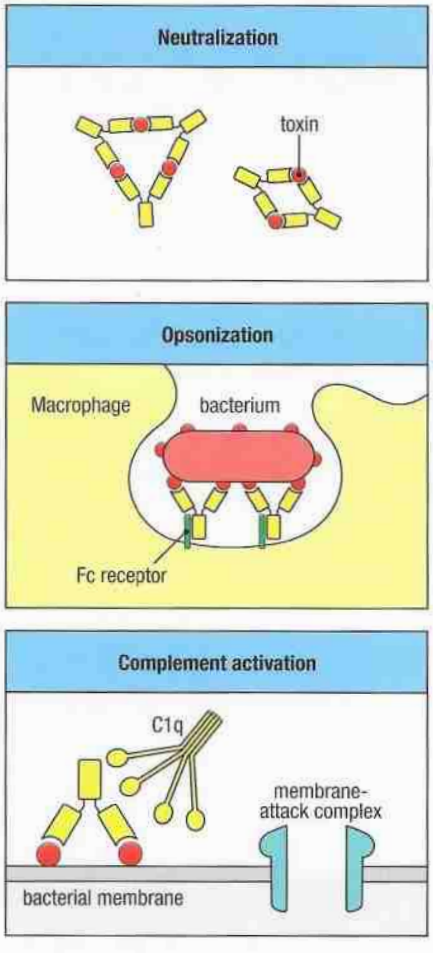

Fig. 10.1 Antibodies mediate the humoral immune response through neutralization, opsonization, and complement activation. After being secreted by plasma cells, antibodies protect the host from infection in three main ways. They can inhibit the toxic effects or infectivity of pathogens or their products by binding to them, a process called neutralization (top panel). When bound to pathogens, the antibody's Fc region can bind to Fc receptors on accessory cells, such as macrophages and neutrophils, helping these cells to ingest and kill the pathogen. This process is called opsonization (middle panel). Antibodies can trigger complement by activating C1, the first step in the classical complement pathway. Deposition of complement proteins enhances opsonization and can also directly kill certain bacterial cells by activating the membrane-attack complex (bottom panel).

third part of the chapter, we discuss in detail how the Fc region of the antibody engages various effector mechanisms to contain and eliminate infections. Like the T-cell response, the humoral immune response produces immunological memory, which is discussed in Chapter 11.

B-cell activation by antigen and helper T cells.

The surface immunoglobulin that serves as the **B-cell antigen receptor (BCR)** plays two roles in B-cell activation in response to pathogens. Like the antigen receptor on T cells, the BCR initiates a signaling cascade upon binding antigens derived from the microbe. In addition, the BCR can deliver the antigen to intracellular sites for antigen processing, generating antigenic peptides bound to MHC class II molecules that are returned to the B-cell surface. These peptide:MHC class II complexes are recognized by antigen-specific helper T cells that have already differentiated in response to the same pathogen. The effector T cells express surface molecules and cytokines that help the B cell to proliferate and to differentiate into antibody-secreting cells and into memory B cells. A structure called the germinal center (see Section 10-6) is formed during an intermediate phase of the antibody response, before the emergence of long-term plasma cells that generate antibody or of memory B cells.

Some microbial antigens can activate B cells directly in the absence of T-cell help, and the ability of B cells to respond directly to these antigens provides a rapid response to many important pathogens. However, the fine-tuning of antibody responses to increase the affinity of the antibody for the antigen and the switching to most immunoglobulin classes other than IgM depend on the interaction of antigen-stimulated B cells with helper T cells and other cells in the secondary (or peripheral) lymphoid organs. Thus, antibodies induced by microbial antigens alone tend to have lower affinity and to be less functionally versatile than those induced with T-cell help.

10-1 Activation of B cells by antigen involves signals from the B-cell receptor and either helper T cells or microbial antigens.

As we learned in Chapter 8, activation of naive T cells requires signals derived from the T-cell receptor as well as co-stimulatory signals provided by professional antigen-presenting cells. Similarly, in addition to signals derived from the B-cell receptor, naive B cells also require accessory signals that can arise either from a helper T cell or, in some cases, directly from microbial constituents (Fig. 10.2).

Protein antigens alone are unable to induce antibody responses in animals or humans who lack T cells, and they are therefore known as **thymus-dependent (TD) antigens** and typically require antigen-specific T-cell help. The T cells involved are CD4 T cells that reside in the lymphoid tissues and are not fully differentiated T_H1, T_H2, or T_H17 effector cells, can become T_{FH} cells (see Section 9-14), and can enter B-cell follicular regions and induce B cells to proliferate and secrete antibody in response to protein antigens. To receive T-cell help, the B cell must display antigen on its surface in a form that a T cell can recognize. This occurs when antigen bound by surface immunoglobulin on the B cell is internalized and degraded within the B cell and peptides derived from it are returned to the cell surface in a complex with MHC class II molecules (see Fig. 10.2, first panel). When the CD4 T cell recognizes these peptide:MHC complexes, it provides the B cell with signals that favor survival and induce proliferation. These signals include the activation of **CD40** on B cells by the T-cell–expressed ligand, **CD40L** (CD154),

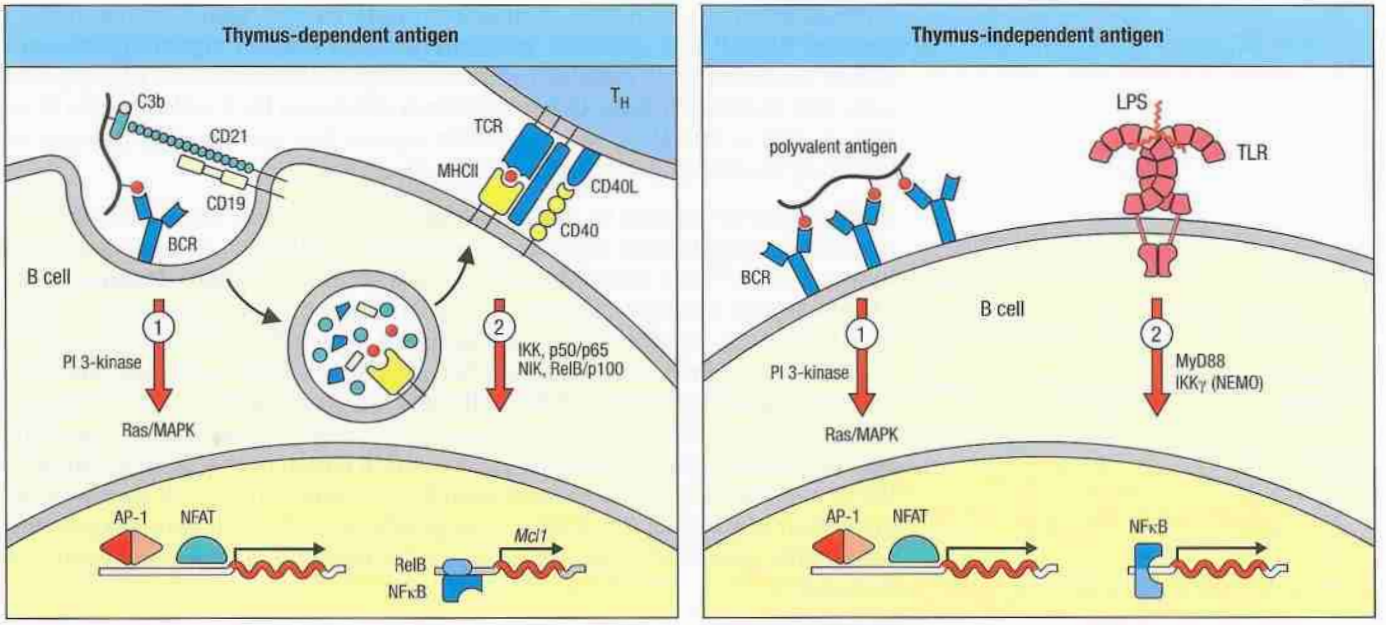

Fig. 10.2 A second signal is required for B-cell activation by either thymus-dependent or thymus-independent antigens. The first signal (indicated as '1') required for B-cell activation is delivered through its antigen receptor (BCR) and activates several pathways as described in Chapter 7. Signaling by the BCR is enhanced by the co-receptors CD21 and CD19, which interact with C3b on opsonized microbial surfaces. For thymus-dependent antigens (first panel), a second signal (indicated as '2') is delivered by a helper T cell (T_H) that recognizes degraded fragments of the antigen as peptides bound to MHC class II molecules on the B-cell surface. CD40L on the helper T cell binds to CD40 on the B cell, activating both the canonical NFκB signaling via IKK and the non-canonical NFκB signaling pathway via NFκB-inducing kinase (NIK). This induces expression of pro-survival genes such as *Mcl1* (myeloid cell leukemia-1). For thymus-independent antigens (second panel), a second signal can be delivered through Toll-like receptors that recognize antigen-associated TLR ligands, such as bacterial lipopolysaccharide (LPS) or bacterial DNA, as described in Chapter 3.

and production of various cytokines by T cells, including **IL-21** (Fig. 10.3). CD40 signaling can activate both the **canonical NFκB pathway** and the **non-canonical NFκB pathway** (see Section 7-24) and enhances B-cell survival by inducing the expression of anti-apoptotic molecules such as Mcl-1 (myeloid cell leukemia-1), a protein related to the Bcl-2 family, and B-cell

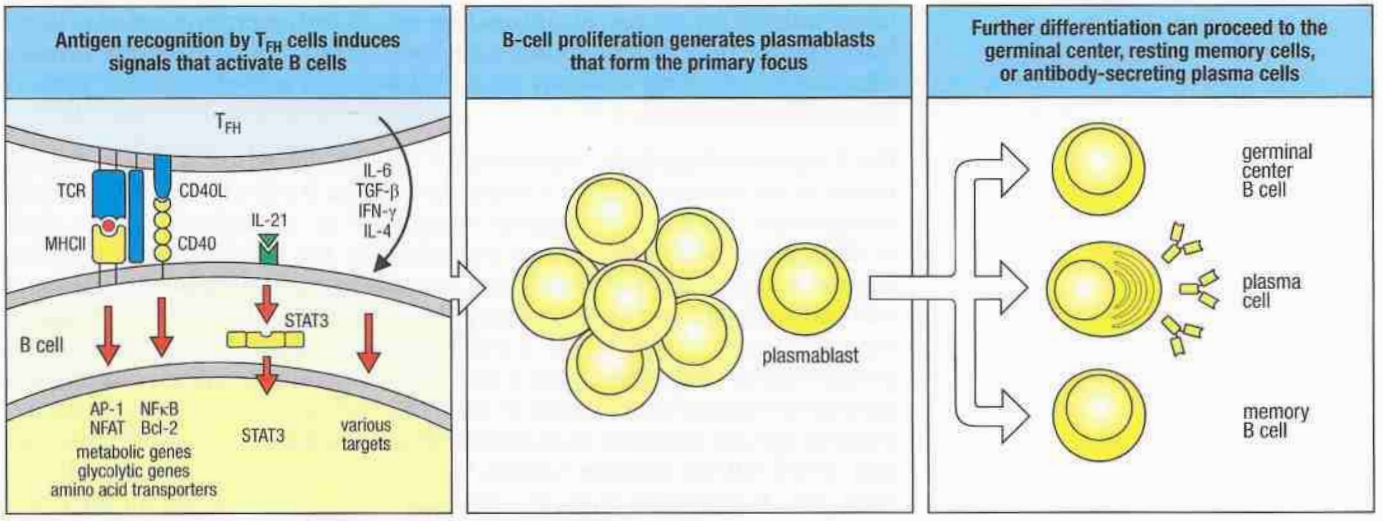

Fig. 10.3 CD4 T cells provide several signals that activate B cells and control their subsequent differentiation. After antigen binding to the B-cell receptor delivers the first signal for B-cell activation (not shown), the T_{FH} cell delivers additional signals when it recognizes a peptide:MHC class II complex on the B-cell surface (first panel). Besides expression of CD40 ligand, the T_{FH} cell secretes several important cytokines, including IL-21, which activates the transcription factor STAT3 to enhance B-cell proliferation and survival. T cells can also produce cytokines that will regulate isotype switching (see Section 10-12). After receiving these signals, activated B cells begin to proliferate (second panel), enter the germinal center, and eventually become plasma cells or memory B cells (third panel).

differentiation by inducing metabolic programs and transcription factors such as BLIMP that promote antibody secretion. IL-21 signaling activates STAT3 and enhances cellular proliferation and differentiation into plasma cells and memory B cells. Other cytokines produced by T cells include IL-6, TGF-β, IFN-γ, and IL-4, which provide signals that can regulate the type of antibody produced, as we will see in Section 10-12.

While B-cell responses to protein antigens rely on help from T cells, some microbial constituents can induce antibody production in the absence of helper T cells. These microbial antigens are known as **thymus-independent (TI) antigens** because they can induce antibody responses in individuals who have no T lymphocytes. Such antigens typically contain highly repetitive epitopes, such as the polysaccharides of bacterial cell walls, and can activate signaling by the BCR on B cells. In such cases, a second signal can be derived from direct recognition of a common microbial constituent, such as lipopolysaccharide (LPS), which can activate TLR signaling in the B cell (see Fig. 10.2, second panel), activating the NFκB pathway, as described in Chapter 3. Thymus-independent antibody responses provide some early protection against extracellular bacteria, and we will return to them later.

10-2 Linked recognition of antigen by T cells and B cells promotes robust antibody responses.

B-cell activation by antigens on microbial surfaces can be greatly stimulated by the concurrent deposition of complement on these pathogens. The **B-cell co-receptor complex** contains the cell-surface proteins CD19, CD21, and CD81 (see Fig. 7.29). When **CD21**, or complement receptor 2 (CR2), binds to the complement fragments C3d and C3dg that are deposited on microbial surfaces (see Section 2-13), it is brought near to the activated B-cell receptor bound to the same surface. CD21 and CD19 are associated with each other, and CD19 becomes phosphorylated by a complex of proteins associated with the activated B-cell receptor. This recruits phosphatidylinositol 3-kinase (PI 3-kinase), which cooperates with the BCR to stimulate several downstream pathways, enhancing proliferation, differentiation, and antibody production (see Fig. 10.2, arrow 1). This effect is shown when mice are immunized with the experimental antigen hen egg-white lysozyme coupled to three linked molecules of C3dg. In this case, less C3dg-modified lysozyme is more effective in inducing antibody in the absence of added adjuvant than is unmodified lysozyme.

For T-dependent antibody responses, the T cells involved are activated by fragments of the same antigen as is recognized by the B cells; this is called **linked recognition**. However, the peptide recognized by the helper T cell is likely to differ from the protein epitope recognized by the B cell's antigen receptor. Natural antigens, such as viruses and bacteria, contain multiple proteins and carry both protein and carbohydrate epitopes. For linked recognition to occur, the peptide recognized by the T cell must be physically associated with the antigen recognized by the B cell's receptor, so that the B cell can take up and present the appropriate peptide to the T cell. For example, a B cell that recognizes an epitope on a viral coat protein will internalize the complete virus particle. The B cell can degrade multiple viral proteins into peptides for display on MHC class II molecules on the B-cell surface. CD4 T cells specific for such viral peptides may have been activated by dendritic cells earlier in the infection. Some of these can become T_{FH} cells and express CXCR5, which allows them to enter the same regions where B cells reside (discussed later). When these activated T_{FH} cells encounter their cognate peptide presented on B cells, the T cells in turn provide specific signals that help B cells to generate antibodies against the viral coat protein (Fig. 10.4).

Fig. 10.4 T cells and B cells that recognize antigens contained within the same molecular complex can engage productively. In this example, an internal viral protein harbors a peptide epitope (shown as red) that is presented by MHC class II molecules and is recognized by a CD4 T cell. The virus also harbors a native epitope on an external viral coat protein (shown as blue) that is recognized by the surface immunoglobulin on a B cell. If the virus is captured and presented by a dendritic cell, a peptide-specific CD4 T cell (blue) becomes activated (top left panel), whereas nonspecific T cells (green) remain inactive. If the virus is recognized by a specific B cell (top right panel), peptides derived from internal viral proteins are processed and presented by MHC class II molecules. When the activated T cell recognizes its peptide on this B cell (bottom panel), the T cell will deliver various accessory signals to the B cell that promote antibody production against the coat protein. This process is known as linked recognition.

Linked recognition relies on the concentration of the appropriate peptide for presentation by MHC class II molecules on the B-cell surface. B cells whose B-cell receptor binds a particular antigen are 10,000 times more efficient at displaying peptide fragments of that antigen on their MHC class II molecules than are B cells that have B-cell receptors of irrelevant specificities. Linked recognition was originally discovered through studies of the production of antibodies against haptens, which are small chemical groups that cannot elicit antibody responses on their own (see Appendix I, Section A-1). But haptens that are coupled to a carrier protein become immunogenic—known as the **hapten carrier effect**—for two reasons. The protein can carry multiple hapten groups, allowing it to cross-link B-cell receptors. T cells that are activated against peptides of the carrier protein and which became T_{FH} cells have also taken part in the germinal center reaction to strengthen the antibody response to the hapten. Accidental coupling of a hapten to a protein is responsible for the allergic responses shown by many people to the antibiotic penicillin, which reacts with host proteins to form a coupled hapten that can stimulate an antibody response, as we will learn in Chapter 14. Vaccine design can take advantage of linked recognition, as in the vaccine used to immunize infants against *Haemophilus influenzae* type b (see Section 16-7).

10-3 B cells that encounter their antigens migrate toward the boundaries between B-cell and T-cell areas in secondary lymphoid tissues.

The frequency of naive B cells specific for most protein antigens is extremely low (less than 1 in 10,000). The frequency can be higher for some conserved carbohydrate or phospholipid antigens, such as galactose-α-1,3-galactose (α-Gal), which may react with up to 0.2% of all peripheral B cells in humans. Nonetheless, the chance of a random encounter between a T and a B cell with the same antigen specificity should be less than 1 in 10^8, making it remarkable that B cells ever interact with T_H cells with similar antigen specificity. For these reasons, linked recognition requires a precise regulation of the migration

Fig. 10.5 Antigen-binding B cells meet T cells at the border between the T-cell area and a B-cell follicle in secondary lymphoid tissues. Antigens enter the spleen from the blood and collect in T-cell zones and follicles (top panel). Naive CCR7-positive T cells and CXCR5-positive B cells migrate to distinct regions where the chemokines CCL19 and CCL21 or CXCL13 and the EBI2 ligand 7α,25-dihydroxycholesterol (7α,25-HC), respectively, are being produced (first lower panel). If a B cell encounters its antigen, either on a follicular dendritic cell (FDC) or a macrophage, it induces expression of CCR7 and of EBI2 (the latter increasing its responsiveness to EBI2 ligands) and migrates toward the border with the T-cell zone (second lower panel). T cells activated by antigen-presenting dendritic cells induce expression of CXCR5 and EBI2 and migrate to this same border, where linked recognition induces further B-cell proliferation. After 2–3 days, some B cells reduce expression of CCR7 but retain EBI2 and migrate in response to 7α,25-HC to the outer follicle (third lower panel). After another day or so, some of the proliferating B cells in the interfollicular regions near the red pulp differentiate into plasmablasts, forming a focus of terminal antibody-secreting cells (fourth lower panel). T cells that induce expression of Bcl-6 become T_{FH} cells that participate with B cells there to form a germinal center reaction.

of activated B and T cells—orchestrated by several sets of ligands and receptors—into specific locations within the lymphoid tissues, which serves to increase the chances of a productive interaction (Fig. 10.5).

Naive T cells and B cells express the **sphingosine 1-phosphate receptor 1 (S1PR1)**, which they use to egress from the secondary lymphoid tissues (see Section 9-5). However, before they exit, they initially occupy and are retained in two distinct zones, the **T-cell areas** and the **primary lymphoid follicles** (or B-cell areas or B-cell zones), respectively. These zones are established by different patterns of chemokine receptor expression and chemokine production. Naive T cells express the chemokine receptor **CCR7** and localize to zones where its ligands, **CCL19** and **CCL21**, are highly expressed by stromal cells and dendritic cells (see Section 9-3). Circulating naive B cells express **CXCR5**, and when they migrate into lymphoid tissues, they enter the primary lymphoid follicles, where the chemokine **CXCL13** is abundant. Within the follicle, stromal cells and a specialized cell type, the **follicular dendritic cell (FDC)**, secrete CXCL13. The FDC is a nonphagocytic cell of non-hematopoietic origin that bears numerous long processes; it functions by trapping antigen using Fc receptors and complement receptors on its cell surface for access by B cells in the follicle.

Once in the follicle, naive B cells encounter the soluble TNF-family cytokine **BAFF** (see Section 8-9), which is secreted by FDCs, stromal cells, dendritic cells, monocytes, and T_{FH} cells and which acts as a survival factor for B cells. BAFF can act through three receptors, but its major actions in promoting survival are through **BAFF-R** (Fig. 10.6). BAFF-R signals through **TRAF3** (see Section 3-7) to activate the non-canonical NFκB pathway and induces expression of Bcl-X_L, an anti-apoptotic member of the Bcl-2 family. Two other receptors for BAFF are **TACI** and **BCMA**, which signal through TRAF2, TRAF5, and TRAF6 to induce signaling pathways

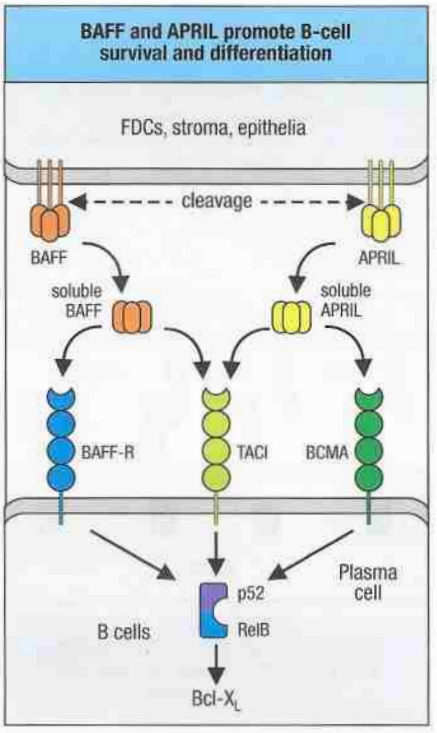

Fig. 10.6 BAFF and APRIL promote B-cell survival and regulate differentiation. BAFF (B-cell activating factor, also called B-lymphocyte stimulator, or BLyS) and APRIL (a proliferation-inducing ligand) are both members of the TNF superfamily of cytokines. They are initially produced as membrane-bound trimers by several cell types. BAFF is produced by FDCs and other cells in the B-cell follicle, where it supports B-cell survival. Its main receptor, BAFF-R, signals through TRAF3 and NIK to activate the non-canonical NFκB pathway, leading to the RelB:p52 transcription factor and inducing expression of Bcl-X_L, a protein similar in function to Bcl-2 described in Section 9-21. BAFF also binds to the receptors TACI (transmembrane activator and calcium modulator and cyclophilin ligand interactor) and BCMA (B-cell maturation antigen), although its affinity for BCMA is relatively weak. Naive and recently activated B cells express only BAFF-R and TACI, while BCMA is expressed by plasma cells. These receptors also activate the non-canonical NFκB pathway.

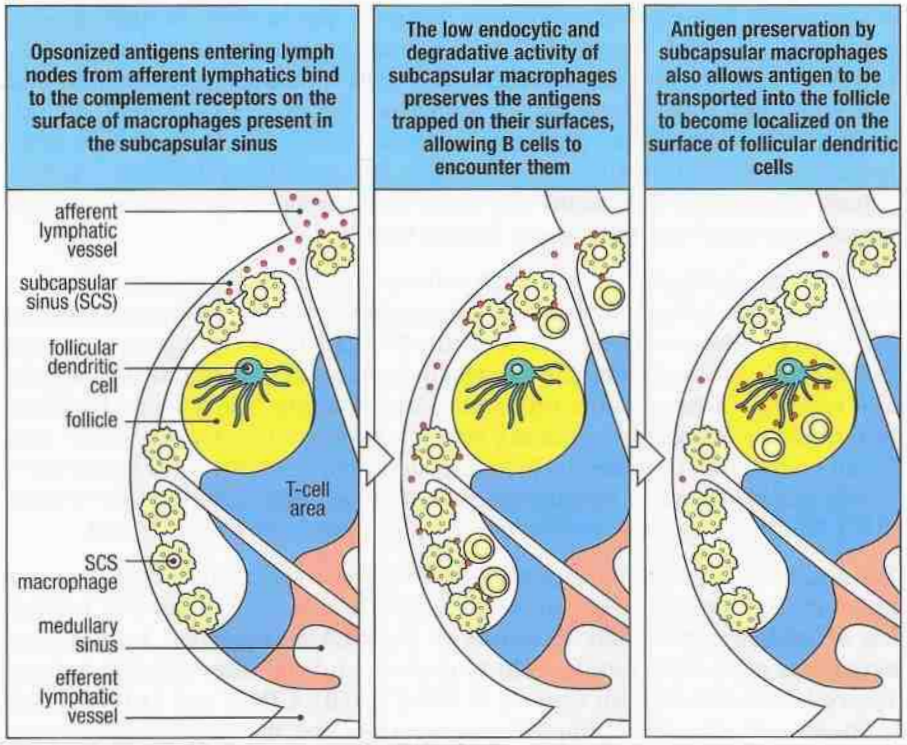
involved in B-cell activation. TACI is highly expressed on follicular and germinal center B cells, but BCMA is expressed by plasma cells and has a relatively low affinity for BAFF. TACI and BCMA also bind the related cytokine **APRIL**, a survival factor for plasma cells.

Antigens derived from microorganisms and viruses are transported into lymph nodes via the afferent lymph and into the spleen via the blood. Opsonized antigens bearing C3b or C3dg accumulate in the B-cell follicles because they are trapped by complement receptors CR1 and CR2 expressed on the surface of FDCs. While small soluble antigens may diffuse directly into the follicle, opsonized particulate antigens can also be taken up by specialized macrophages residing in the **subcapsular sinus** (SCS) of lymph nodes and the **marginal sinus** of the spleen, regions that are both adjacent to the B-cell follicles (Fig. 10.7). These macrophages seem to retain the antigen on their surface rather than ingesting and degrading it. These antigens can then be sampled and carried by antigen-specific follicular B cells. B cells of any antigen specificity could also acquire antigen from these macrophages via their complement receptors and transport it within the follicle. In the spleen, marginal zone B cells shuttle between that site and the follicle, carrying antigen trapped in the marginal zone for deposition on FDCs. SCS macrophages can also actively function to restrict the dissemination of infection. For example, in mice, infection of these macrophages in lymph nodes by vesicular stomatitis virus (VSV), a relative of rabies virus, triggers the cells to produce interferon and to recruit



Opsonized antigens entering lymph nodes from afferent lymphatics bind to the complement receptors on the surface of macrophages present in the subcapsular sinus

Fig. 10.7 Opsonized antigens are captured and preserved by subcapsular sinus macrophages. Macrophages residing in the lymph node subcapsular sinus (SCS) express complement receptors 1 and 2 (CR1 and CR2, respectively), are poorly endocytic, and have reduced levels of lysosomal enzymes compared with macrophages in the medulla. Opsonized antigen arriving from the afferent lymphatics binds to CR1 and CR2 on the surface of SCS macrophages. Instead of being completely degraded by these macrophages, some antigen is retained on the cell surface, where it can be presented and transferred to the surface of follicular B cells. B cells are then able to transport the antigen into the follicle, where it can be trapped on the surfaces of follicular dendritic cells.

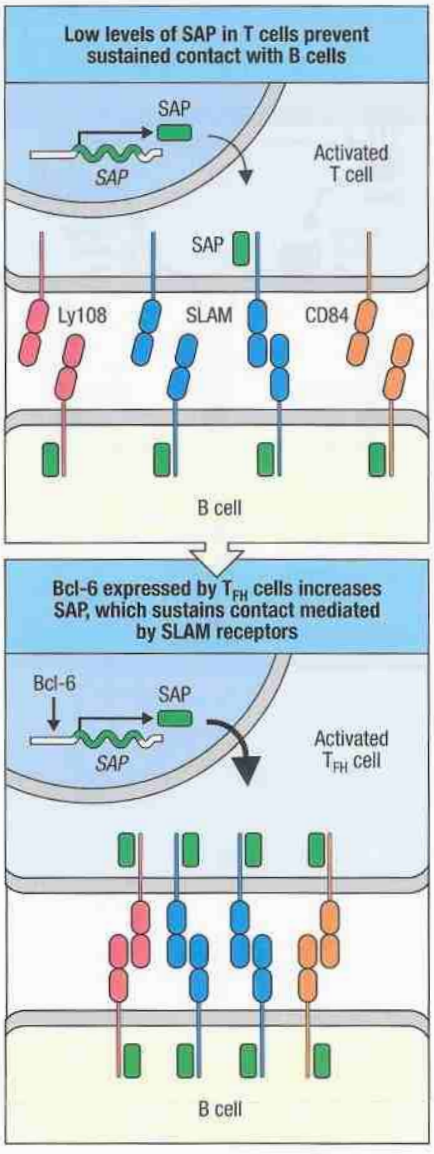

Fig. 10.8 Induction of SAP in T_{FH} cells allows SLAM family receptors to mediate sustained contact with B cells. The SLAM receptor family members SLAM, Ly108, and CD84 are expressed on T cells and B cells and mediate homotypic interactions that lead to adhesion between cells. SLAM can also enhance signaling by the T-cell receptor to augment production of cytokines such as IL-21 that help B cells. The SLAM-associated molecule SAP is a signaling adaptor that is required for one SLAM receptor to sustain binding with another. T cells initially express SAP at low levels that are insufficient for sustained adhesion between T and B cells. Fully differentiated T_{FH} cells express high levels of the transcription factor Bcl-6, which increases SAP expression to a level sufficient to sustain cell–cell interactions and allow for the delivery of CD40L and cytokine signals to B cells.

plasmacytoid dendritic cells (pDCs). Type I interferon produced by pDCs restricts further viral spread, which would otherwise eventually pass on to the central nervous system.

After a naive follicular B cell first encounters specific antigen, either soluble antigen or displayed by FDCs or macrophages, within a few hours it will become positioned in the outer follicles of lymphoid tissue close to the sites where antigen enters the lymph node or spleen. This positioning is orchestrated by the B cell's expression of a chemoattractant receptor, **EBI2** (GPR183), whose ligands are oxysterols such as 7α,25-dihydroxycholesterol. Non-hematopoietic reticular cells in the outer follicular and interfollicular regions are the primary sources of these ligands. After sampling antigens there for 6 hours to 1 day, the B cell induces expression of CCR7, which functions together with EBI2 to distribute activated B cells along the interface between the B-cell follicle and the T-cell zone, where CCL21 is expressed.

During an immune response, T cells are activated within the T-cell zones by dendritic cells. When naive T cells are activated, some will proliferate, differentiate into effector cells, up-regulate expression of S1PR1, and exit the lymphoid tissue. However, others will up-regulate CXCR5 and migrate to the border with the B-cell follicle. There, T cells can encounter B cells activated during the same response, increasing the chance that they might recognize linked antigens presented by activated B cells that have recently moved to this location (see Fig. 10.5).

10-4 T cells express surface molecules and cytokines that activate B cells, which in turn promote T_{FH} cell development.

When a CD4 T cell encounters an activating peptide presented by B cells, it responds by expressing receptors and cytokines that in turn activate B cells. As mentioned earlier, the CD40L expressed by CD4 T cells activates CD40 on B cells to increase B-cell survival and also induces B-cell expression of co-stimulatory molecules, especially those of the B7 family. CD40L expressed by CD4 T cells provides a general help for B cells, and in human CD40L deficiency, there is loss of all switched Ig isotypes. T cells also secrete several cytokines that regulate B-cell proliferation and antibody production. Primary among these is IL-21, which is produced early in immune responses and which activates the transcription factor **STAT3** in B cells to support proliferation and differentiation. IL-21 exerts similar autocrine effects on CD4 T cells, including T_{FH} cells. Later in the antibody response, the T cells will produce other cytokines, such as IL-4 and IFN-γ, that are characteristic of the other T helper subsets (described in Chapter 9). These will impact B-cell differentiation, particularly class switching, as we discuss later.

This first interaction between T and B cells not only provides important help to B cells but also influences T-cell differentiation by means of signals provided by the B cell. The co-stimulatory molecule B7.2 (CD86) is up-regulated during B-cell activation and stimulates T cells by ligation of CD28. Activated B cells also express **ICOSL**, another member of the B7 family and a ligand for **ICOS** (inducible co-stimulatory protein), which is expressed by T cells. This T- and B-cell interaction, provided by linked recognition, activates ICOS signaling in T cells and is important for the completion of T_{FH} differentiation (see Section 9-15), leading to induction of the transcription factors **Bcl-6** and **c-Maf**.

The ability of T_{FH} cells to successfully deliver these signals to B cells depends on intimate contact between these cells. Specific adhesion molecules, including several Ig superfamily receptors of the **SLAM (signaling lymphocyte activation molecule)** family, help to prolong and stabilize cell–cell contact. T_{FH} cells and B cells both express SLAM (CD150), **CD84**, and **Ly108**, which promote cell adhesion through homotypic binding interactions (Fig. 10.8).

The cytoplasmic regions of these SLAM family receptors all interact with an adaptor protein, **SAP (SLAM-associated protein)**, which becomes highly expressed by T_{FH} cells and which is necessary for prolonging cell–cell contact mediated by these receptors. The transcription factors Bcl-6 and c-Maf characteristic of T_{FH} cells are also required for SAP expression and so help sustain the contact between B and T_{FH} cells. The SAP gene is inactivated in **X-linked lymphoproliferative (XLP) syndrome**, which is associated with a T-cell and NK-cell lymphoproliferative disorder and with a defect in antibody production due to failed interactions between T_{FH} cells and B cells in the germinal center, discussed later. In contrast to CD40L deficiency, in XLP syndrome there is often hypergammaglobulinemia and hyper-IgE.

X-linked Lymphoproliferative Syndrome

The regulated migration of activated B cells and T_{FH} cells to the same location in the secondary lymphoid organ increases the chance that linked recognition will occur and deliver appropriate help for B-cell differentiation. B cells stimulated chronically with antigen that fail to interact with a T_{FH} cell within 1–2 days will become anergic and exhibit a shorter life span (~5 days) compared with naive B cells (~40 days). B cells that are transiently exposed to antigen can return to the naive state in the absence of T cell help.

10-5 Some activated B cells differentiate into antibody-secreting plasmablasts and plasma cells.

After their initial activation by antigen, B cells migrate to the boundary of the follicle where they interact with helper T cells. B cells that have received T-cell help migrate from the follicle border to continue to proliferate and differentiate. Two to three days after activation, B cells begin to decrease expression of CCR7 and retain expression of EBI2 (see Fig. 10.5). Decreased expression of CCR7 causes B cells to move away from the boundary with the T-cell zone: EBI2 directs their migration back to the interfollicular regions and the subcapsular sinus in the lymph nodes, or, in the spleen, to the splenic bridging channels, a region between the T-cell area and the red pulp. Here, some B cells will form an emerging aggregate of differentiating B cells, which in lymph nodes is located in the medullary cords, where lymph drains out of the node. In the spleen, this can be seen as extrafollicular foci in the splenic red pulp, which are called **primary foci**. Primary foci are apparent by about 5 days after an infection or immunization with an antigen not previously encountered.

B cells proliferate for several days, and this constitutes the first phase of the primary humoral immune response. Some of these proliferating B cells differentiate into antibody-synthesizing **plasmablasts** in the primary focus. Not all B cells activated by the initial interaction with CD4 T_H cells will move into the primary focus. Some will migrate into the lymphoid follicle as described later. Plasmablasts are cells that have begun to secrete antibody, yet are still dividing and express many of the characteristics of activated B cells that allow their interaction with T cells. After a few more days, the plasmablasts in the primary focus stop dividing and may eventually die. Subsequently, plasmablasts or B cells arising from the germinal centers can migrate to the bone marrow and become long-lived plasma cells, where they continue antibody production. Many long-lived plasma cells are generated long after the primary focus has dissipated, suggesting that they arise from B cells that entered the germinal center reaction.

The properties of resting B cells, plasmablasts, and plasma cells are compared in Fig. 10.9. The differentiation of a B cell into a plasma cell is accompanied by many morphological changes reflecting the commitment of a plasma cell to the secretion of large amounts of antibody (several thousand antibody molecules per second), which can constitute up to 20% of all the protein synthesized by a plasma cell. Plasmablasts and plasma cells have a prominent perinuclear Golgi apparatus and an extensive rough endoplasmic reticulum that is

	Intrinsic properties			Inducible by antigen stimulation		
B-lineage cell	**Surface Ig**	**Surface MHC class II**	**High-rate Ig secretion**	**Growth**	**Somatic hyper-mutation**	**Class switch**

Plasmablast	High	Yes	Yes	Yes	Unknown	Yes
Plasma cell	IgA, IgE: High IgG: Low	Yes	Yes	No	No	No

Fig. 10.9 Plasma cells secrete antibody at a high rate but can no longer respond to antigen. Resting naive B cells have membrane-bound immunoglobulin (usually IgM and IgD) and MHC class II molecules on their surface. Although their V genes do not carry somatic mutations, B cells can take up antigen and present it to helper T cells. The T cells in return induce the B cells to proliferate and to undergo isotype switching and somatic hypermutation, but B cells do not secrete significant amounts of antibody during this period. Plasmablasts have an intermediate phenotype. They secrete antibody but retain substantial surface immunoglobulin and MHC class II molecules and so can continue to take up and present antigen to T cells. Plasmablasts early in the immune response and those activated by T-independent antigens have usually not undergone somatic hypermutation and class switching, and therefore secrete IgM. Plasma cells are terminally differentiated cells that secrete antibodies. Plasma cells have low levels of surface immunoglobulin but can express MHC class II molecules and may suppress T_{FH} activity in a negative feedback pathway while differentiating. Early in the immune response, they differentiate from unswitched activated B cells and secrete IgM; later in the response, they derive from activated B cells that entered the germinal center reaction and underwent class switching and somatic hypermutation. Plasma cells have lost the ability to change the class of their antibody or undergo further somatic hypermutation.

rich in immunoglobulin molecules that are being synthesized and exported into the lumen of the endoplasmic reticulum for secretion. Plasmablasts still express B7 co-stimulatory molecules B7.1 and B7.2 and MHC class II molecules; by contrast, plasma cells will eventually turn down the expression of MHC class II molecules. Nevertheless, T cells still provide important signals for plasma-cell differentiation and survival, such as IL-6 and CD40 ligand. While some plasma cells survive for only days to a few weeks after their final differentiation, others are very long lived and account for the persistence of antibody responses.

10-6 The second phase of a primary B-cell immune response occurs when activated B cells migrate into follicles and proliferate to form germinal centers.

Some activated B cells move into a primary lymphoid follicle together with their associated T_{FH} cells (Fig. 10.10), where they continue to proliferate and ultimately form a **germinal center**; follicles with germinal centers are also called **secondary lymphoid follicles**. Down-regulating EBI2 by B cells appears to favor germinal center formation. In mice lacking EBI2 expression in B cells, antigen-activated B cells failed to move to the border with the T-cell zone and remained near the follicular center. These mice were able to form germinal centers but generated fewer plasmablasts.

Germinal centers are composed mainly of proliferating B cells, but antigen-specific T cells make up about 10% of germinal center lymphocytes and

Fig. 10.10 Activated B cells form germinal centers in lymphoid follicles. Activation of B cells in a lymph node is shown here. Top panel: Naive circulating B cells enter lymph nodes from the blood via high endothelial venules (HEVs) and are attracted by chemokines into the primary lymphoid follicle; if these B cells do not encounter antigen in the follicle, they leave via the efferent lymphatic vessel. Second panel: B cells that have bound antigen move to the border with the T-cell area, where they may encounter activated helper T cells specific for the same antigen; these T cells interact with the B cells and activate them to begin proliferating and encourage some of them to differentiate into plasmablasts. Some B cells activated at the T-cell–B-cell border migrate as antibody-secreting plasmablasts to form extrafollicular foci in the red pulp (spleen) or an initial aggregate in the medullary cords (lymph nodes). Other B cells move back into the interior of the follicle, where they continue to proliferate and form a germinal center. Germinal centers are sites of sustained B-cell proliferation and differentiation and affinity maturation. Follicles in which germinal centers have formed are known as secondary follicles. Within the germinal center, B cells begin their differentiation into either long-lived plasma cells or memory B cells. Third and fourth panels: Plasma cells leave the germinal center and migrate to the medullary cords, where they are short-lived and persist for only a few days, or leave the lymph node altogether via the efferent lymphatics and migrate to the bone marrow, where they can persist for many months to years.

provide indispensable help to the B cells. The germinal center is an area of active cell division that forms within a surrounding region of resting B cells in the primary follicle. Proliferating germinal center B cells displace the resting B cells toward the periphery of the follicle, forming a **mantle zone** of resting cells around the two distinguishable areas of activated B cells, called the **light zone** and the **dark zone** (Fig. 10.11, left panel). The germinal center grows in size as the immune response proceeds, and then shrinks and finally disappears when the infection is cleared. Germinal centers are present for about 3–4 weeks after initial antigen exposure to proteins, and often for much longer when induced by live infections such as influenza viruses.

The primary focus and the germinal center reaction differ in the quality of antibody that they produce. Plasmablasts, germinal center B cells, and early memory B cells begin to emerge during the first 4–5 days of an immune response. Plasmablasts in primary foci primarily can secrete antibodies of

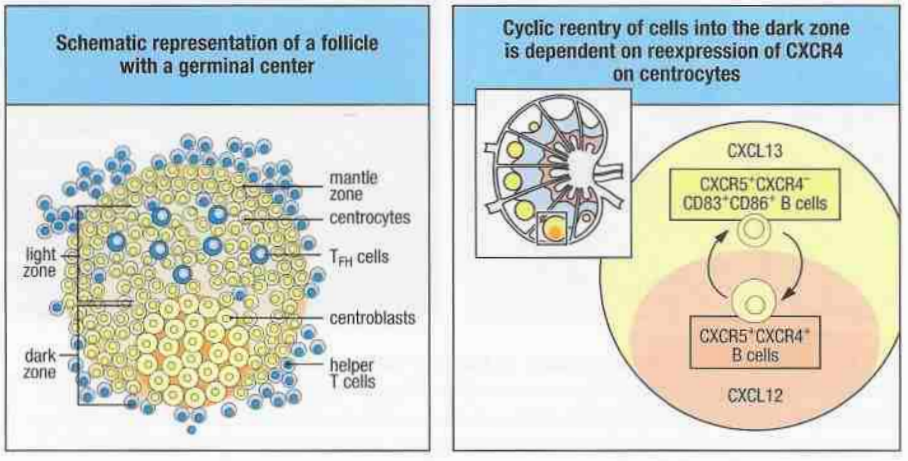

Fig. 10.11 The structure of a germinal center. The germinal center is a specialized microenvironment in which B-cell proliferation, somatic hypermutation, and selection for strength of antigen binding all occur. Closely packed centroblasts, which express CD83, CD86, CXCR4, and CXCR5, form the dark zone of the germinal center; the less densely packed light zone contains centrocytes, which express only CXCR5. Stromal cells in the dark zone produce CXCL12, which attracts the CXCR4-expressing centroblasts. Cyclic reentry describes the process by which B cells can lose and gain expression of CXCR4 and thus move from the light zone to the dark zone and back again.

the IgM isotype but can also undergo class switching to produce other isotypes independently of the germinal center reaction, which may offer some immediate protection. Recent evidence suggests that most class switching occurs before entry of B cells into the germinal center reaction. In contrast, B cells in the germinal center reaction undergo several processes that produce antibodies that are more effective in eliminating infections facilitated by their higher levels of Bcl-6 expression. These processes include **somatic hypermutation**, which alters the V regions of immunoglobulin genes (discussed shortly) and enables a process called **affinity maturation**, which selects for the survival of mutated B cells that have a high affinity for the antigen. In addition, class switching allows the selected B cells to produce antibodies with a variety of effector functions. These B cells will differentiate either into plasma cells that secrete higher-affinity and class-switched antibody in the latter part of the primary immune response or into memory B cells as described in Chapter 11. We will discuss mechanisms of class switching after a description of the germinal center reaction, even though Ig class switching can occur outside the germinal center and may occur even in TI responses.

B cells in the germinal center divide rapidly, every 6–8 hours. Initially, these rapidly proliferating B cells, called **centroblasts**, express the chemokine receptors CXCR4 and CXCR5 but markedly reduce their expression of surface immunoglobulin, particularly of IgD. Centroblasts proliferate primarily in the dark zone of the germinal center, named for its densely packed appearance in hematoxylin and eosin (H&E)-stained microscopic tissue sections (Fig. 10.12). Stromal cells in the dark zone produce **CXCL12 (SDF-1)**, a ligand for CXCR4 that acts to retain centroblasts in this region. As time goes on, some centroblasts reduce their rate of cell division, reduce CXCR4 expression, and begin

Fig. 10.12 Germinal centers are sites of intense cell proliferation and cell death. The photomicrograph (first panel) shows a section through a human tonsillar germinal center. Centroblasts, seen in the lower part of this photomicrograph, form the so-called dark zone of the germinal center. Above this region is the light zone, which appears lighter in H&E-stained micrographs in part due to the presence of the highly networked dendritic extensions of FDCs. The second panel shows immunofluorescent staining of a germinal center. B cells are found in the dark zone, light zone, and mantle zone. Proliferating cells are stained green for Ki67, an antigen expressed in nuclei of dividing cells, revealing the rapidly proliferating centroblasts in the dark zone. The dense network of follicular dendritic cells, stained red, mainly occupies the light zone. Centrocytes in the light zone proliferate to a lesser degree than centroblasts. Small recirculating B cells occupy the mantle zone at the edge of the B-cell follicle. Large masses of CD4 T cells, stained blue, can be seen in the T-cell zones, which separate the follicles. There are also significant numbers of T cells in the light zone of the germinal center.

to produce higher levels of surface immunoglobulin. These B cells are termed **centrocytes**. The loss of CXCR4 allows centrocytes to move into the light zone, containing abundant FDCs that produce the chemokine CXCL13 (BLC), a ligand for CXCR5 (see Fig. 10.11, right panel).

10-7 Germinal center B cells undergo V-region somatic hypermutation, and cells with mutations that improve affinity for antigen are selected.

Somatic hypermutation introduces mutations that change anywhere from one to a few amino acids in the immunoglobulin, producing closely related B-cell clones that differ in their affinity for antigen (Fig. 10.13). These mutations in the V genes are initiated by an enzyme called **activation-induced cytidine deaminase,** or **AID**, which is expressed by B cells in the extrafollicular foci and germinal centers. Before describing the enzymatic mechanisms initiated by AID, we first present a general overview of this process in which random mutations can improve antibody affinity.

The immunoglobulin V-region genes accumulate mutations at a rate of about one base pair change per 10^3 base pairs per cell division, while the rate of mutations in the rest of the cell's DNA is much lower: around one base pair change per 10^{10} base pairs per cell division. Somatic hypermutation also affects some DNA flanking the rearranged V gene but does not generally extend into the C-region exons. Because each V region (for both the heavy and light chain) is encoded by about 360 base pairs and about three out of every four base changes will alter the amino acid encoded, there is about a 50% chance during each B-cell division that a mutation will occur to the receptor.

The point mutations accumulate in a stepwise manner as the descendants of each B cell proliferate in the germinal center to form B-cell clones (Fig. 10.14). An altered receptor can affect the ability of a B cell to bind antigen and thus will affect the fate of the B cell in the germinal center. Most mutations have a negative impact on the ability of the B-cell receptor to bind the original antigen by preventing the correct folding of the immunoglobulin molecule or by blocking the complementarity-determining regions from binding antigen. Detrimental

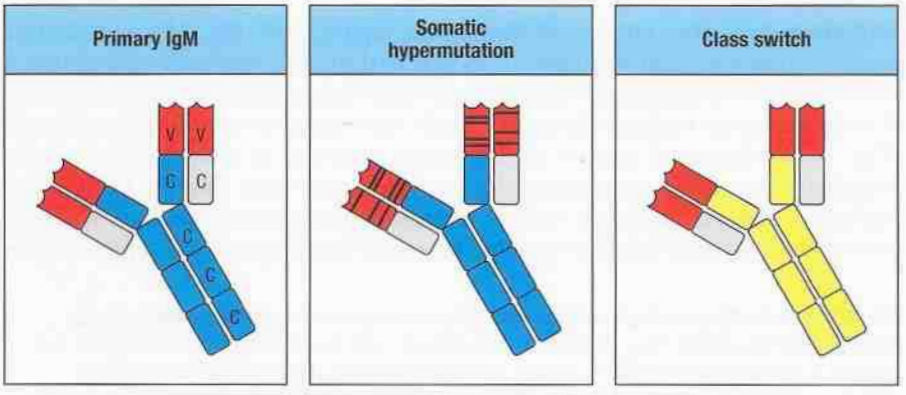

Fig. 10.13 The primary antibody repertoire is diversified by processes that modify the rearranged immunoglobulin gene. First panel: The primary antibody repertoire is initially composed of IgM-containing variable regions (red) produced by V(D)J recombination and constant regions (blue) from the μ gene segment. The range of reactivity of this primary repertoire can be further modified by somatic hypermutation, by class switch recombination at the immunoglobulin loci, and in some species by gene conversion (not shown). Second panel: Somatic hypermutation results in mutations (shown as blue lines) being introduced into the heavy-chain and light-chain V regions (red), altering the affinity of the antibody for its antigen. Third panel: In class switch recombination, the initial μ heavy-chain C regions (blue in first two panels) are replaced by heavy-chain regions of another isotype (shown as yellow), modifying the effector activity of the antibody but not its antigen specificity.

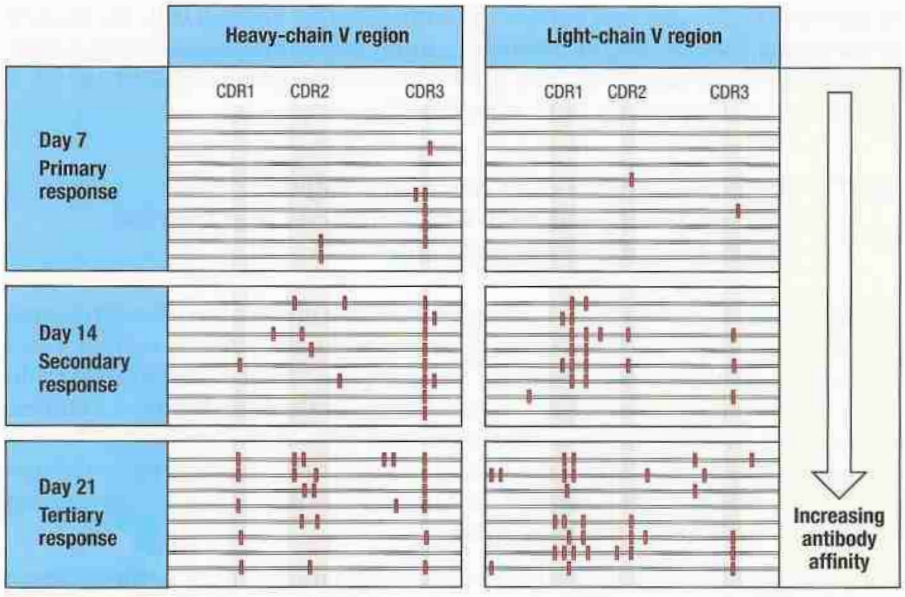

Fig. 10.14 Somatic hypermutation introduces mutations into the rearranged immunoglobulin variable (V) regions that improve antigen binding. The process of somatic hypermutation can be tracked by sequencing immunoglobulin V regions from hybridomas (clones of antibody-producing cells; see Appendix I, Section A-8) established at different time points after the experimental immunization of mice. The result of one experiment is depicted here. Each V region sequenced is represented by a horizontal line. The complementarity-determining regions CDR1, CDR2, and CDR3 are shown by pink shading. Mutations that change the amino acid sequence are represented by red bars. Within a few days of immunization, the V regions within a particular clone of responding B cells begin to acquire mutations, and over the course of the next week more mutations accumulate (top panels). B cells whose V regions have accumulated deleterious mutations and can no longer bind antigen die. B cells whose V regions have acquired mutations that improve the affinity of the B-cell receptor for antigen are able to compete more effectively for antigen and receive signals that drive their proliferation and expansion. The antibodies they produce also have this improved affinity. This process of mutation and selection can continue in the lymph node germinal center through multiple cycles in response to secondary and tertiary immune responses elicited by further immunization with the same antigen (center and bottom panels). In this way, the antigen-binding efficiency of the antibody response is improved over time.

mutations may alter conserved framework regions (see Fig. 4.9) and disrupt basic immunoglobulin structure. Cells that harbor such detrimental mutations are eliminated by apoptosis either because they can no longer make a functional B-cell receptor or because they cannot take up antigen as well as sibling B cells (Fig. 10.15). Germinal centers are filled with apoptotic B cells that are quickly engulfed by macrophages, giving rise to the characteristic **tingible body macrophages**. These contain dark-staining nuclear debris in their cytoplasm. This process of elimination is implied by the relative scarcity of amino acid replacements

Fig. 10.15 Selection for high-affinity mutants in the germinal center relies on help provided by T_{FH} cells. After activated B cells interact with T_{FH} cells at the follicle border, they migrate to germinal centers (GCs), where the following events depicted here occur. In the dark zone of the GC, somatic hypermutation alters the immunoglobulin V regions (first panel). In some B cells (yellow), the mutated B-cell receptor (BCR) will have low or no affinity for the antigen, while in other B cells (orange), the mutated BCR affinity may be higher. After exiting the dark zone, the B cells with higher-affinity BCRs will capture antigen (red) trapped on follicular dendritic cells (FDCs) and then process and present it on MHC class II molecules (second panel). B cells with low-affinity BCRs will fail to capture and present antigen. B cells that present linked antigen epitopes to T_{FH} cells (dark blue) will receive help through CD40L and IL-21, which promote survival and proliferation. B cells that lack antigen on MHC class II molecules receive no help and will eventually die (third panel). T cells that do not recognize the antigen presented by B cells (light blue) will not participate. Some of the proliferating B cells undergo repeated cycles of entry to the dark zone, mutation, and selection (fourth panel), and other progeny B cells undergo differentiation to either memory B cells or plasma cells (not shown).

in the framework regions, reflecting the loss of cells that had mutated any one of the many residues that are critical for immunoglobulin V-region folding. This process prevents rapidly dividing B cells from expanding to numbers that would overwhelm the lymphoid tissues. Less frequently, mutations may improve the affinity of a B-cell receptor for antigen, and these mutations will be selectively expanded (see Fig. 10.15) because the cells expressing receptors with such mutations will have an increased survival rate compared with that of low-affinity cells. Positive selection is evident in the accumulation of numerous amino acid replacements in the complementarity-determining regions (CDRs), which determine antibody specificity and affinity (see Fig. 10.14), a process we discuss in the next section. The result of selection for enhanced binding to antigen is that the nucleotide changes that alter amino acid sequences, and thus protein structure, tend to be clustered in the CDRs of the immunoglobulin V-region genes, whereas silent, or neutral, mutations that preserve amino acid sequence and do not alter protein structure are scattered throughout the V region.

ANIMATION 10.1

10-8 Positive selection of germinal center B cells involves contact with T_{FH} cells and CD40 signaling.

Selection of B cells with improved affinity for antigen occurs in increments. It was originally discovered *in vitro* that resting B cells could be kept alive by simultaneously cross-linking their B-cell receptors and ligating their cell-surface CD40. *In vivo* these signals are delivered by antigen and by T_{FH} cells, respectively. The details of selection in the germinal center have become more clear recently from studies based on *in vivo* two-photon laser-scanning microscopy (see Appendix I, Section A-10). They show that positive selection of a B cell depends on the B cell's ability to take up antigen and to receive signals delivered by T_{FH} cells. It is thought that somatic hypermutation occurs in the centroblasts in the dark zone; when a centroblast reduces its rate of proliferation and becomes a centrocyte, it increases the number of B-cell receptors on its surface and moves to the light zone, where there are abundant FDCs. Antigen can be trapped and stored for long periods in the form of immune complexes on FDCs (**Fig. 10.16** and **Fig. 10.17**). The centrocyte's ability to bind antigen determines its relative ability to acquire antigen, in competition with the other clonally related centrocytes harboring different mutations. Centrocytes whose receptors bind antigen better will capture and present more peptides on their

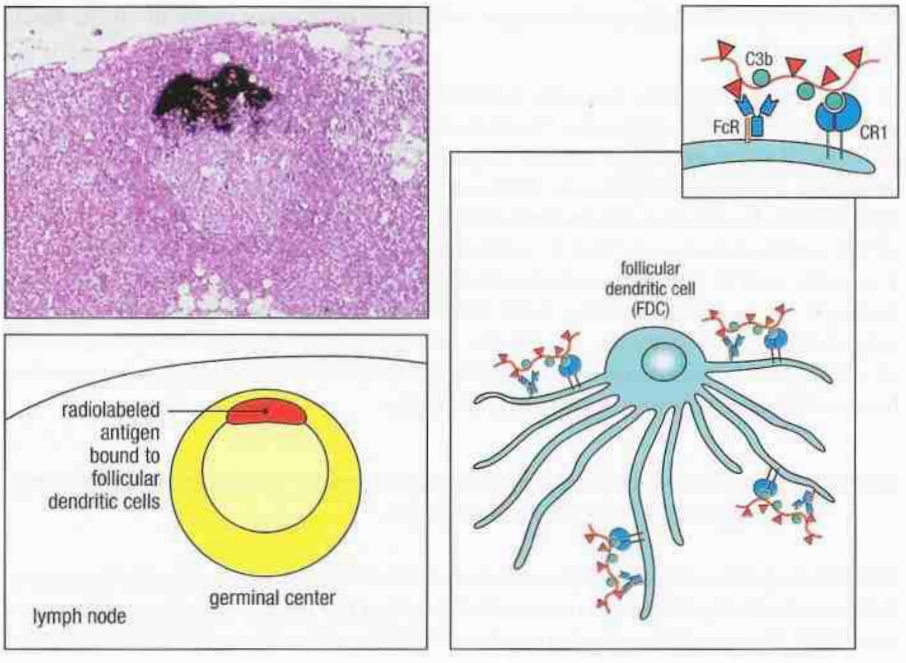

Fig. 10.16 Antigens are trapped in immune complexes that bind to the surface of follicular dendritic cells. Radiolabeled antigen localizes to, and persists in, lymphoid follicles of draining lymph nodes [see the light micrograph and the schematic representation (left panels), showing a germinal center in a lymph node]. The intense dark staining shows the localization in the germinal center of radiolabeled antigen that had been injected 3 days previously. The antigen is in the form of antigen:antibody:complement complexes bound to Fc receptors and to complement receptors CR1 or CR2 on the surface of the FDC, as depicted in the right panel and inset. These complexes may also be internalized and recycled by a nondegradative endocytic pathway (not shown). FcR, Fc receptor.

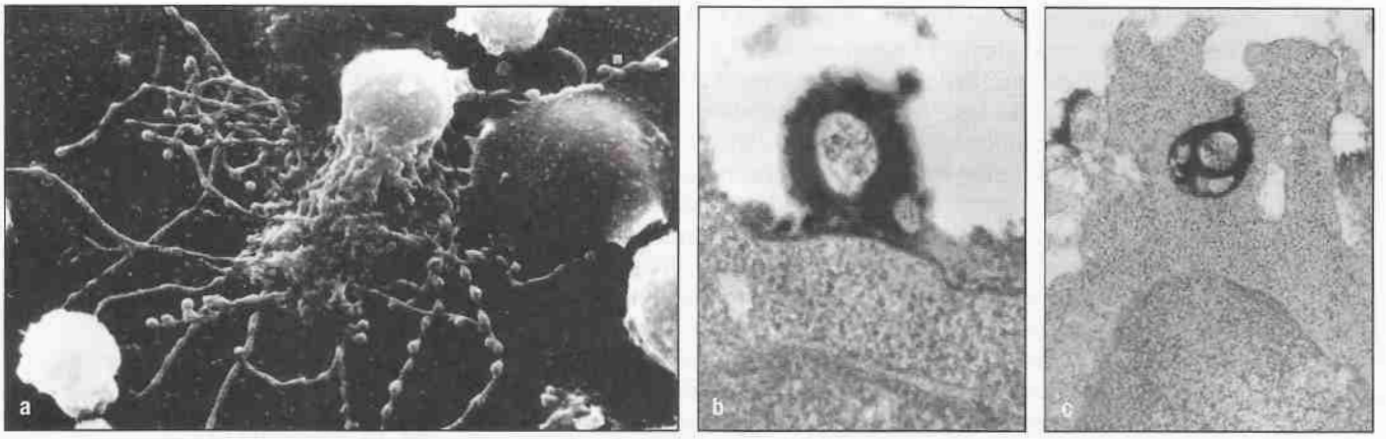

Fig. 10.17 Immune complexes bound to FDCs form iccosomes, which are released and can be taken up by B cells in the germinal center. FDCs have a prominent cell body and many dendritic processes. Immune complexes, bound to complement receptors and Fc receptors on the FDC surface, become clustered, forming prominent bead-like structures along the dendrites (a). An intermediate form of FDC is shown, which has both straight filiform dendrites and others that are becoming beaded. These beads are shed from the cell as *iccosomes* (immune complex–coated bodies), which can bind to a B cell in the germinal center (b) and be taken up by it (c). In panels b and c, the iccosome has been formed with immune complexes containing horseradish peroxidase, which is used to form electron-dense material that appears dark in the transmission electron micrographs.

surface MHC class II molecules. T_{FH} cells in the germinal center recognize these peptides and, as before, are activated to deliver to the B-cell signals that promote survival. Centrocytes whose mutations reduce antigen-binding affinity will take up less antigen, and so will receive weaker survival signals from T_{FH} cells. Successful B cells will reexpress CXCR4 and return to the dark zone, where they will undergo additional rounds of division, in effect becoming centroblasts again. Germinal center B cells that fail to acquire sufficient antigen from FDCs to engage T_{FH} cells will become apoptotic and disappear. This process of B-cell migration within the germinal center is known as the **cyclic reentry model** (see Fig. 10.11, right panel). In this way, the affinities of B cells are continually refined during the germinal center response (see Section 10-6). The selection process can be quite stringent. The germinal center may begin with perhaps a few hundred different clones. Competition among these various clones is based not only on their affinity for antigen but also on which epitope of which antigens they recognize. Although some clones may leave few progeny as antigen-producing B cells, they may leave progeny in the form of memory B cells.

In the germinal center, T_{FH} cells and B cells interact to deliver signals that are important for both cells (see Section 10-4). Mice that lack ICOS or SAP are deficient in the germinal center reaction and have severely reduced class-switched antibody responses because of defective T_{FH} cell function. CD40 signaling in B cells is activated by CD40L on T_{FH} cells and increases expression of the survival molecule Mcl-1, a relative of Bcl-2. These interactions between T_{FH} cells and B cells are enhanced by signals from SLAM family receptors through the adaptor protein SAP. Intravital laser-scanning microscopy has revealed that mice lacking the SLAM receptor CD84 have reduced numbers of conjugates between antigen-specific T cells and B cells, and these mice also have a reduced humoral response to antigen.

10-9 Activation-induced cytidine deaminase introduces mutations into genes transcribed in B cells.

Activation-Induced Cytidine Deaminase Deficiency

Now that we have discussed the cellular processes involved in somatic hypermutation and affinity maturation, we will delve into the details of the mutation process itself. The enzyme activation-induced cytidine deaminase (AID) is important

for both somatic hypermutation and class switch recombination, as mice lacking AID have defects in both processes. People with mutations in the AID gene that inactivate the enzyme—that is, who have **activation-induced cytidine deaminase deficiency, or AID deficiency**—also lack both somatic hypermutation and class switching. This condition leads to the production of predominantly IgM antibodies and the absence of affinity maturation, a syndrome known as **hyper IgM type 2 immunodeficiency** (discussed in Section 13-9).

AID is related to enzymes that deaminate cytosine to uracil in making nucleotide precursors for RNA and DNA synthesis. Its closest homolog, **APOBEC1 (apolipoprotein B mRNA editing catalytic polypeptide 1)**, is an RNA-editing enzyme that deaminates cytosine in the context of RNA. However, AID fulfills its activity in antibody gene diversification by acting on cytosine in the DNA of the immunoglobulin locus. When AID deaminates cytidine residues in the immunoglobulin V regions, somatic hypermutation is initiated; when cytidine residues in switch regions are deaminated, class switch recombination is initiated.

AID can deaminate cytidine residues in single-stranded DNA but not double-stranded DNA (Fig. 10.18). AID typically acts when its target genes are being transcribed, so that the DNA double helix is temporarily unwound. Because AID is expressed primarily in germinal center B cells, but is also expressed in activated B cells, AID primarily targets the actively transcribed, rearranged V regions of the immunoglobulin genes. This process is thought to rely in part on the highly active transcription of the rearranged V regions in these B cells, where RNA polymerase may generate transient single-strand regions. Somatic hypermutation does not occur in loci that are not being actively transcribed. Rearranged V_H and V_L genes are mutated even if they are 'nonproductive' rearrangements and are not being expressed as protein, as long as they are being transcribed. Some actively transcribed genes in B cells besides those for immunoglobulins can also be affected by the somatic mutation process, but at a much lower rate. AID is also expressed in human and mouse B-cell progenitors, where it may play a role in promoting self-tolerance in developing B cells, and in non-Peyer's-patch lamina propria B cells, where it may be involved in T-independent IgA class switch and somatic mutation.

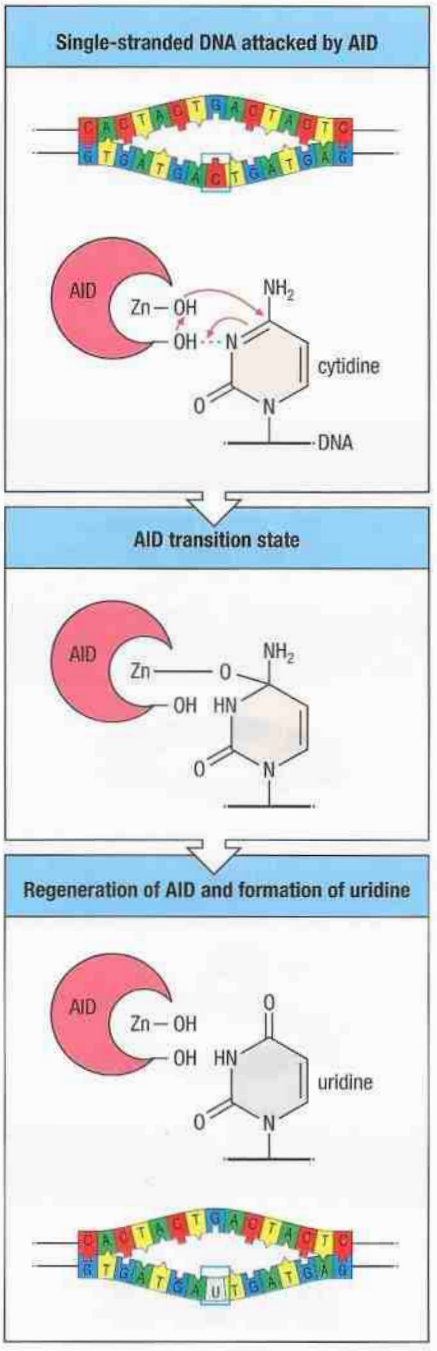

Fig. 10.18 Activation-induced cytidine deaminase (AID) is the initiator of mutations in somatic hypermutation, gene conversion, and class switching. The activity of AID, which is expressed only in B cells, requires access to the cytidine side chain of a single-strand DNA molecule (first panel), which is normally prevented by the hydrogen bonding in double-stranded DNA. AID initiates a nucleophilic attack on the exposed cytosine ring (second panel), which is resolved by the deamination of the cytidine to form uridine (third panel).

10-10 Mismatch and base-excision repair pathways contribute to somatic hypermutation after initiation by AID.

The uridine produced by AID represents a dual lesion in DNA: it is foreign to normal DNA, and it is a mismatch with the guanosine nucleoside on the opposite DNA strand. The presence of uridine in DNA can trigger several types of DNA repair—including the **mismatch repair** and the **base-excision repair** pathways—which further alter the DNA sequence. The various repair processes lead to different mutational outcomes (Fig. 10.19). In the mismatch repair pathway, the presence of uridine is detected by the mismatch repair proteins **MSH2** and **MSH6** (MSH2/6). They recruit nucleases that remove the complete uridine nucleotide along with several adjacent nucleotides from the damaged DNA strand. This removal is followed by a fill-in 'patch repair' by a DNA polymerase; but unlike the repair process in other cells, in B cells this DNA synthesis is error-prone and tends to introduce mutations at nearby A-T base pairs. Two error-prone polymerases that may be involved are and Polη and Polθ.

The initial steps in the base-excision repair pathway are shown in Fig. 10.20. In this pathway, the enzyme **uracil-DNA glycosylase (UNG)** removes the uracil base from the uridine to create an abasic site in the DNA. If no further modification is made, at the next round of DNA replication this will result in the random insertion of a nucleotide opposite the abasic site by DNA polymerase, leading to mutation. The action of UNG may, however, be followed by the

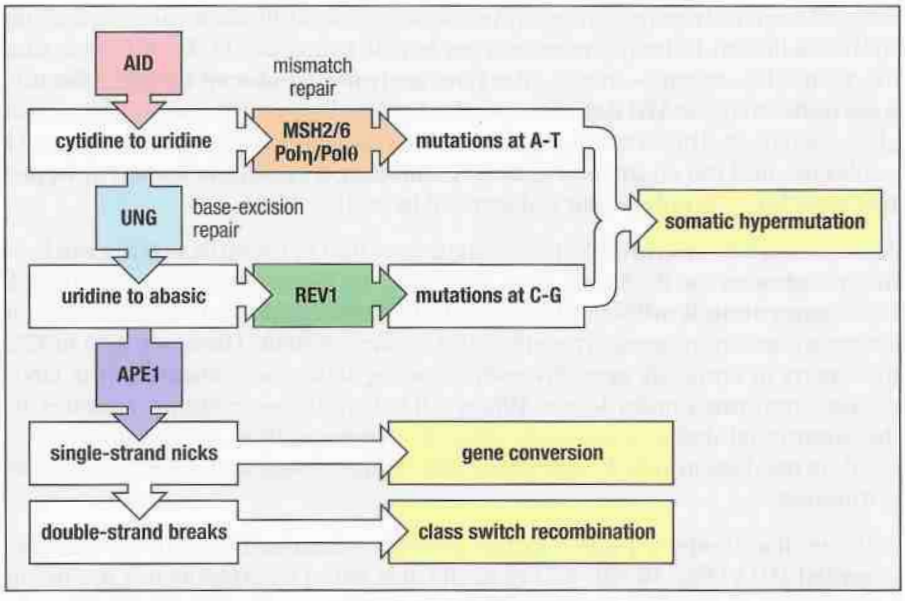

Fig. 10.19 AID initiates DNA lesions whose repair leads to somatic hypermutation, class switch recombination, or gene conversion. When AID converts a cytidine (C) to uridine (U) in the DNA of an immunoglobulin gene, the final mutation produced depends on which repair pathways are used. Somatic hypermutation can result from either the mismatch repair (MSH2/6) pathway combined with an error-prone polymerase activity or from the base-excision repair (UNG) pathway. Acting together, these pathways can generate point mutations at and around the site of the original C-G pair. REV1 is a DNA repair enzyme that can synthesize DNA, or recruit other enzymes that can synthesize DNA, over the abasic sites in damaged DNA. REV1 itself will insert only C opposite the abasic site, but it can help recruit other polymerases that can also insert A, G, and T. The end result is insertion of a random nucleotide at the C-G residues where AID initially acted. Both class switch recombination and gene conversion require the formation of a single-strand break in the DNA. A single-strand break is formed when apurinic/apyrimidinic endonuclease-1 (APE1) removes a damaged residue from the DNA as part of the repair process (see Fig. 10.20, bottom two panels). In class switch recombination, single-strand breaks made in two of the so-called switch regions upstream of the C-region genes are converted to double-strand breaks. The cell's machinery for repairing double-strand breaks, which is very similar to the later stages of V(D)J recombination, then rejoins the DNA ends in a way that leads to a recombination event in which a different C-region gene is brought adjacent to the rearranged V region. Gene conversion results from the broken DNA strand using homologous sequences flanking the immunoglobulin gene as a template for repair DNA synthesis, thus replacing part of the gene with new sequences.

action of another enzyme, **apurinic/apyrimidinic endonuclease-1 (APE1)**, which excises the abasic residue to create a single-strand discontinuity (known as a single-strand nick) in the DNA at the site of the original cytidine. Repair of the single-strand nick proceeding through double-strand breaks may result in gene conversion. Gene conversion is not used in the diversification of immunoglobulin genes in humans and mice, but is of importance in some other mammals and in birds.

Somatic hypermutation involves both mutation at the original cytidines targeted by AID and mutation at nearby non-cytidine nucleotides. If the original

APE1
Single-strand nick in DNA

Fig. 10.20 The base-excision repair pathway produces single-strand nicks in DNA by the sequential actions of AID, uracil-DNA glycosylase (UNG), and apurinic/apyrimidinic endonuclease-1 (APE1). Double-stranded DNA (first panel) can be made accessible to AID by transcription that unwinds the DNA helix locally (second panel). AID, which is specifically expressed in activated B cells, converts cytidine residues to uridine residues (third panel). The ubiquitous base-excision repair enzyme UNG can then remove the uracil ring from uridine, creating an abasic site (fourth panel). The repair endonuclease APE1 then cuts the sugar–phosphate DNA backbone next to the abasic residue (fifth panel), thereby forming a single-strand nick in the DNA (sixth panel). APE1 does not excise the deoxyribose to form a single-strand nick in DNA, but rather cuts the DNA backbone to yield a 5′-deoxyribose phosphate terminus that is then removed by, for example, DNA polymerase b.

U-G mismatch is recognized by UNG, then an abasic site will be generated in the DNA (see Fig. 10.19). If no further modification is made to this site, it can be replicated without instructive base pairing from the template strand by a class of **error-prone 'translesion' DNA polymerases** that normally repair gross damage to DNA, such as that caused by ultraviolet (UV) radiation. These polymerases can incorporate any nucleotide into the new DNA strand opposite the abasic site, and after a further round of DNA replication this can result in a stable mutation at the site of the original C-G base pair.

In the mismatch repair pathway in B cells, but not in other cell types, the DNA lesion is repaired by error-prone DNA polymerases rather than by more accurate polymerases that faithfully copy the undamaged template strand. Individuals with a defect in the translesion polymerase **Polη** have relatively fewer mutations than usual at A-T, but not at C-G, in their hypermutated immunoglobulin V regions. This fact suggests that Polη is the repair polymerase involved in this pathway of somatic hypermutation. These individuals also have a form of **xeroderma pigmentosum**, a condition resulting from the inability of their cells to repair DNA damage caused by UV radiation.

10-11 AID initiates class switching to allow the same assembled V_H exon to be associated with different C_H genes in the course of an immune response.

All the progeny of a particular B cell activated in an immune response will express the same V_H gene that was generated during its development in the bone marrow, although the gene may be modified by somatic hypermutation. In contrast, that B cell's progeny may express several different C-region isotypes as the cells mature and proliferate during the immune response. The first antigen receptors expressed by B cells are IgM and IgD, and the first antibody produced in an immune response is always IgM. Later in the immune response, the same assembled V region may be expressed in IgG, IgA, or IgE antibodies. This change is known as **class switching** (or **isotype switching**), and, unlike the expression of IgD, it involves irreversible DNA recombination. It is stimulated in the course of an immune response by external signals such as cytokines released by T_H cells.

Switching from IgM to the other immunoglobulin classes occurs only after B cells have been stimulated by antigen. It is achieved through **class switch recombination**, which is a type of nonhomologous DNA recombination that is guided by stretches of repetitive DNA known as **switch regions**. Switch regions lie in the intron between the J_H gene segments and the C_μ gene, and at equivalent sites upstream of the genes for each of the other heavy-chain isotypes, with the exception of the C_δ gene, which does not require DNA rearrangement for its expression (Fig. 10.21, first panel). When a B cell switches from the coexpression of IgM and IgD to the expression of another subtype, DNA recombination occurs between S_μ and the S region immediately upstream of the newly chosen constant-region gene. In such a recombination event, the C_μ coding regions and the entire intervening DNA between C_μ and the S region undergoing rearrangement are deleted. Figure 10.21 illustrates switching from C_μ to C_ε in the mouse. All switch recombination events produce genes that can encode a functional protein, because the switch sequences are located in the intron between the assembled V_H exon and C exons, so that changes there cannot cause frameshift mutations.

ANIMATION 10.2

The enzyme AID initiates class switch recombination and acts only on regions of DNA being transcribed. Certain properties of the switch region sequences promote the accessibility to AID when they are being transcribed. Each switch region consists of many repeats of a G-rich sequence element on the non-template strand. For example, S_μ consists of about 150 repeats of the sequence (GAGCT)n(GGGGGT), where n is usually 3 but can be as many as 7.

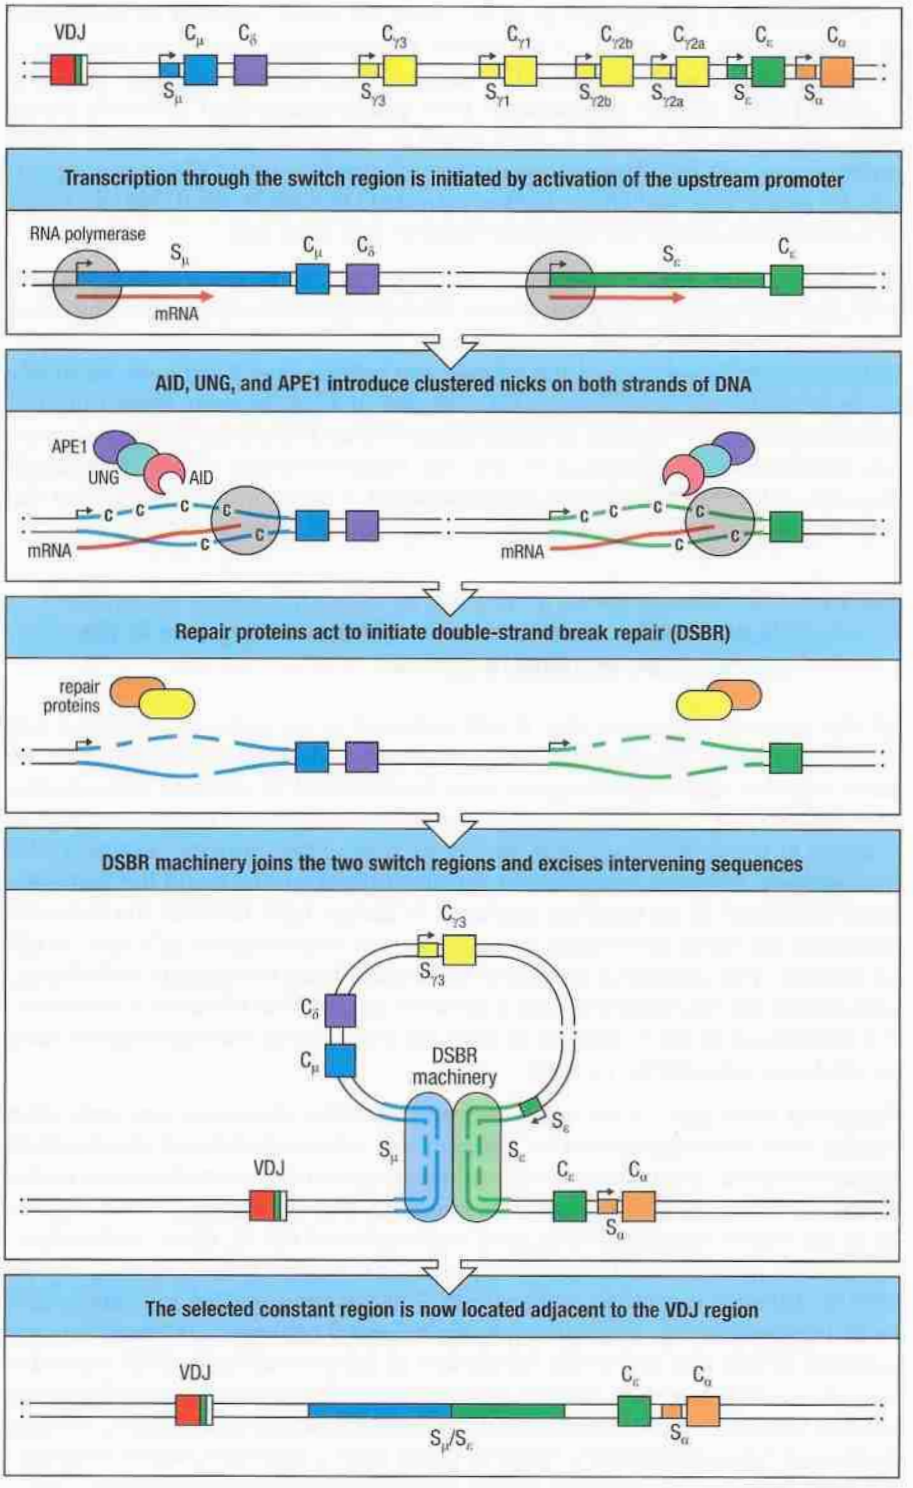

Fig. 10.21 Class switching involves recombination between specific switch signals. The top panel shows the organization of a rearranged immunoglobulin heavy-chain locus before class switching. Second panel: This figure illustrates switching between the μ and ε isotypes in the mouse heavy-chain locus. Switch regions (S) are repetitive DNA sequences that guide class switching and are found upstream of each of the immunoglobulin C-region genes, with the exception of the C_δ gene. Switching is guided by the initiation of transcription by RNA polymerase (shaded circle) through these regions from promoters (shown as arrows) located upstream of each S. Because of the repetitive sequences, RNA polymerase can stall within the S regions, allowing these regions to serve as substrates for AID, and subsequently for UNG and APE1. Third panel: These enzymes introduce a high density of single-strand nicks into the non-template DNA strand and the template strand. Staggered nicks are converted to double-strand breaks by a mechanism that is not yet understood. Fourth panel: These breaks are then recognized by the cell's double-strand break repair machinery, which involves DNA-PKcs, Ku proteins, and other repair proteins. Bottom two panels: The two switch regions, in this case S_μ and S_ε, are brought together by the repair proteins, and class switching is completed by excision of the intervening region of DNA (including C_μ and C_δ) and ligation of the S_μ and S_ε regions.

The sequences of the other switch regions ($S\gamma$, $S\alpha$, and S_ε) differ in exact sequence, but all contain repeats of the GAGCT and GGGGGT sequences. It appears that movement of RNA polymerase through this highly repetitive region is occasionally halted—called **polymerase stalling**. This may be caused by bubble-like structures, called **R-loops**, that form when the transcribed RNA displaces the non-template strand of the DNA double helix (see Fig. 10.21, third panel) due to the RNA having many G residues in tandem on one strand.

Polymerase stalling seems closely connected with the recruitment of AID to specific switch regions being transcribed. A multi-subunit RNA processing/

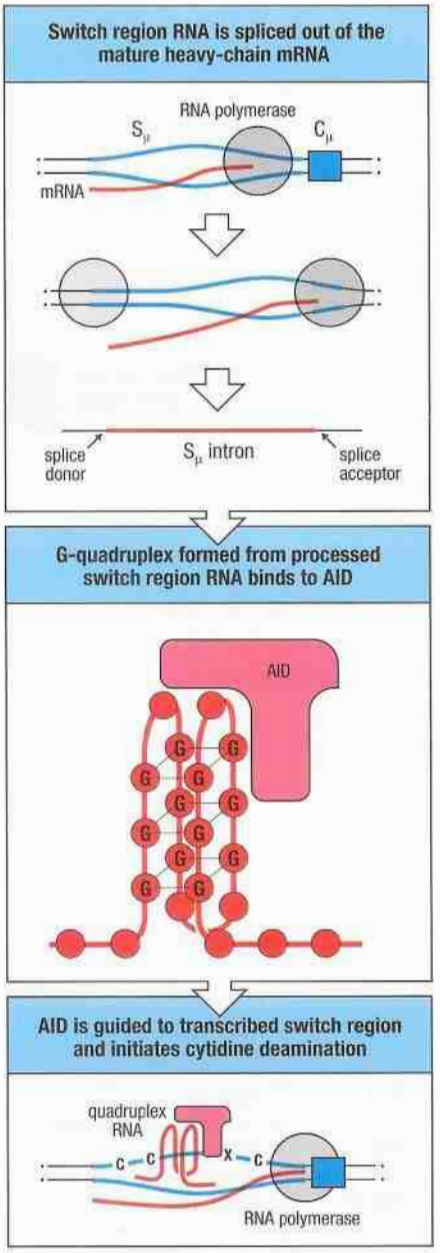

Fig. 10.22 RNA processed from switch region introns interacts with AID and guides its activity. Top panel: Promoters upstream of each switch region initiate transcription by RNA polymerase upstream of a rearranged V_H gene, as in the case of C_μ, shown here, or a noncoding exon for all other constant regions. In all cases, the switch region itself lies within an intron upstream of the exons encoding the constant regions. This intronic switch region RNA is removed from the primary RNA transcript by splicing at specific splice acceptor and donor sites. Middle panel: After splicing, the switch region RNA is further processed, and its repetitive elements allow the formation of putative G-quadruplex structures. Evidence indicates that these RNAs are able to bind AID, as implied in the diagram. Bottom panel: The RNA acts as a guide to bring AID to the switch region by the ability of the G-quadruplex to hybridize with the original DNA template strand from which it was transcribed.

degradation complex, the **RNA exosome**, associates with AID and accumulates on transcribed switch regions, and the protein **Spt5** associates with the stalled polymerase; both are necessary for AID to generate double-strand breaks. Recent evidence indicates that AID is selectively guided to the transcribed switch by an additional mechanism that bears some similarities to the mechanism that operates in the CRISPR/Cas9 genome editing system (see Appendix I, Section A-36). After an RNA polymerase has completed transcription of one RNA template, the intron RNA harboring the switch region is spliced out. Recall that the RNA derived from the switch region contains many repeated copies of the sequences described above, with each switch region having a slightly different repeat sequence. This intronic RNA is then processed to generate many copies of an RNA structure, called a **G-quadruplex**, that is based on the G-rich repetitive element of the switch region (Fig. 10.22). This G-quadruplex serves a dual purpose, both binding to AID and, on the basis of sequence complementarity, associating with the switch region from which it was transcribed. Thus the G-quadruplex guides AID to the appropriate switch region, where particular palindromic sequences, such as AGCT, act as good substrates to allow its cytidine deaminase activity to act on both strands concurrently. In this way, the G-quadruplex functions in a manner similar to the synthetic guide RNAs that deliver the Cas9 endonuclease to specific genomic regions, as described in Appendix I, Section A-36). In addition, transcribed switch region DNA may also form G-quadruplex structures and recruit AID directly, providing multiple mechanisms by which the deaminase could access the DNA during class switch recombination.

After the generation of double-strand breaks in switch regions, general cellular mechanisms for repairing these breaks lead to the nonhomologous recombination between switch regions that results in class switching (see Fig. 10.21, fourth and fifth panels). The ends to be joined are brought together by the alignment of repetitive sequences common to the different switch regions, and rejoining of the DNA ends then leads to excision of all DNA between the two switch regions and the formation of a chimeric region at the junction. Loss of AID completely blocks class switching, but deficiency of UNG in both mice and humans severely impairs class switching, suggesting sequential actions of AID and UNG in generating DNA breaks. Joining of DNA ends is probably mediated by classic nonhomologous end joining [as in V(D)J recombination] as well as by a poorly understood alternative end-joining pathway. Class switching is sometimes impaired in the disease **ataxia telangiectasia**, which is caused by mutations in the DNA-PKcs family kinase **ATM**, a known DNA repair protein. The role of ATM in class switching is not yet entirely clear, however.

Ataxia Telangiectasia

10-12 Cytokines made by T_H cells direct the choice of isotype for class switching in T-dependent antibody responses.

We are now ready to explain how a particular heavy chain is selected during an immune response. It is this choice of antibody isotype that ultimately determines the effector function of antibodies, and we will see that it is largely controlled by the cytokines that are produced by T_{FH} cells in the germinal

center reaction. As discussed earlier, interactions between germinal center B cells and T_H cells are essential for class switching. CD40 ligand expressed by activated helper T cells activates signaling by CD40 on B cells. Genetic deficiency of CD40 ligand greatly reduces class switching and causes abnormally high levels of plasma IgM, a condition known as **hyper IgM syndrome**. People with this defect lack antibodies of classes other than IgM and exhibit severe humoral immunodeficiency, manifested as repeated infections with common bacterial pathogens. Much of the IgM in hyper IgM syndrome may be induced by thymus-independent antigens on the pathogens that chronically infect these individuals. Nevertheless, people with CD40 ligand deficiency can make IgM antibodies in response to thymus-dependent antigens, which indicates that in the B-cell response, CD40L–CD40 interactions are most important in sustaining a response in the germinal center that leads to class switching and affinity maturation, rather than in the initial activation of B cells.

CD40 Ligand Deficiency

The selection of a particular C region for class switch recombination is not random but is regulated by the cytokines produced by T_H cells and other cells during the immune response. Different cytokines preferentially induce switching to different isotypes (Fig. 10.23). Cytokines induce class switching in part by inducing the production of RNA transcripts through the switch regions that lie 5′ to each heavy-chain C gene segment. When activated B cells are exposed to the cytokine IL-4, for example, transcription from promoters that lie upstream of the switch regions of $C_{\gamma 1}$ and C_ε can be detected a day or two before switching occurs. This will make it possible for switching to occur to either of these two heavy-chain C genes, but in any particular germinal center B cell, recombination will occur in only one. In the example of class switching shown in Fig. 10.21, transcription through the S_ε regions caused the rearrangement between the S_μ and S_ε regions, making the IgE isotype antibody. This results because IL-4 signaling activates the transcription factor **STAT6**, which initiates transcription of the Iε promoter upstream of the S_ε region. I regions are sequences immediately upstream of the switch regions. These sequences contain promoters that initiate transcription across the switch regions and are named according to the switch region they transcribe. Other cytokines activate other promoters upstream of other I-region promoters upstream of other switch regions to produce other antibody classes. T_H cells also produce IL-21, which promotes switching to IgG1 and IgG3. Transforming growth factor-β (TGF-β) induces switching to IgG2b ($C_{\gamma 2b}$) and IgA (C_α). Interferon-γ (IFN-γ) induces switching to IgG2a and IgG3. IL-5 promotes the maturation of IgA-producing B cells and can induce switching to IgG1. While it is clear that the transcription across switch regions influences their selection in undergoing class switch recombination, the basis on which cytokines are produced by T_{FH} cells and their precise impact on S-region transcription are still an active area of research.

Cytokines	Isotype
IL-4	IgG1, IgE
IFN-γ	IgG3, IgG2a
TGF-β	IgG2b, IgA
IL-21	IgG3, IgG1, IgA
IL-5	IgG1, IgA

Fig. 10.23 Different cytokines induce switching to different antibody classes. Cytokines induce the production of certain antibody classes by promoting transcription of mRNA from promoters upstream of the various switch regions for the different classes of antibodies. The properties of the switch region promoters determine the cytokine to which it will respond. These 'sterile' transcripts initially encode only for the C region, and not for the entire antibody. Both the process of transcription across the switch regions and the RNA derived from it contribute to allowing AID to induce the DNA rearrangement that will join the V region with a new C region for the selected isotype.

10-13 B cells that survive the germinal center reaction eventually differentiate into either plasma cells or memory cells.

When B cells have undergone affinity maturation and class switching, some eventually exit from the germinal center as developing plasma cells that produce large amounts of antibody. Germinal centers produce many more B cells than eventually are exported as memory B cells or plasma cells, indicating that entry into the memory-cell or plasma-cell compartment is tightly regulated. In B cells, the transcription factors Pax5 and Bcl-6 inhibit the expression of transcription factors required for plasma-cell differentiation, and both Pax5 and Bcl-6 are down-regulated when the B cell starts differentiating. The transcription factor IRF4 then induces the expression of **BLIMP-1**, a transcriptional repressor that switches off genes required for B-cell proliferation, class switching, and affinity maturation. B cells in which BLIMP-1 is induced become plasma cells; they cease proliferating, increase the synthesis and secretion

of immunoglobulins, and change their cell-surface properties. Plasma cells down-regulate CXCR5 and up-regulate S1PR1, CXCR4, and $\alpha_4\beta_1$ integrins so that they can leave the germinal centers and home to peripheral tissues.

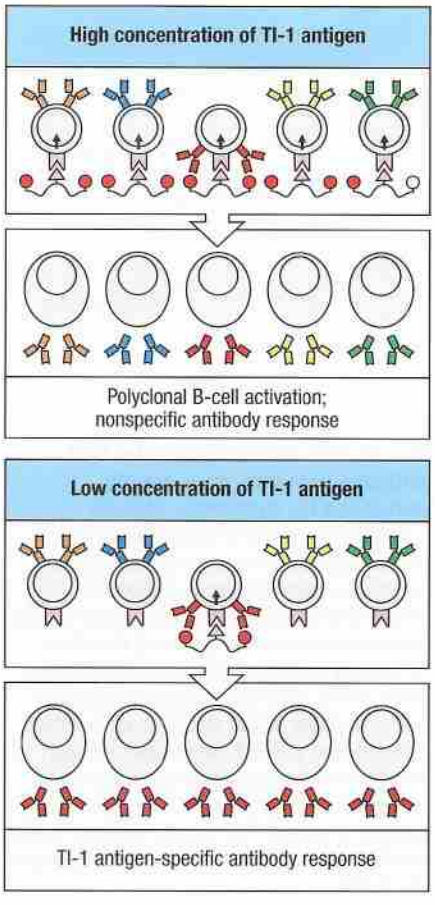
Some plasma cells deriving from germinal centers in lymph nodes or spleen migrate to the bone marrow, where a subset live for a long period, whereas others migrate to the medullary cords in lymph nodes or to the splenic red pulp. In general, plasma cells formed from early primary foci and germinal centers live for only a few days and are localized to the lymph node medullary cords or splenic red pulp. Plasma cells formed later in germinal centers migrate to the bone marrow and can persist for months, years, and even decades depending on the vaccine or infection. The persistence of plasma cells is the major determinant of the duration of humoral immunity. B cells that have been activated in germinal centers in mucosal tissues, and which are predominantly switched to IgA production, stay within the mucosal system. A splice variant of **XBP1 (X-box binding protein 1)** is expressed in plasma cells and helps to regulate their secretory capacity. Plasma cells in the bone marrow are the source of long-lasting, high-affinity class-switched antibody.

Other germinal center B cells differentiate into **memory B cells**. Memory B cells are long-lived descendants of cells that were once stimulated by antigen. Although some can form early in an immune response before the formation of germinal centers, most long-lived memory B cells have proliferated in the germinal center. They divide very slowly if at all; they express surface immunoglobulin but secrete no antibody or do so only at a low rate. Because the precursors of some memory B cells arise from the germinal center reaction, memory B cells can inherit the genetic changes that occur there, including somatic hypermutation and the gene rearrangements that result in a class switch. The signals that control which path of differentiation a B cell takes are still being investigated. We will briefly return to memory B cells in Chapter 11.

10-14 Some antigens do not require T-cell help to induce antibody responses.

Humans and mice with T-cell deficiencies are able to produce antibodies against thymus-independent (TI) antigens, which we introduced in Section 10-1. These antigens include certain bacterial polysaccharides, polymeric proteins, and lipopolysaccharides, which are able to stimulate naive B cells in the absence of T-cell help. These nonprotein bacterial products cannot elicit classical T-cell responses, yet they induce antibody responses in normal individuals. In addition, there are TI antigens that are not derived from bacteria; these include plant-derived mitogens and lectins, viral antigens, and superantigens, and some parasite-derived antigens.

Thymus-independent antigens fall into two classes, TI-1 and TI-2, which activate B cells by two different mechanisms. **TI-1 antigens** rely on activity that can directly induce B-cell division without T-cell help. We now understand that TI-1 antigens contain molecules that cause the proliferation and differentiation of most B cells regardless of their antigen specificity; this is known as **polyclonal activation** (Fig. 10.24, top panel). TI-1 antigens are therefore often called **B-cell mitogens**, a mitogen being a substance that induces cells to undergo



High concentration of TI-1 antigen
Polyclonal B-cell activation;
nonspecific antibody response
Low concentration of TI-1 antigen
TI-1 antigen-specific antibody response

Fig. 10.24 TI-1 antigens induce polyclonal B-cell responses at high concentrations and antigen-specific antibody responses at low concentrations. At high antigen concentration, the signal delivered by the B cell–activating moiety of TI-1 antigens is sufficient to induce B-cell proliferation and antibody secretion in the absence of specific antigen binding to surface immunoglobulin. Thus, all B cells respond (top panel). At low antigen concentration, only B cells specific for the TI-1 antigen bind enough of it to focus its B cell–activating properties onto the B cell; this gives a specific antibody response to epitopes on the TI-1 antigen (bottom panel).

mitosis. For example, LPS and bacterial DNA are both TI-1 antigens because they activate TLRs expressed by B cells (see Section 3-5) and can act as mitogens. Naive murine B cells constitutively express many of the TLRs, but naive human B cells do not express high levels of most TLRs until they receive stimulation through the B-cell receptor. So by the time a B cell has been stimulated by antigen through its B-cell receptor, it is likely to express several TLRs and be responsive to stimulation by TLR ligands that accompany the antigens. Thus, when B cells are exposed to concentrations of TI-1 antigens that are 10^3–10^5 times lower than those used for polyclonal activation, only those B cells whose B-cell receptors specifically bind the TI-1 antigen become activated. At these low concentrations, amounts of TI-1 antigen sufficient for B-cell activation can be concentrated on the B-cell surface only with the aid of this specific binding (Fig. 10.24, bottom panel). B-cell responses to TI-1 antigens in the early stages of an infection may be important in defense against several extracellular pathogens, but they do not lead to affinity maturation or memory B cells, both of which require antigen-specific T-cell help.

The second class of thymus-independent antigens—**TI-2 antigens**—consists of molecules that have highly repetitive structures, such as bacterial capsular polysaccharides. These contain no intrinsic B cell–stimulating activity. Whereas TI-1 antigens can activate both immature and mature B cells, TI-2 antigens can activate only mature B cells; immature B cells, as we saw in Section 8-7, are inactivated by encounter with repetitive epitopes. Infants and young children up to about 5 years of age do not make fully effective antibody responses against polysaccharide antigens, and this might be because most of their B cells are immature, and because their spleen and lymphoid structures (for example, marginal zone) and dendritic cells are not fully developed.

Responses to several TI-2 antigens are prominently made by marginal zone B cells, a subset of non-recirculating B cells that line the border of the splenic white pulp, and by **B-1 B cells** (see Section 8-10). Marginal zone B cells are rare at birth and accumulate with age; they might therefore be responsible for most physiological TI-2 responses, which increase in efficiency with age. TI-2 antigens probably act by simultaneously cross-linking a critical number of B-cell receptors on the surface of antigen-specific mature B cells (Fig. 10.25, left

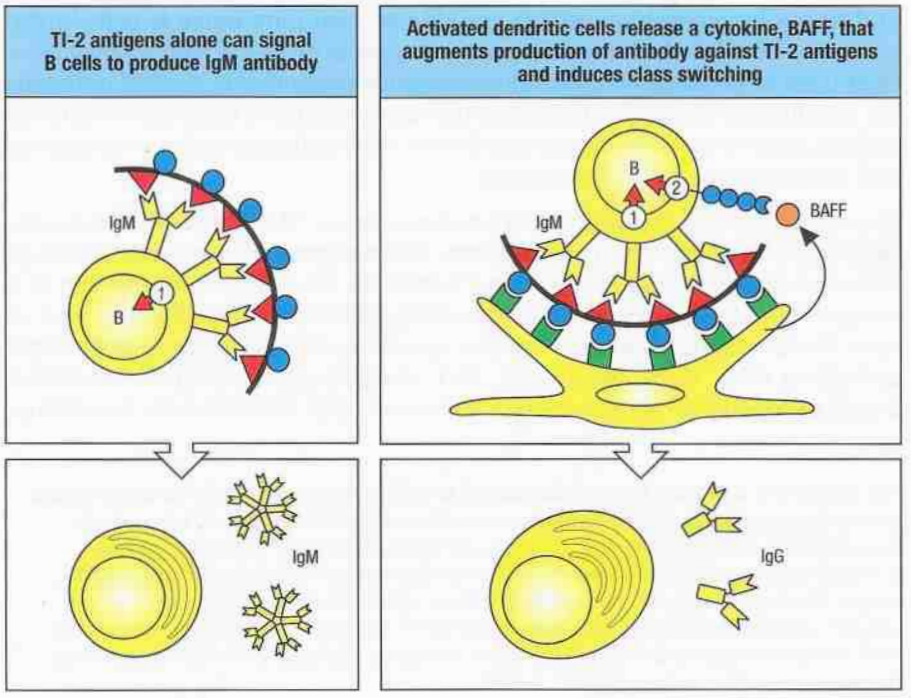


Fig. 10.25 B-cell activation by TI-2 antigens requires, or is greatly enhanced by, cytokines. Multiple cross-linking of the B-cell receptor by TI-2 antigens can lead to IgM antibody production (left panels), but there is evidence that, in addition, cytokines greatly augment these responses and also lead to isotype switching (right panels). It is not clear where such cytokines originate, but one possibility is that dendritic cells, which may be able to bind the antigen through innate immune system receptors on their surface and so present it to the B cells, secrete a soluble TNF family cytokine called BAFF, which can activate class switching by the B cell.

panels). Dendritic cells and macrophages can provide co-stimulatory signals for activation of B cells by TI-2 antigens. One of these co-stimulatory signals is BAFF, which can be secreted by dendritic cells and interacts with the receptor TACI on the B cell (Fig. 10.25, right panels). The density of TI-2 antigen epitopes is critical; excessive cross-linking of B-cell receptors renders mature B cells unresponsive or anergic, as in immature B cells, while too low a density may be insufficient for activation.

An important class of TI-2 antigens arises during infection by **capsulated bacteria**. Many common extracellular bacterial pathogens are surrounded by a polysaccharide capsule that enables them to resist ingestion by phagocytes. The bacteria not only escape direct destruction by phagocytes but also avoid stimulating T-cell responses against bacterial peptides presented by macrophages. IgM antibodies rapidly produced against the capsular polysaccharide independent of peptide-specific T-cell help will coat the bacteria, promoting their ingestion and destruction by phagocytes early in the infection.

Not all antibodies against bacterial polysaccharides are produced strictly through this TI-2 mechanism. We mentioned earlier the importance of antibodies against the capsular polysaccharide of *Haemophilus influenzae* type b in protective immunity to this bacterium. The immunodeficiency disease **Wiskott–Aldrich syndrome** is caused by defects in T cells that impair their interaction with B cells (see Chapter 13). Individuals with Wiskott–Aldrich syndrome respond poorly to protein antigens, but, unexpectedly, also fail to make IgM and IgG antibody against polysaccharide antigens and are highly susceptible to infection with encapsulated bacteria such as *H. influenzae*. The failure to make IgM seems to be due in part to greatly reduced development of the marginal zone of the spleen, which contains B cells responsible for making much of the 'natural' IgM antibody against ubiquitous carbohydrate antigens. In addition, early studies indicate that TI-2 responses are helped by IL-2 produced by T cells. Thus, IgM and IgG antibodies induced by TI-2 antigens are likely to be an important part of the humoral immune response in many bacterial infections, and in humans at least, the production of class-switched antibodies to TI-2 antigens might normally rely on some degree of T-cell help.

As well as producing IgM, TI responses can include switching to certain other antibody classes, such as IgG3 in the mouse. This is probably the result of help from dendritic cells (see Fig. 10.25, right panels), which provide secreted cytokines, such as BAFF, and membrane-bound signals to proliferating plasmablasts as they respond to TI antigens. The distinguishing features of thymus-dependent (TD), TI-1, and TI-2 antibody responses are summarized in Fig. 10.26.

Summary.

B-cell activation by many antigens requires both binding of the antigen by the B-cell surface immunoglobulin—the B-cell receptor—and interaction of the B cell with antigen-specific helper T cells. Helper T cells recognize peptide fragments derived from the antigen internalized by the B cells and displayed by the B cells as peptide:MHC class II complexes. Helper T cells stimulate B cells by conjugation in germinal centers, with binding of CD40 ligand on the T cell to CD40 on the B cell, and by their release of various cytokines, such as IL-21. Activated B cells also express molecules, such as B7.2 and ICOSL, that can stimulate T cells. The initial interaction between B and T cells occurs at the border of the T-cell and B-cell areas of secondary lymphoid tissue, to which antigen-activated helper T cells and B cells migrate in response to chemokines. Further interactions between T_{FH} cells and B cells continue after migration into the follicle and the formation of a germinal center.

Fig. 10.26 Properties of different classes of antigen that elicit antibody responses. Some data indicate a minor role for T cells in antibody responses to TI-2 antigens; robust responses to TI-2 antigens can be observed in T cell–deficient mice.

	TD antigen	TI-1 antigen	TI-2 antigen
Antibody response in infants	Yes	Yes	No
Antibody production in congenitally athymic individual	No	Yes	Yes
Antibody response in absence of all T cells	No	Yes	Yes
Primes T cells	Yes	No	No
Polyclonal B-cell activation	No	Yes	No
Requires repeating epitopes	No	No	Yes
Examples of antigen	Diphtheria toxin Viral hemagglutinin Purified protein derivative (PPD) of *Mycobacterium tuberculosis*	Bacterial lipopoly-saccharide *Brucella abortus*	Pneumococcal polysaccharide *Salmonella* polymerized flagellin Dextran Hapten-conjugated Ficoll (polysucrose)

T cells induce a phase of vigorous B-cell proliferation in the germinal center reaction and direct the differentiation of clonally expanded B cells into either antibody-secreting plasma cells or memory B cells. Immunoglobulin genes expressed in B cells are diversified in the germinal center reaction by somatic hypermutation and class switching, initiated by activation-induced cytidine deaminase (AID). Unlike V(D)J recombination, these processes occur only in B cells. Somatic hypermutation diversifies the V region through the introduction of mutations that are selected for providing greater affinity for the antigen as the immune response proceeds. Class switching does not affect the V region but increases the functional diversity of immunoglobulins by replacing the C_μ region in the original immunoglobulin heavy-chain locus with another heavy-chain C region that will produce IgG, IgA, or IgE antibodies. Class switching provides antibodies with the same antigen specificity but distinct effector capacities. The switching to different antibody isotypes is regulated by cytokines released from helper T cells. Some nonprotein antigens stimulate B cells in the absence of linked recognition by peptide-specific helper T cells. Responses to these thymus-independent antigens are accompanied by only limited class switching and do not induce memory B cells. However, such responses have a crucial role in host defense against pathogens whose surface antigens cannot elicit peptide-specific T-cell responses. By contrast, evidence for memory in the TI-2 response is the permanent expansion of antigen-specific nonswitched memory B cells.

The distributions and functions of immunoglobulin classes.

Extracellular pathogens can invade most sites within the body, and so antibodies must be equally widely distributed to combat them. Most classes of antibodies are distributed by diffusion from their site of synthesis, but specialized transport mechanisms are required to deliver antibodies across the epithelial surfaces lining the mucosa of organs such as the lungs and intestine.

The particular heavy-chain isotype of the antibody can either limit antibody diffusion or engage specific transporters that deliver the antibody across epithelia. This part of the chapter describes these mechanisms and the antibody classes that use them to enter compartments of the body where their particular effector functions are appropriate. Here we restrict our discussion to the protective functions of antibodies that result solely from their binding to pathogens, and in the next part of the chapter, we discuss the effector cells and molecules that are specifically engaged by different antibody classes.

10-15 Antibodies of different classes operate in distinct places and have distinct effector functions.

The different classes of antibodies (see Fig. 4.6) are adapted to function in different compartments of the body. The functional activities and distributions for human antibodies are listed in Fig. 10.27. Because a given V region can become associated with any C region through class switching, the clonal progeny of a single B cell can produce antibodies that share the same specificity yet provide all of the protective functions appropriate for each body compartment. All naive B cells express cell-surface IgM and IgD. IgM is the first antibody secreted by activated B cells but is less than 10% of the immunoglobulin found in plasma. Little IgD antibody is produced at any time, while IgE contributes a small but biologically important part of the immune response. IgG and IgA are the predominant antibody classes. The overall predominance of IgG is also due in part to its longer lifetime in the plasma (see Fig. 4.7).

IgM antibodies are produced first in a humoral immune response and tend to be of low affinity. However, IgM molecules form pentamers that are stabilized by a single J-chain molecule (see Fig. 4.8) and have 10 antigen-binding sites, conferring higher overall avidity when binding to multivalent antigens such as bacterial capsular polysaccharides. This higher avidity of the pentamer compensates for the low affinity of the individual antigen-binding site within the IgM monomers. Because of the large size of the pentamers, IgM is found mainly in the bloodstream and, to a lesser extent, in the lymph, rather than in intercellular spaces within tissues. The pentameric structure of IgM makes it especially effective in activating the complement system, as we will see in

Functional activity	IgM	IgD	IgG1	IgG2	IgG3	IgG4	IgA	IgE
Neutralization	+	–	++	++	++	++	++	–
Opsonization	+	–	++	*	++	+	+	–

Sensitization of mast cells	–	–	+	–	+	–	–	+++
Activates complement system	+++	–	++	+	+++	–	+	–

Distribution	IgM	IgD	IgG1	IgG2	IgG3	IgG4	IgA	IgE
Transport across epithelium	+	–	–	–	–	–	+++ (dimer)	–
Transport across placenta	–	–	+++	+	++	+/–	–	–
Diffusion into extravascular sites	+/–	–	+++	+++	+++	+++	++ (monomer)	+
Mean serum level (mg ml^{-1})	1.5	0.04	9	3	1	0.5	2.1	3×10^{-5}

Fig. 10.27 Each human immunoglobulin class has specialized functions and a unique distribution. The major effector functions of each class (+++) are shaded in dark red, whereas lesser functions (++) are shown in dark pink, and very minor functions (+) in pale pink. The distributions are marked similarly, with actual average levels in serum being shown in the bottom row. IgA has two subclasses, IgA1 and IgA2. The IgA column refers to both. *IgG2 can act as an opsonin in the presence of an Fc receptor of the appropriate allotype, found in about 50% of people of Caucasian descent. The correspondence between human and mouse isotypes is as follows: human IgG1 = mouse IgG2a; human IgG2 = mouse IgG3; human IgG3 = mouse IgG2b; human IgG4 = mouse IgG1; human IgA1/2 = mouse IgA.

Section 10-19. In the absence of a J chain, IgM hexamers can also form, and these fix complement more efficiently than do pentamers, possibly because C1q is also a hexamer. However, the *in vivo* role of IgM hexamers in protecting against infections has not been fully established.

Infection of the bloodstream has serious consequences unless it is controlled quickly, and the rapid production of IgM and its efficient activation of the complement system are important in controlling such infections. These adaptive IgM responses are often dependent on T-cell help. Some IgM is produced by conventional B cells that have not undergone class switching, but most is produced by B-1 B cells. In mice, activated B-1 B cells residing in the peritoneal cavity and pleural spaces migrate to the spleen or intestinal lymphoid tissues, where they will mature into plasma cells. These cells secrete antibodies against commonly encountered carbohydrate antigens, including those of bacteria, and do not require T-cell help; they therefore provide a preformed repertoire of IgM antibodies in blood and body cavities that can recognize invading pathogens (see Section 8-10).

Antibodies of the other classes—IgG, IgA, and IgE—are smaller and diffuse easily out of the blood into the tissues. IgA can form dimers (see Fig. 4.8), but IgG and IgE are always monomeric. The affinity of the individual antigen-binding sites for their antigen is therefore critical for the effectiveness of these antibodies, and most of the B cells expressing these classes have been selected in the germinal centers for their increased affinity for antigen after somatic hypermutation.

IgG is the principal class of antibody in human blood and extracellular fluid, whereas IgA is the principal class in secretions, the most important being those from the epithelia lining the intestinal and respiratory tracts. IgG efficiently opsonizes pathogens for engulfment by phagocytes and activates the complement system, but IgA is a less potent opsonin and a weak activator of complement. IgG operates mainly in the tissues, where accessory cells and molecules are available, whereas dimeric IgA operates mainly on epithelial surfaces, where complement and phagocytes are not normally present; therefore, IgA functions chiefly as a neutralizing antibody. Monomeric IgA can be produced by plasma cells that differentiate from class-switched B cells in lymph nodes and spleen, and it acts as a neutralizing antibody in extracellular spaces and in the blood. This monomeric IgA is predominantly of the subclass IgA1; the ratio of IgA1 to IgA2 in the blood is 10:1. The IgA antibodies produced by plasma cells in the gut are dimeric and predominantly of subclass IgA2; the ratio of IgA2 to IgA1 in the gut is 3:2.

Finally, IgE antibody is present only at very low levels in blood or extracellular fluid, but it is bound avidly by receptors on **mast cells** that are found just beneath the skin and mucosa and along blood vessels in connective tissue. Antigen binding to this cell-associated IgE triggers mast cells to release powerful chemical mediators that induce reactions such as coughing, sneezing, and vomiting, which in turn can expel infectious agents, as discussed later in this chapter.

10-16 Polymeric immunoglobulin receptor binds to the Fc regions of IgA and IgM and transports them across epithelial barriers.

In the mucosal immune system, IgA-secreting plasma cells are found predominantly in the lamina propria, which lies immediately below the basement membrane of many surface epithelia. From there the IgA antibodies can be transported across the epithelium to its external surface, for example to the lumen of the gut or of the bronchi (Fig. 10.28). IgA antibody synthesized in the lamina propria is secreted as a dimeric IgA molecule associated with a single

bacterial toxin
pIgR

Fig. 10.28 Dimeric IgA is the major class of antibody present in the lumen of the gut. IgA is synthesized by plasma cells in the lamina propria and transported into the lumen of the gut through epithelial cells at the base of the crypts. pIgR is used to transport IgA across the epithelial cells. Dimeric IgA binds to the layer of mucus overlying the gut epithelium and acts as an antigen-specific barrier to pathogens and toxins in the gut lumen.

J chain. This polymeric form of IgA binds specifically to a receptor called the **polymeric immunoglobulin receptor (pIgR)**, which is present on the basolateral surfaces of the overlying epithelial cells. When the pIgR has bound a molecule of dimeric IgA, the complex is internalized and carried in a transport vesicle through the cytoplasm of the epithelial cell to its luminal surface. This process is called transcytosis. IgM also binds to the pIgR and can be secreted into the gut by the same mechanism. Upon reaching the luminal surface of the enterocyte, the antibody is released into the mucus layer covering the gut lining by proteolytic cleavage of the extracellular domain of the pIgR. The cleaved extracellular domain of the pIgR is known as **secretory component** (frequently abbreviated to **SC**) and remains associated with the antibody. Secretory component is bound to the part of the Fc region of IgA that contains the binding site for the Fcα receptor I, which is why secretory IgA does not bind to this receptor. Secretory component serves several physiological roles. It binds to mucins in mucus, acting as 'glue' to bind secreted IgA to the mucus layer on the luminal surface of the gut epithelium, where the antibody binds and neutralizes gut pathogens and their toxins (see Fig. 10.28). Secretory component also protects the antibodies against cleavage by gut enzymes.

The principal sites of IgA synthesis and secretion are the gut, the respiratory epithelium, the lactating breast, and various other exocrine glands such as the salivary and tear glands. It is believed that the primary functional role of IgA antibodies is to protect epithelial surfaces from infectious agents, just as IgG antibodies protect the extracellular spaces inside tissues. By binding bacteria, including commensal organisms, virus particles, and toxins, IgA antibodies prevent the attachment of bacteria and viruses to epithelial cells and the uptake of toxins. This action provides a first line of defense against a wide variety of pathogens. IgA is also thought to have an additional role in the gut, that of regulating the gut microbiota (see Chapter 12). The alveolar spaces in the lower respiratory tract lack the thicker mucosal layer characteristic of the upper respiratory tract, because efficient gas diffusion would be impeded by a mucus layer covering the alveolar epithelium. IgG can rapidly transudate into these spaces and is the major isotype responsible for protection there.

10-17 The neonatal Fc receptor carries IgG across the placenta and prevents IgG excretion from the body.

Newborn infants are especially vulnerable to infection, having had no previous exposure to the microbes in the environment they enter at birth. IgA antibodies are secreted in breast milk and are transferred to the gut of the newborn infant, where they provide protection from newly encountered bacteria until

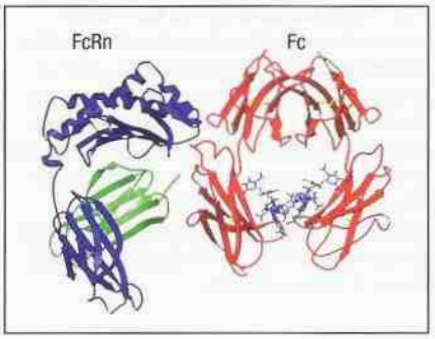

Fig. 10.29 The neonatal Fc receptor (FcRn) binds to the Fc portion of IgG. The structure of a molecule of FcRn (blue) is shown bound to one chain of the Fc portion of IgG (red), at the interface of the $C_\gamma2$ and $C_\gamma3$ domains, with the $C_\gamma2$ region at the top. The b_2-microglobulin component of the FcRn is green. The dark-blue structure attached to the Fc portion of IgG is a carbohydrate chain, reflecting glycosylation. FcRn transports IgG molecules across the placenta in humans and also across the gut in rats and mice. It also has a role in maintaining the levels of IgG in adults. Although only one molecule of FcRn is shown binding to the Fc portion, it is thought that it takes two molecules of FcRn to capture one molecule of IgG.

the infant can synthesize its own protective antibody. IgA is not the only protective antibody that a mother passes on to her baby. Maternal IgG is transported across the placenta directly into the bloodstream of the fetus during intrauterine life; at birth, human babies have levels of plasma IgG as high as those of their mothers, and with the same range of antigen specificities. The selective transport of IgG from mother to fetus is due to an IgG transport protein in the placenta, **FcRn (neonatal Fc receptor)**, which is closely related in structure to MHC class I molecules. Despite this similarity, FcRn binds IgG quite differently from the binding of peptide to MHC class I molecules, because its peptide-binding groove is occluded. It binds to the Fc portion of IgG molecules (Fig. 10.29). Two molecules of FcRn bind one molecule of IgG, bearing it across the placenta. Maternal IgG is ingested by the newborn from its mother's milk and colostrum, the protein-rich fluid secreted by the early postnatal mammary gland. In this case, FcRn transports the IgG from the lumen of the neonatal gut into the blood and tissues. Considerations of the factors that affect antibody binding to FcRn are also important in approaching maternal vaccination as a means of protecting fetuses before birth. FcRn is also found in adults in the gut, liver, endothelial cells, and on podocytes of the kidney glomeruli. Its function in adults is to maintain the levels of IgG in plasma, which it does by binding antibody, endocytosing it, and recycling it to the blood, thus preventing its excretion from the body. In the kidney, expression on podocytes is thought to aid in clearance of IgG from the glomerular basement membrane.

By means of these specialized transport systems, mammals are supplied from birth with antibodies against pathogens common in their environments. As they mature and make their own antibodies of all isotypes, these are distributed selectively to different sites in the body (Fig. 10.30). Thus, throughout life, class switching and the distribution of antibody classes throughout the body provide effective protection against infection in extracellular spaces.

10-18 High-affinity IgG and IgA antibodies can neutralize toxins and block the infectivity of viruses and bacteria.

Pathogens can cause damage to a host by producing toxins or by infecting cells directly, and antibodies can protect by blocking both of these actions. Many bacteria cause disease by secreting toxins that damage or disrupt the function of the host's cells (Fig. 10.31). Many toxins consist of separate domains for exerting toxicity and for binding to specific cell-surface receptors by which they enter cells. Antibodies that bind a toxin's receptor-binding site can prevent cell entry and protect cells from attack (Fig. 10.32). Antibodies that act in this way to neutralize toxins are referred to as **neutralizing antibodies**. Most toxins are active at nanomolar concentrations: a single molecule of diphtheria toxin can kill a cell. To neutralize toxins, therefore, antibodies must be able to diffuse into the tissues and bind the toxin rapidly and with high affinity. The ability of IgG antibodies to diffuse easily throughout the extracellular fluid, and their high affinity for antigen once affinity maturation has taken place, make them the principal antibodies that neutralize toxins in tissues. High-affinity IgA antibodies similarly neutralize toxins at the mucosal surfaces of the body.

Diphtheria and tetanus toxins are two bacterial toxins in which the toxic and receptor-binding functions are on separate protein chains. It is therefore possible to immunize individuals, usually as infants, with modified toxin molecules

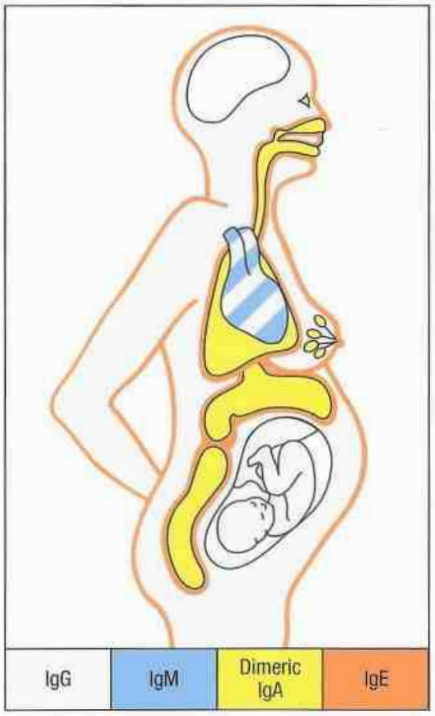

Fig. 10.30 Immunoglobulin classes are selectively distributed in the body. IgG and IgM predominate in blood (shown here for simplicity by IgM and IgG in the heart), whereas IgG and monomeric IgA are the major antibodies in extracellular fluid within the body. Dimeric IgA predominates in secretions across epithelia, including breast milk. The fetus receives IgG from the mother by transplacental transport. IgE is found mainly associated with mast cells just beneath epithelial surfaces (especially of the respiratory tract, gastrointestinal tract, and skin). The brain is normally devoid of immunoglobulin.

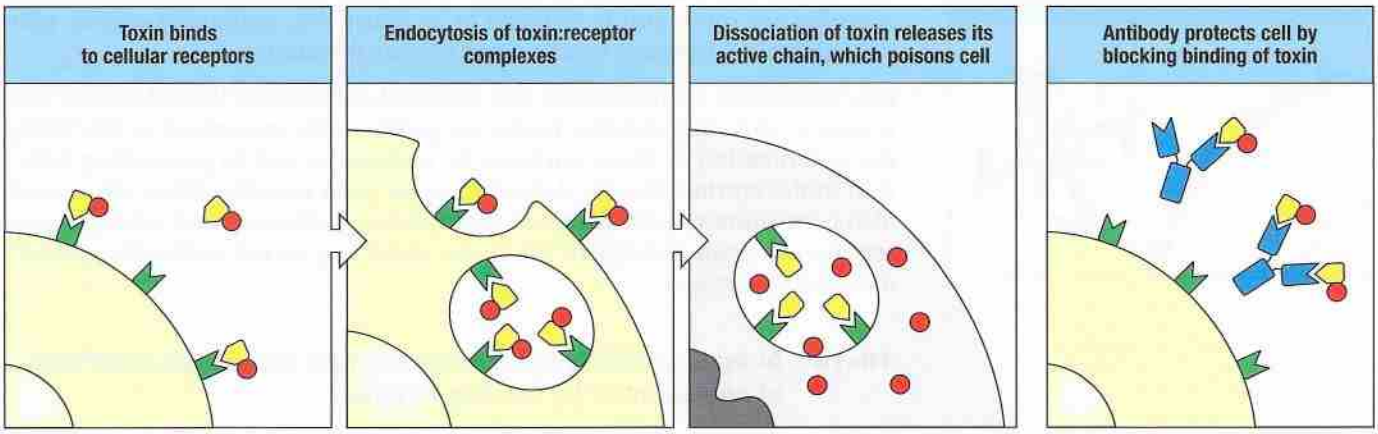
Disease	Organism	Toxin	Effects *in vivo*
Tetanus	*Clostridium tetani*	Tetanus toxin	Blocks inhibitory neuron action, leading to chronic muscle contraction
Diphtheria	*Corynebacterium diphtheriae*	Diphtheria toxin	Inhibits protein synthesis, leading to epithelial cell damage and myocarditis
Gas gangrene	*Clostridium perfringens*	Clostridial toxin	Phospholipase activation, leading to cell death
Cholera	*Vibrio cholerae*	Cholera toxin	Activates adenylate cyclase, elevates cAMP in cells, leading to changes in intestinal epithelial cells that result in loss of water and electrolytes
Anthrax	*Bacillus anthracis*	Anthrax toxic complex	Increases vascular permeability, leading to edema, hemorrhage, and circulatory collapse
Botulism	*Clostridium botulinum*	Botulinum toxin	Blocks release of acetylcholine, leading to paralysis
Whooping cough	*Bordetella pertussis*	Pertussis toxin	ADP-ribosylation of G proteins, leading to lymphoproliferation
		Tracheal cytotoxin	Inhibits cilia and causes epithelial cell loss
Scarlet fever	*Streptococcus pyogenes*	Erythrogenic toxin	Vasodilation, leading to scarlet fever rash
		Leukocidin Streptolysins	Kill phagocytes, allowing bacterial survival
Food poisoning	*Staphylococcus aureus*	Staphylococcal enterotoxin	Acts on intestinal neurons to induce vomiting. Also a potent T-cell mitogen (SE superantigen)
Toxic-shock syndrome	*Staphylococcus aureus*	Toxic-shock syndrome toxin	Causes hypotension and skin loss. Also a potent T-cell mitogen (TSST-1 superantigen)

Fig. 10.31 Many common diseases are caused by bacterial toxins. The toxins shown here are all exotoxins—proteins secreted by the bacteria. High-affinity IgG and IgA antibodies protect against these toxins. Bacteria also have nonsecreted endotoxins, such as lipopolysaccharide, which are released when the bacterium dies and may also mediate pathogenesis of disease.

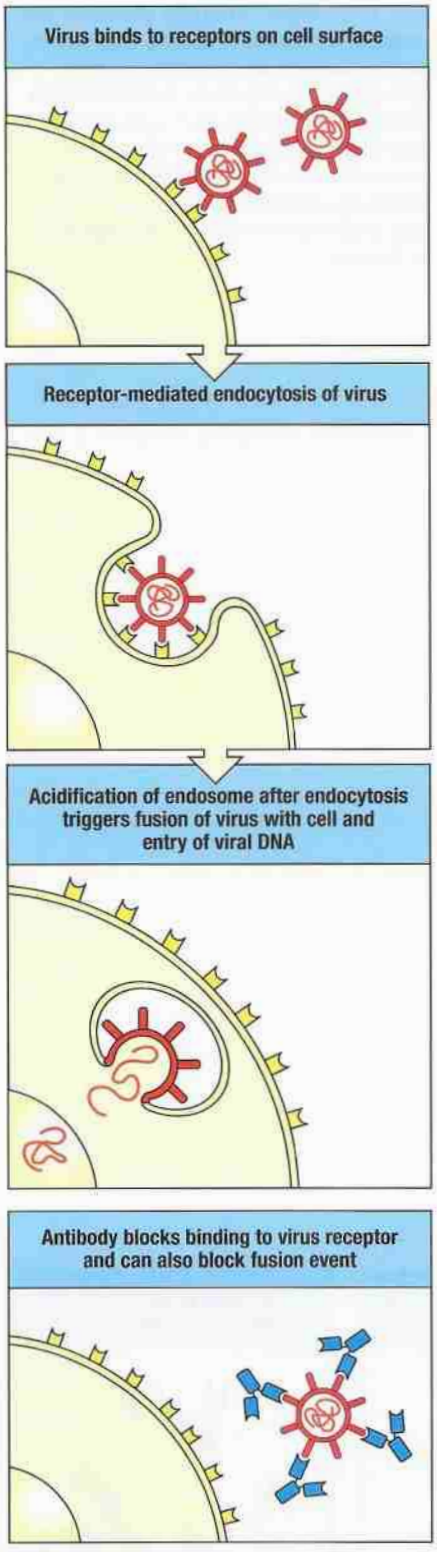
in which the toxic chain has been denatured. These modified toxins, called **toxoids**, lack toxic activity but retain the receptor-binding site. Thus, immunization with the toxoid induces neutralizing antibodies that protect against the native toxin.

Some insect or animal venoms are so toxic that a single exposure can cause severe tissue damage or death. For these toxins, the adaptive immune



Toxin binds to cellular receptors
Endocytosis of toxin:receptor complexes
Dissociation of toxin releases its active chain, which poisons cell
Antibody protects cell by blocking binding of toxin

Fig. 10.32 Neutralization of toxins by IgG antibodies protects cells from damage. The damaging effects of many bacteria are due to the toxins they produce (see Fig. 10.31). These toxins are usually composed of several distinct moieties. One part of the toxin molecule binds a cell-surface receptor, which enables the molecule to be internalized. Another part of the toxin molecule then enters the cytoplasm and poisons the cell. Antibodies that inhibit toxin binding can prevent, or neutralize, these effects.



Virus binds to receptors on cell surface
Receptor-mediated endocytosis of virus
Acidification of endosome after endocytosis triggers fusion of virus with cell and entry of viral DNA
Antibody blocks binding to virus receptor and can also block fusion event

Fig. 10.33 Viral infection of cells can be blocked by neutralizing antibodies. For a virus to multiply within a cell, it must introduce its genes into the cell. The first step in entry is usually the binding of the virus to a receptor on the cell surface. For enveloped viruses, as shown in the figure, entry into the cytoplasm requires fusion of the viral envelope and the cell membrane. For some viruses this fusion event takes place on the cell surface (not shown); for others it can occur only within the more acidic environment of endosomes, as shown here. Non-enveloped viruses must also bind to receptors on cell surfaces, but they enter the cytoplasm by disrupting endosomes. Antibodies bound to viral surface proteins neutralize the virus, inhibiting either its initial binding to the cell or its subsequent entry.

response is too slow to be protective. Exposure to these venoms is a rare event, and protective vaccines have not been developed for use in humans. Instead, neutralizing antibodies are generated by immunizing other species, such as horses, with insect and snake venoms to produce anti-venom antibodies, or **antivenins**. The antivenins are injected into exposed individuals to protect them against the toxic effects of the venom. Transfer of antibodies in this way is known as **passive immunization** (see Appendix I, Section A-30).

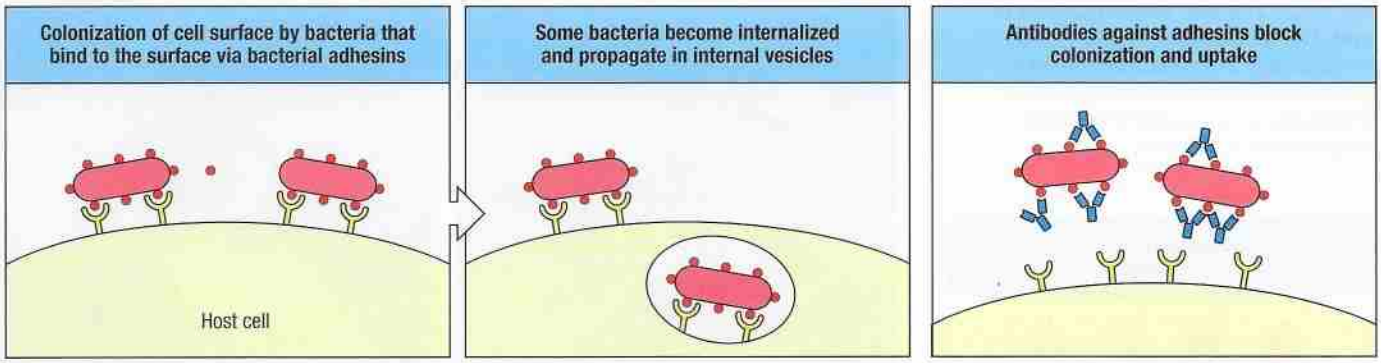
Animal viruses infect cells by binding to a particular cell-surface receptor. These are often cell-type-specific proteins that determine which cells a virus can infect, or its **tropism**. Many antibodies that neutralize viruses do so by directly blocking the binding of virus to surface receptors (Fig. 10.33). The **hemagglutinin** of influenza virus, for example, binds to terminal sialic acid residues on the carbohydrates of glycoproteins present on epithelial cells of the respiratory tract. It is known as hemagglutinin because it recognizes and binds to similar sialic acid residues on chicken red blood cells and agglutinates these red blood cells. Antibodies against the hemagglutinin can prevent infection by the influenza virus. Such antibodies are called **virus-neutralizing antibodies**, and, as with the neutralization of toxins, high-affinity IgA and IgG antibodies are particularly important. In the case of HIV and influenza, so called **broadly neutralizing antibodies** block infection by multiple strains of the virus (see Section 13-35). However, antibodies can also neutralize viruses by interfering with the fusion mechanisms used to enter the cell's cytoplasm after binding to surface receptors.

Many bacteria have cell-surface molecules called **adhesins** that enable them to bind to the surface of host cells. This adherence is crucial to the ability of these bacteria to cause disease, whether they subsequently enter the cell, as do *Salmonella* species, or remain attached to the cell surface as extracellular pathogens (Fig. 10.34). *Neisseria gonorrhoeae*, the causative agent of the sexually transmitted disease gonorrhea, has a cell-surface protein known as **pilin** that enables the bacterium to adhere to the epithelial cells of the urinary and reproductive tracts and is essential to its infectivity. Antibodies against pilin can inhibit this adhesive reaction and prevent infection.

IgA antibodies secreted onto the mucosal surfaces of the intestinal, respiratory, and reproductive tracts are particularly important in inhibiting the colonization of these surfaces by pathogens and in preventing infection of the epithelial cells. Adhesion of bacteria to cells within tissues can also contribute to pathogenesis, and IgG antibodies against adhesins protect tissues from damage in much the same way as IgA antibodies protect mucosal surfaces.

10-19 Antigen:antibody complexes activate the classical pathway of complement by binding to C1q.

Chapter 2 introduced the complement system as an essential component of innate immunity. Complement activation can proceed in the absence of antibody via the **lectin pathway** through the actions of mannose-binding lectin (MBL) and ficolins. But complement is also an important effector of antibody



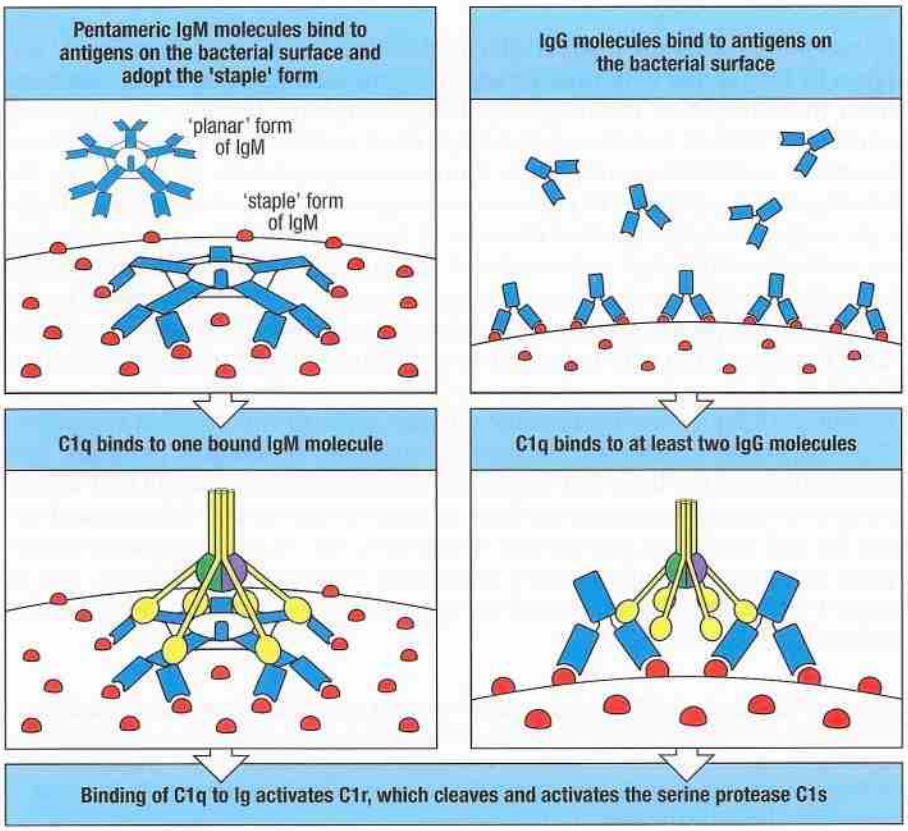
Colonization of cell surface by bacteria that bind to the surface via bacterial adhesins
Host cell
Some bacteria become internalized and propagate in internal vesicles
Antibodies against adhesins block colonization and uptake

Fig. 10.34 Antibodies can prevent the attachment of bacteria to cell surfaces. Many bacterial infections require an interaction between the bacterium and a cell-surface receptor. This is particularly true for infections of mucosal surfaces. The attachment process involves very specific molecular interactions between bacterial adhesins and their receptors on host cells; antibodies against bacterial adhesins can block such infections.

responses via the **classical pathway**. The different pathways of complement activation converge to coat pathogen surfaces or antigen:antibody complexes with covalently attached complement fragment C3b, which acts as an opsonin to promote uptake and removal by phagocytes. In addition, the terminal complement components can form a membrane-attack complex that damages some bacteria.

In the classical pathway, complement activation is triggered by C1, a complex of C1q and the serine proteases C1r and C1s (see Section 2-7). Complement activation is initiated when antibodies that are attached to the surface of a pathogen then bind to C1 via C1q (Fig. 10.35). C1q can be bound by either IgM or IgG antibodies, but, because of the structural requirements of binding to C1q, neither of these antibody classes can activate complement in solution; the complement reactions are initiated only when the antibodies are already bound to multiple sites on a cell surface, normally that of a pathogen.

Each globular head of a C1q molecule can bind to one Fc region, and binding of two or more heads activates the C1 complex. In plasma, the **pentameric**



Pentameric IgM molecules bind to antigens on the bacterial surface and adopt the 'staple' form
'planar' form of IgM
'staple' form of IgM
IgG molecules bind to antigens on the bacterial surface
C1q binds to one bound IgM molecule
C1q binds to at least two IgG molecules
Binding of C1q to Ig activates C1r, which cleaves and activates the serine protease C1s

Fig. 10.35 The classical pathway of complement activation is initiated by the binding of C1q to antibody on a pathogen surface. When a molecule of IgM binds several identical epitopes on a pathogen surface, it is bent into the 'staple' conformation, which allows the globular heads of C1q to bind to the Fc regions of IgM (left panels). Multiple molecules of IgG bound on the surface of a pathogen allow the binding of a single molecule of C1q to two or more Fc regions (right panels). In both cases, the binding of C1q to the Fc regions induces a conformational change that activates the associated C1r, which becomes an active enzyme that cleaves the pro-enzyme C1s, generating a serine protease that initiates the classical complement cascade (see Chapter 2).

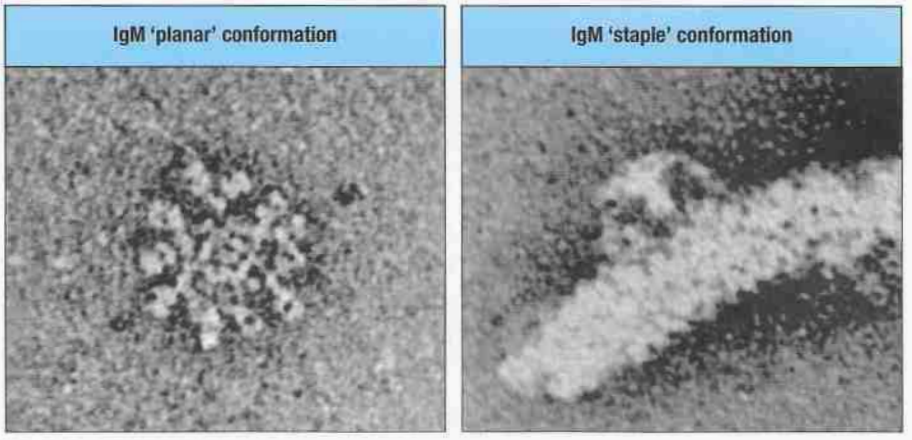


Fig. 10.36 The two conformations of IgM. The left panel shows the 'planar' conformation of soluble IgM; the right panel shows the 'staple' conformation of IgM bound to a bacterial flagellum. Magnification ×760,000.

IgM molecule has a planar conformation that does not bind C1q (**Fig. 10.36**, left panel); however, binding to the surface of a pathogen deforms the IgM pentamer so that it looks like a staple (Fig. 10.36, right panel), and this distortion exposes binding sites for the C1q heads. Although C1q binds with low affinity to some subclasses of IgG in solution, the binding energy required for C1q activation is achieved only when a single molecule of C1q can bind two or more IgG molecules that are held within 30–40 nm of each other as a result of binding antigen. This requires that multiple molecules of IgG be bound to a single pathogen or to an antigen in solution. For this reason, IgM is much more efficient than IgG in activating complement. The binding of C1q to a single bound IgM molecule or to two or more bound IgG molecules (see Fig. 10.35) leads to activation of the protease activity of C1r, triggering the complement cascade.

10-20 Complement receptors and Fc receptors both contribute to removal of immune complexes from the circulation.

Fc receptors confer the distinct effector functions to the various antibody isotypes by interacting with their Fc regions. One such function is the clearance from the circulation of antigen:antibody complexes (immune complexes), which can include toxins or debris from dead host cells and microorganisms bound by neutralizing antibodies. Immune complexes can be cleared by the binding of the antibody's Fc region to Fc receptors expressed on various phagocytic cells in tissues. Another function of Fc receptors is in a process known as antibody-dependent cell-mediated cytotoxicity (ADCC), discussed later in Section 10-23. The clearance of immune complexes by Fc receptors is also helped by complement activation, which occurs when the Fc region activates C1q. The deposition of C4b and C3b onto the immune complex aids clearance by binding to complement receptor 1 (CR1) on the surface of erythrocytes (see Section 2-13 for a description of the different types of complement receptors). The erythrocytes transport the bound complexes of antigen, antibody, and complement to the liver and spleen. Here, macrophages bearing CR1 and Fc receptors remove the complexes from the erythrocyte surface without destroying the cell, and then degrade the complexes (**Fig. 10.37**). Even larger aggregates of particulate antigen, such as bacteria, viruses, and cell debris, can be coated with complement, picked up by erythrocytes, and transported to the spleen for destruction.

Fig. 10.37 Erythrocyte CR1 helps to clear immune complexes from the circulation. CR1 on the erythrocyte surface has an important role in the clearance of immune complexes from the circulation. Immune complexes bind to CR1 on erythrocytes, which transport them to the liver and spleen, where they are removed by macrophages expressing receptors for both Fc and bound complement components.

Complement-coated immune complexes that are not removed from the circulation tend to deposit in the basement membranes of small blood vessels, most notably those of the renal glomerulus, where the blood is filtered to form urine. Immune complexes that pass through the basement membrane of the glomerulus bind to CR1 present on the renal podocytes, which are cells that lie beneath the basement membrane. The functional significance of these receptors in the kidney is unknown; however, they have an important role in the pathology of some autoimmune diseases. In the autoimmune disease **systemic lupus erythematosus (SLE)** (see Section 15-12), excessive levels of circulating immune complexes lead to their deposition in large amounts on the podocytes, damaging the glomerulus; kidney failure is the principal danger in this disease. In mice, the experimental mouse strain known as MRL/lpr develops a disease similar to SLE in humans. In these mice, inhibition of the alternative pathway of complement using a soluble form of **CRIg (complement receptor of the immunoglobulin superfamily)** leads to reduced severity of skin and renal disease. In humans, the strongest genetic risk factor for SLE is C1q deficiency, although this is very rare. Mutations in complement receptors 2 and 3 and the Fc receptor FcγRII-A are also associated with increased susceptibility to develop lupus, implying the involvement of both complement receptors and Fc receptor pathways in clearing immune complexes.

Systemic Lupus Erythematosus

Antigen:antibody complexes can also be a cause of pathology in individuals with deficiencies in the early components of complement (C1, C2, and C4). These deficiencies result in the classical complement pathway not being activated properly and immune complexes not being cleared effectively because they do not become tagged with complement. These individuals also suffer tissue damage as a result of immune-complex deposition, especially in the kidneys.

Summary.

The T cell–dependent antibody response begins with IgM secretion but quickly progresses to the production of additional antibody classes. Each class of antibody is specialized both in its localization in the body and in the functions it can perform. IgM antibodies are found mainly in blood; they are pentameric in structure. IgM is specialized to activate complement efficiently upon binding antigen and to compensate for the low affinity of a typical IgM antigen-binding site. IgG antibodies are usually of higher affinity and are found in blood and in extracellular fluid, where they can neutralize toxins, viruses, and bacteria, opsonize them for phagocytosis, and activate the complement system. IgA antibodies are synthesized as monomers, which enter blood and extracellular fluids, or they are secreted as dimeric molecules by plasma cells in the lamina propria of various mucosal tissues. IgA dimers are selectively secreted into breast milk for delivery to the newborn or transported across the epithelial layer into sites such as the lumen of the gut, where they neutralize toxins and viruses and block the entry of bacteria across the intestinal epithelium. Most IgE antibody is bound to the surface of mast cells that reside mainly just below the body surface; antigen binding to this IgE triggers local defense reactions. Antibodies can defend the body against extracellular pathogens and their toxic products in several ways. The simplest is by direct interactions with pathogens or their products; for example, by binding to the active sites of toxins and neutralizing them or by blocking their ability to bind to host cells through specific receptors. When antibodies of the appropriate isotype bind to antigens, they can activate the classical pathway of complement, which leads to the elimination of the pathogen by the various mechanisms described in Chapter 2. Soluble immune complexes of antigen and antibody also fix complement and are cleared from the circulation via complement receptors on red blood cells.

The destruction of antibody-coated pathogens via Fc receptors.

The neutralization of toxins, viruses, or bacteria by high-affinity antibodies can protect against infection but does not, on its own, solve the problem of how to remove the pathogens and their products from the body. Moreover, many pathogens cannot be neutralized by antibody and must be destroyed by other means. Many pathogen-specific antibodies do not bind to neutralizing targets on pathogen surfaces and thus need to be linked to other effector mechanisms to play their part in host defense. We have already seen how the binding of antibody to antigen can activate complement. Another important defense mechanism is the activation of a variety of **accessory effector cells** bearing Fc receptors, which are specific for the Fc portion of antibodies. These receptors facilitate the phagocytosis of antibody-bound extracellular pathogens by macrophages, dendritic cells, and neutrophils. Other, nonphagocytic cells of the immune system—NK cells, eosinophils, basophils, and mast cells (see Fig. 1.8)—are triggered to secrete stored mediators when their Fc receptors are engaged by antibody-coated pathogens. These mechanisms maximize the effectiveness of all antibodies regardless of where they bind.

10-21 The Fc receptors of accessory cells are signaling receptors specific for immunoglobulins of different classes.

The **Fc receptors** are a family of cell-surface molecules that bind the Fc portion of immunoglobulins. Each member of the Fc family recognizes immunoglobulin of one or a few closely related heavy-chain isotypes through a recognition domain on the α chain of the Fc receptor. Most Fc receptors are themselves members of the immunoglobulin gene superfamily. Different cell types bear different sets of Fc receptors, and the isotype of the antibody thus determines which types of cells will be engaged in a given response. In addition to the isotype, glycosylation of the constant regions can influence how tightly Fc receptors are engaged. The different Fc receptors, the cells that express them, and their specificities for different antibody classes are shown in Fig. 10.38.

Most Fc receptors function as part of a multi-subunit complex. Only the α chain is required for antibody recognition; the other chains are required for transport of the receptor to the cell surface and for signal transduction when an Fc region is bound. Some Fcγ receptors, the Fcα receptor I, and the high-affinity receptor for IgE (FcεRI) all use a γ chain for signaling. This chain, which is closely related to the ζ chain of the T-cell receptor complex (see Section 7-7), associates noncovalently with the Fc-binding α chain. The human FcγRII-A is a single-chain receptor in which the cytoplasmic domain of the α chain replaces the function of the γ chain. These Fc receptors all transduce activating signals by virtue of their immunoreceptor tyrosine-based activation motifs, which become tyrosine phosphorylated upon receptor aggregation and recruit Src and Syk/ZAP-70 family tyrosine kinases. These tyrosine kinases propagate signals downstream. FcγRII-B1 and FcγRII-B2 are also single-chain receptors but function as inhibitory receptors because they contain an immunoreceptor tyrosine-based inhibition motif (ITIM) that engages the inositol 5′-phosphatase SHIP (see Section 7-26). The most prominent function of Fc receptors is the activation of accessory cells to attack pathogens, but they also contribute in other ways to immune responses. For example, FcγRII-B receptors negatively regulate the activities of B cells, mast cells, macrophages, and neutrophils by adjusting the threshold at which immune complexes will activate these cells. Fc receptors expressed by dendritic cells enable them to ingest antigen:antibody complexes efficiently and thus process these antigens and present their peptides to T cells.

Fig. 10.38 Distinct receptors for the Fc region of the different immunoglobulin classes are expressed on different accessory cells. The subunit structure and binding properties of these receptors and the cell types expressing them are shown. All are immunoglobulin superfamily members except FcεRII, which is a lectin and can form trimers. The exact chain composition of any receptor can vary from one cell type to another. For example, FcγRIII in neutrophils is expressed as a molecule with a glycosylphosphatidylinositol membrane anchor without γ chains, whereas in NK cells it is a transmembrane molecule associated with γ chains. The FcγRII-B1 differs from the FcγRII-B2 by the presence of an additional exon in the intracellular region (indicated by yellow triangle). This exon prevents the FcγRII-B1 from being internalized after cross-linking. The binding affinities are taken from data on human receptors. *Only some allotypes of FcγRII-A bind IgG2. †In eosinophils, the molecular mass of the CD89α chain is 70–100 kDa.

Antibody-coated viruses that enter the cytoplasm are cleared by a system that employs a novel class of Fc receptor called **TRIM21 (tripartite motif-containing 21)**, which is expressed by a variety of immune and nonimmune cell types. TRIM21 is a cytosolic IgG receptor that has a higher affinity for IgG than that of any other Fc receptor, and it also has **E3 ligase** activity. When a virus that has bound IgG enters the cytoplasm, TRIM21 attaches to the antibody and uses its E3 ligase activity to ubiquitinate itself. This leads to the delivery of the virus-antibody complex to the proteasome, causing proteasomal degradation of virions in the cytosol before translation of virally encoded genes can occur.

10-22 Fc receptors on phagocytes are activated by antibodies bound to the surface of pathogens and enable the phagocytes to ingest and destroy pathogens.

Macrophages and neutrophils are important Fc-bearing cells in humoral immune responses. Many bacteria that are not pathogenic in normal individuals are directly recognized, ingested, and destroyed by these phagocytic cells. However, some bacterial pathogens have a **polysaccharide capsule**, a large structure that lies outside the bacterial cell membrane and resists direct engulfment by phagocytes. Such pathogens become susceptible to phagocytosis only when they are coated with antibodies and complement, which engage the Fcγ or Fcα receptors and the complement receptor CR1 on phagocytic cells, triggering bacterial uptake (Fig. 10.39). The stimulation of phagocytosis by complement-coated antigens binding to complement receptors is particularly important early in the immune response, before isotype-switched antibodies have been made. Capsular

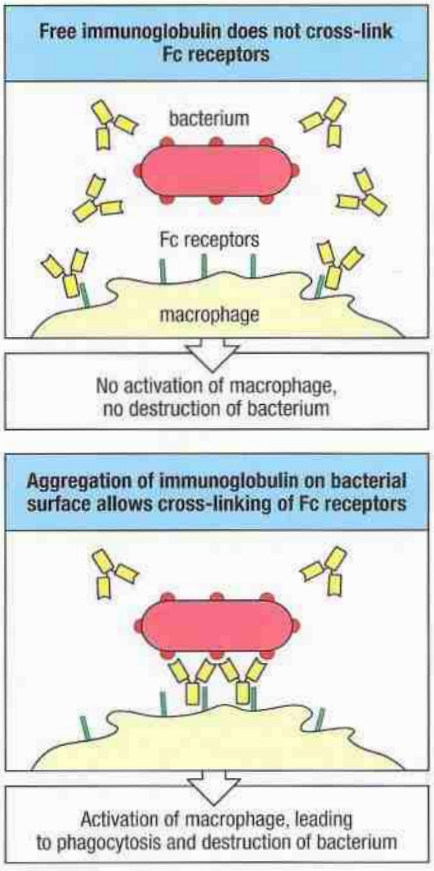
Fig. 10.39 Fc and complement receptors on phagocytes trigger the uptake and degradation of antibody-coated bacteria. Many bacteria resist phagocytosis by macrophages and neutrophils. Antibodies bound to these bacteria, however, enable the bacteria to be ingested and degraded through the interaction of the multiple Fc domains arrayed on the bacterial surface with Fc receptors on the phagocyte surface. Antibody coating also induces activation of the complement system and the binding of complement components to the bacterial surface. These can interact with complement receptors (for example, CR1) on the phagocyte. Fc receptors and complement receptors synergize in inducing phagocytosis. Bacteria coated with IgG antibody and complement are therefore more readily ingested than those coated with IgG alone. Binding of Fc and complement receptors signals the phagocyte to increase the rate of phagocytosis, to fuse lysosomes with phagosomes, and to increase its bactericidal activity.

polysaccharides belong to the TI-2 class of thymus-independent antigens and can therefore stimulate the early production of IgM antibodies, which are very effective at activating the complement system. IgM binding to encapsulated bacteria thus triggers the opsonization of these bacteria by complement and their prompt ingestion and destruction by phagocytes bearing complement receptors. Recently, Fcα/μR was discovered as a receptor that binds both IgA and IgM. Fcα/μR is expressed primarily on macrophages and B cells in the lamina propria of the intestine and in germinal centers. It is thought to have a role in the endocytosis of IgM antibody complexed with bacteria such as *Staphylococcus aureus*.

Phagocyte activation can initiate an inflammatory response that causes tissue damage. It is important that Fc receptors on phagocytes be able to distinguish antibody molecules that are bound to a pathogen from the free antibody molecules that are not bound to anything. This distinction is made possible by the aggregation of antibodies that occurs when they bind to multimeric antigens or to multivalent particulate antigens such as viruses and bacteria. Individual Fc receptors on a cell surface bind monomers of free antibody with low affinity, but when presented with an antibody-coated particle, the simultaneous binding by multiple Fc receptors results in binding of high avidity, and this is the principal mechanism by which bound antibodies are distinguished from free immunoglobulin (Fig. 10.40). The result is that Fc receptors enable cells to detect pathogens via the antibody molecules bound to them. Fc receptors therefore give phagocytic cells that lack intrinsic specificity the ability to identify and remove specific pathogens and their products from the extracellular spaces.

Phagocytosis is greatly enhanced by interactions between the molecules coating an opsonized microorganism and receptors on the phagocyte surface. When an antibody-coated pathogen binds to Fcγ receptors, for example,



Free immunoglobulin does not cross-link Fc receptors
bacterium
Fc receptors
macrophage
No activation of macrophage, no destruction of bacterium
Aggregation of immunoglobulin on bacterial surface allows cross-linking of Fc receptors
Activation of macrophage, leading to phagocytosis and destruction of bacterium

Fig. 10.40 Bound antibody is distinguishable from free immunoglobulin by its state of aggregation. Free immunoglobulin molecules bind most Fc receptors with very low affinity and cannot cross-link Fc receptors. Antigen-bound immunoglobulin, however, binds to Fc receptors with high avidity because several antibody molecules that are bound to the same surface bind to multiple Fc receptors on the surface of the accessory cell. This Fc receptor cross-linking sends a signal to activate the cell bearing it. With Fc receptors that have ITIMs, the result is inhibition.

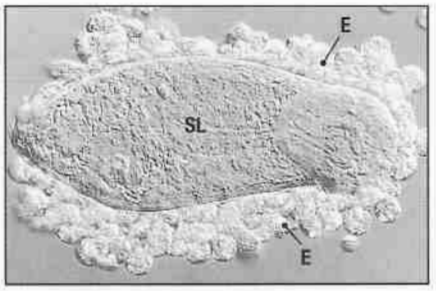


Fig. 10.41 Eosinophil attack on a schistosome parasite is facilitated by specific antibody binding to parasite surface antigens. This electron micrograph is of eosinophils that were obtained from the blood of a healthy donor and incubated with schistosome larvae (SL) and IgG antibodies specific for surface antigens of the larvae. Shown is one larva. In the incubation, antibodies first bind to the larval antigens, which allows numerous eosinophils (E) to bind to the Fc part of the antibodies using their Fcγ receptors. Electron micrograph courtesy of A. Butterworth.

the cell surface of the phagocyte extends around the surface of the pathogen through successive binding of the Fcγ receptors to the antibody Fc regions bound to the pathogen. This is an active process that is triggered by the stimulation of the Fcγ receptors. Phagocytosis leads to enclosure of the pathogen (or particle) in an acidified cytoplasmic vesicle—the phagosome. This then fuses with one or more lysosomes to generate a phagolysosome; lysosomal enzymes are released into the vesicle interior, where they destroy the bacterium (see Fig. 10.39). The process of intracellular killing by phagocytes was described in more detail in Chapter 3.

Some particles are too large for a phagocyte to ingest; parasitic worms are one example. In this case, the phagocyte attaches to the surface of the antibody-coated parasite via its Fcγ, Fcα, or Fcε receptors, and the contents of the secretory granules or lysosomes of the phagocyte are released by exocytosis. The contents are discharged directly onto the surface of the parasite and damage it. Thus, stimulation of Fcγ and Fcα receptors can trigger either the internalization of external particles by phagocytosis or the externalization of internal vesicles by exocytosis. The principal leukocytes involved in the destruction of bacteria are macrophages and neutrophils, whereas large parasites such as helminths are usually attacked by eosinophils (Fig. 10.41), nonphagocytic cells that can bind antibody-coated parasites via several different Fc receptors, including the low-affinity Fcε receptor for IgE, CD23 (see Fig. 10.38). Cross-linking of these receptors by antibody-coated surfaces activates the eosinophil to release its granule contents, which include proteins toxic to parasites (see Fig. 14.10). Cross-linking by antigen of IgE bound to the high-affinity FcεRI on mast cells and basophils also results in exocytosis of their granule contents, as we describe later.

10-23 Fc receptors activate NK cells to destroy antibody-coated targets.

Virus-infected cells are usually destroyed by T cells that recognize virus-derived peptides bound to cell-surface MHC molecules. But in addition, cells infected by some viruses can signal the presence of infection by their expression of viral envelope proteins on their cell surface. Such proteins can be recognized by antibodies originally produced against the virus particle. Host cells with such antibodies bound to them can be killed by NK cells, which we described in Chapter 3. Recall that NK cells express a limited repertoire of invariant receptors recognizing a range of ligands that are induced on abnormal cells, such as those infected with viruses. On recognition of a ligand, NK cells kill the target cells directly without the need for antibody.

As well as this innate function, NK cells can recognize and destroy antibody-coated target cells in a process called **antibody-dependent cell-mediated cytotoxicity (ADCC)**. This is triggered when antibody bound to the surface of a cell interacts with Fc receptors on the NK cell (Fig. 10.42). NK cells express the receptor FcγRIII (CD16), which recognizes the IgG1 and IgG3 subclasses. The killing mechanism is analogous to that of cytotoxic T cells, involving the release of cytoplasmic granules containing perforin and granzymes (see Section 9-22). ADCC has been shown to have a role in the defense against infection by viruses and represents another mechanism by which antibodies can direct an antigen-specific attack by an effector cell that itself lacks

killing

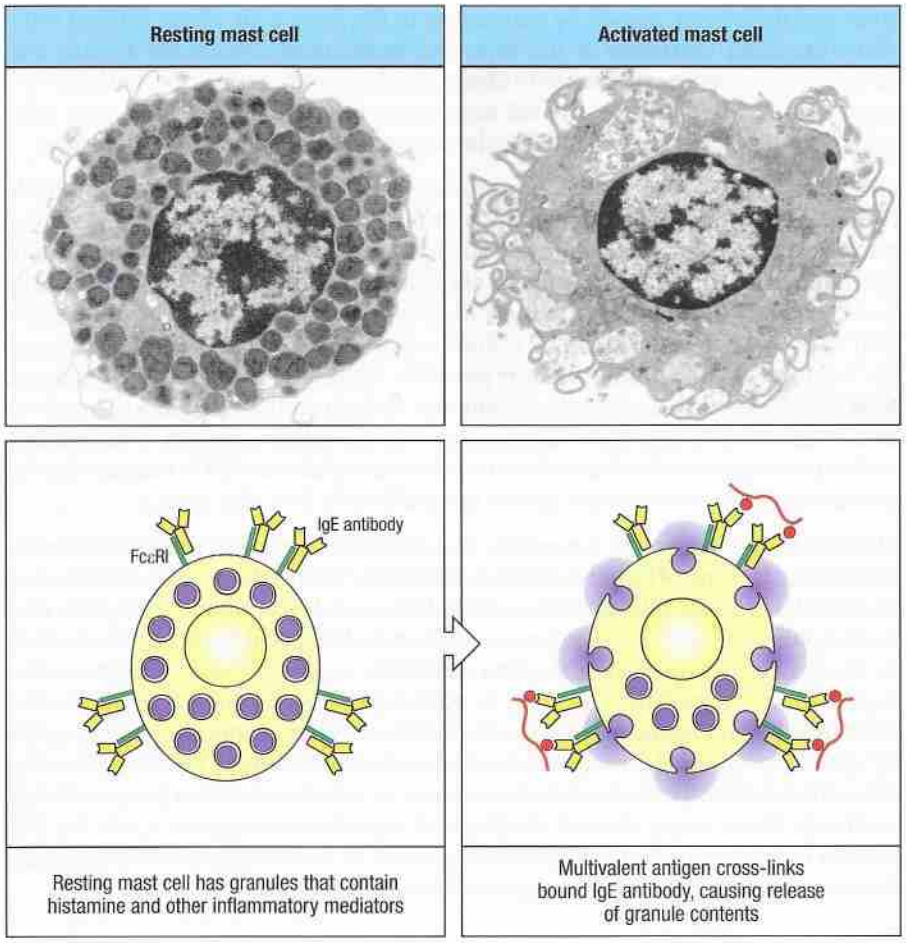
Fig. 10.42 Antibody-coated target cells can be killed by NK cells in antibody-dependent cell-mediated cytotoxicity (ADCC). NK cells (see Chapter 3) are large granular non-T, non-B lymphoid cells that have FcγRIII (CD16) on their surface. When these cells encounter cells coated with IgG antibody, they rapidly kill the target cell. ADCC is only one way in which NK cells can contribute to host defense.

specificity for antigen. ADCC carried out by NK cells is being considered as a potential immunotherapeutic approach in treating cancer by directing their lytic activity to cells expressing tumor-specific antigens.

10-24 Mast cells and basophils bind IgE antibody via the high-affinity Fcε receptor.

When pathogens breach an epithelial barrier, one important host defense relies on the activation of mast cells. These cells are found in particularly high concentrations in vascularized connective tissues just beneath epithelial surfaces, including the submucosal tissues of the gastrointestinal and respiratory tracts and the dermis of the skin. These large cells (see Fig. 1.8) have distinctive cytoplasmic granules that contain a mixture of chemical mediators, including histamine, that act rapidly to make local blood vessels more permeable. Mast cells have Fc receptors specific for IgE (FcεRI) and IgG (FcγRIII) and can be activated to release their granules and to secrete lipid inflammatory mediators and cytokines via antibody bound to these receptors. Most Fc receptors bind stably to the Fc regions of antibodies only when the antibodies have themselves bound antigen, and cross-linking of multiple Fc receptors is needed for strong binding. In contrast, FcεRI binds IgE antibody monomers with a very high affinity—approximately 10^{10} M^{-1}. Thus, even at the low levels of circulating IgE present in normal individuals, a substantial portion of the total IgE is bound to the FcεRI that is expressed on mast cells in tissues and on circulating basophils.

Mast cells are not directly activated by the binding of IgE to their FcεRI or by the binding of monomeric antigen to this IgE. Mast-cell activation occurs only when the bound IgE is cross-linked by multivalent antigens. This signal activates the mast cell to release the contents of its granules, which occurs in seconds (Fig. 10.43), to synthesize and release lipid mediators such as prostaglandin D2 and leukotriene C4, and to secrete cytokines such as TNF-α, thereby initiating a local inflammatory response. The release of stored histamine increases local blood flow and vascular permeability, which quickly leads to an accumulation of fluid and blood proteins, including antibodies, in the surrounding tissue. Shortly afterward there is an influx of blood-borne cells such as neutrophils and, later, monocytes, eosinophils, and effector lymphocytes. This influx can last from a few minutes to a few hours and produces an inflammatory response at the site of infection. Beyond their role as a front-line host defense against pathogens at epithelial barriers, mast cells are also



Resting mast cell
Activated mast cell

FcεRI
Resting mast cell has granules that contain histamine and other inflammatory mediators
Multivalent antigen cross-links bound IgE antibody, causing release of granule contents

Fig. 10.43 IgE antibody cross-linking on mast-cell surfaces leads to a rapid release of inflammatory mediators. Mast cells are large cells found in connective tissue and can be distinguished by their secretory granules, which contain many inflammatory mediators. They bind stably to monomeric IgE antibodies through the very high-affinity receptor FcεRI. Antigen cross-linking of the bound IgE antibody molecules triggers rapid degranulation, releasing inflammatory mediators into the surrounding tissue. These mediators trigger local inflammation, which recruits cells and proteins required for host defense to sites of infection. These cells are also triggered during allergic reactions when allergens bind to IgE on mast cells.

of medical importance because of their involvement in IgE-mediated allergic responses, discussed in Chapter 14. In allergic responses, mast cells are activated by exposure to normally innocuous antigens (allergens), such as pollen, to which the individual has previously mounted a sensitizing immune response that produces allergen-specific IgE.

10-25 IgE-mediated activation of accessory cells has an important role in resistance to parasite infection.

Mast cells are thought to serve at least three important functions in host defense. First, their location near body surfaces allows them to recruit both pathogen-specific elements, such as antigen-specific lymphocytes, and nonspecific effector elements, such as neutrophils, macrophages, basophils, and eosinophils, to sites where infectious agents are most likely to enter the internal milieu. Second, the inflammation they cause increases the flow of lymph from sites of antigen deposition to the regional lymph nodes, where naive lymphocytes are first activated. Third, the ability of mast-cell products to trigger muscular contraction can contribute to the physical expulsion of pathogens from the lungs or the gut. Mast cells respond rapidly to the binding of antigen to surface-bound IgE antibodies, and their activation leads to the initiation of an inflammatory response and the recruitment and activation of basophils and eosinophils, which contribute further to the inflammatory response (see Chapter 14). IgE-mediated responses are important in the defense against parasite infestation.

A role for mast cells in the clearance of parasites is suggested by the accumulation of mast cells in the intestine, known as **mastocytosis**, that accompanies helminth infection, and by observations in W/W^V mutant mice, which have a profound

mast-cell deficiency caused by a mutation in the gene c-*kit*. These mutant mice show impaired clearance of the intestinal nematodes *Trichinella spiralis* and *Strongyloides* species. Clearance of *Strongyloides* is even more impaired in W/W^V mice that lack IL-3 and so also fail to produce basophils. Thus, both mast cells and basophils seem to contribute to defense against these helminth parasites.

Other evidence points to the importance of IgE antibodies and eosinophils in the defense against parasites. Infection with certain types of multicellular parasites, particularly helminths, is strongly associated with the production of IgE antibodies and the presence of abnormally large numbers of eosinophils (eosinophilia) in blood and tissues. Furthermore, experiments in mice show that depletion of eosinophils by polyclonal anti-eosinophil antisera increases the severity of infection with the parasitic helminth *Schistosoma mansoni*. Eosinophils seem to be directly responsible for helminth destruction; examination of infected tissues shows degranulated eosinophils adhering to helminths, and experiments *in vitro* have shown that eosinophils can kill *S. mansoni* in the presence of anti-schistosome IgG or IgA antibodies (see Fig. 10.41).

The role of IgE, mast cells, basophils, and eosinophils can also be seen in resistance to the feeding of blood-sucking ixodid ticks. Skin at the site of a tick bite has degranulated mast cells and an accumulation of degranulated basophils and eosinophils, an indicator of recent activation. Subsequent resistance to feeding by these ticks develops after the first exposure, suggesting a specific immunological mechanism. Mice deficient in mast cells show no such acquired resistance to ticks, and in guinea pigs the depletion of either basophils or eosinophils by specific polyclonal antibodies also reduces resistance to tick feeding. Finally, experiments in mice showed that resistance to ticks is mediated by specific IgE antibody. Thus, many clinical studies and experiments support a role for this system of IgE bound to the high-affinity FcεRI in host resistance to pathogens that enter across epithelia or exoparasites such as ticks that breach it.

Summary.

Antibody-coated pathogens are recognized by effector cells through Fc receptors that bind to various antibody C regions. Binding activates the cell and triggers destruction of the pathogen, through either phagocytosis, granule release, or both. Fc receptors compose a family of proteins, each of which recognizes particular antibody classes, or isotypes. Fc receptors on macrophages and neutrophils recognize the constant regions of IgG or IgA antibodies bound to a pathogen and trigger the engulfment and destruction of such bacteria. Binding to the Fc receptor also induces the production of microbicidal agents in the intracellular vesicles of the phagocyte. Eosinophils are important in the elimination of parasites too large to be engulfed; they bear Fc receptors specific for the constant region of IgG, as well as receptors for IgE; aggregation of these receptors triggers the release of toxic substances onto the surface of the parasite. NK cells, tissue mast cells, and blood basophils also release their granule contents when their Fc receptors are engaged. The high-affinity receptor for IgE is expressed constitutively by mast cells and basophils and can bind free monomeric antibody. When IgE bound to a mast cell is cross-linked by multivalent antigens, it triggers the release of histamine and other mediators that increase the blood flow to sites of infection, thus enabling an immediate response to pathogens at their site of first entry. Mast cells are found principally below epithelial surfaces of the skin and beneath the basement membrane of the digestive and respiratory tracts.

Summary to Chapter 10.

The humoral immune response to infection involves the production of antibody by plasma cells derived from B lymphocytes, the binding of this antibody

to the pathogen, and the elimination of the pathogen by phagocytic cells and molecules of the humoral immune system. The production of antibody typically involves help from CD4 T cells that are reactive to a peptide fragment of the antigen recognized by the B cell, a phenomenon called linked recognition. An activated B cell first moves to the T-zone–B-zone boundary in secondary lymphoid tissues, where it may encounter its cognate T cell and begin to proliferate. Some B cells become plasmablasts, while others move to the germinal center, where somatic hypermutation and class switch recombination can take place. B cells that bind antigen with the highest affinity are selected for survival and further differentiation, leading to affinity maturation of the antibody response. Cytokines made by helper T cells direct class switching, leading to the production of antibody of various classes that can be distributed to various body compartments.

IgM antibodies are produced early in an infection by conventional B cells and are also made in the absence of infection by subsets of nonconventional B cells in particular locations (as natural antibodies). IgM has a major role in protecting against infection in the bloodstream, whereas isotypes secreted later in an adaptive immune response, such as IgG, diffuse into the tissues. Antigens that have highly repeating antigenic determinants and which contain mitogens—called TI antigens—can elicit IgM and some IgG independently of T-cell help, and this provides an early protective immune response. Multimeric IgA is produced in the lamina propria and is transported across epithelial surfaces, whereas IgE is made in small amounts and binds avidly to receptors on the surface of basophils and mast cells.

Antibodies that bind with high affinity to critical sites on toxins, viruses, and bacteria can neutralize them. However, pathogens and their products are destroyed and removed from the body largely through uptake into phagocytes and degradation inside these cells. Antibodies that coat pathogens bind to Fc receptors on phagocytes, which are thereby triggered to engulf and destroy the pathogen. Binding of antibody C regions to Fc receptors on other cells leads to the exocytosis of stored mediators; this is particularly important in parasite infections, in which Fcε-expressing mast cells are triggered by the binding of antigen to IgE antibody to release inflammatory mediators directly onto parasite surfaces. Antibodies can also initiate the destruction of pathogens by activating the complement system. Complement components can opsonize pathogens for uptake by phagocytes and recruit phagocytes to sites of infection. Receptors for complement components and Fc receptors often synergize in activating the uptake and destruction of pathogens and immune complexes. Thus, the humoral immune response is targeted to the infecting pathogen through the production of specific antibody; however, the effector actions of that antibody are determined by its heavy-chain isotype.

Discussion Questions

10.1 Describe the differences between thymus-dependent (TD) and thymus-independent (TI) antigens. What kind of T cells provide help for activation of naive B cells in response to TD antigens, and by what mechanism?

10.2 What is meant by linked recognition regarding T-cell help for B-cell responses? In what way is this process a 'coincidence detector,' and what advantages does this process provide?

10.3 What part of the antibody molecule determines its particular effector function? Compare and contrast the properties of the IgM and the various IgG isotypes.

10.4 The locations of T and B cells change during a TD antibody response. Describe the mechanisms that regulate their movement at the various stages of a response.

10.5 Describe the processes that regulate the cyclic reentry of centroblasts and centrocytes between the light and dark zones of the germinal center reaction.

10.6 Somatic hypermutation induced by AID in activated B cells is converted into affinity maturation by selective processes in the germinal center. Describe these processes and explain how they lead to enhanced antibody affinity for antigen.

10.7 Which class of antibody is responsible for activation of mast cells, and how does this process occur? What type of pathogens is this class of antibody directed against, and what undesirable reactions can these antibodies cause?

10.8 Describe the interaction between antibodies and the complement system, and explain how this interaction aids in the elimination of pathogens.

10.9 What classes of maternal antibodies are found in breast milk, and how are they transported to the newborn? Birds possess this class of antibody and secrete it into the crop milk they feed to their offspring. What does this fact indicate about mammalian evolution?

Integrated Dynamics of Innate and Adaptive Immunity

11

Throughout this book we have examined the separate ways in which the innate and the adaptive immune responses protect against invading pathogens. In this chapter, we consider how the cells and molecules of the immune system work as an integrated defense system to eliminate or control different types of infectious agents, and also how the adaptive immune system provides long-lasting protective immunity. In Chapters 2 and 3, we saw how innate immunity is brought into play in the earliest phases of an infection and is probably sufficient to prevent colonization of the body by most microorganisms encountered in the environment. We also introduced **innate lymphoid cells (ILCs)**, which, although lacking antigen-specific receptors, have many of the same functional features as effector CD4 T-cell subsets and cytotoxic CD8 T cells and act early during infection to generate distinct types of immune responses to different types of pathogens. Although present in many tissues, ILCs are most abundant in barrier tissues, such as the intestinal and respiratory mucosae, which they populate in the perinatal period and where they reside throughout life, poised to respond rapidly to pathogens to impair or eliminate their spread at these major sites of entry.

However, most pathogens have developed strategies to evade innate immune defenses and establish a focus of infection. In these circumstances, the innate immune response sets the stage for the induction of an adaptive immune response, which is orchestrated by signals that emanate from innate immune sensor cells, such as conventional dendritic cells (cDCs), and is coordinated with innate immune effector cells to bring about pathogen clearance. In the **primary immune response**, which occurs against a pathogen encountered for the first time, tissue-resident ILCs respond rapidly to cytokines that are released by innate immune sensor cells at the site of infection to bias the recruitment of circulating innate immune effector cells toward those most appropriate for limiting pathogen growth and dissemination over the first few hours to days of invasion. Concurrent with this response, clonal expansion and differentiation of naive lymphocytes into effector T cells and antibody-secreting B cells is initiated in secondary lymphoid organs. However, the adaptive response requires several days to weeks to fully mature, largely due to the rarity of antigen-specific precursor cells that must increase their numbers and functionality over the early course of infection. After their clonal expansion and initial differentiation in the secondary lymphoid tissues, effector T cells migrate to sites of infection where, along with pathogen-specific antibodies, they enhance the recruitment and functions of innate immune effector cells and, in most cases, effectively target the pathogen for elimination (Fig. 11.1).

During this period, specific **immunological memory** is also established by adaptive immune cells. This ensures a rapid reinduction of antigen-specific antibody and effector T cells on encounter with the same pathogen during a **secondary (or recall) immune response**, thus providing long-lasting and often lifelong protection against the pathogen. Immunological memory is discussed in the last part of this chapter. Memory responses differ in several ways from primary responses. We discuss the reasons for this, and what is known about how immunological memory is maintained.

IN THIS CHAPTER

Integration of innate and adaptive immunity in response to specific types of pathogens.

Effector CD4 T cells augment the effector functions of innate immune cells.

Immunological memory.

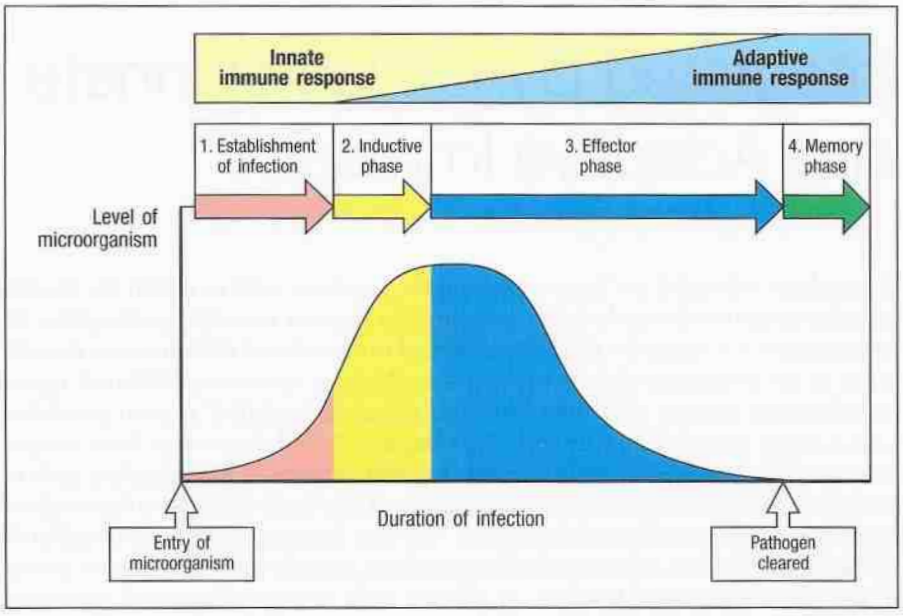

Fig. 11.1 The course of a typical acute infection that is cleared by an adaptive immune response. 1. The infectious agent colonizes, and its numbers increase as it replicates. The innate immune response is initiated immediately after detection of the pathogen. 2. When antigens from the pathogen are presented by dendritic cells to lymphocytes, the adaptive immune response is initiated; the pathogen continues to grow, restrained by responses of the innate immune system. At this stage, immunological memory also starts to be induced. 3. After 4–7 days, effector cells and molecules of the adaptive immune response begin to contribute to the host response and act to clear the infection. 4. When the infection has been cleared and antigen becomes undetectable, the immune response ceases, but persistent antibody and memory T and B cells provide lasting protection against reinfection in most cases.

Integration of innate and adaptive immunity in response to specific types of pathogens.

The immune response is dynamic, and both its nature and intensity change over time. It begins with the antigen-independent responses of innate immunity and becomes both more focused on the pathogen and more potent as the antigen-specific adaptive immune response matures. The character of the response differs contingent on the type of pathogen encountered. Different types of pathogens (intracellular and extracellular bacteria, viruses, helminth parasites, and fungi) elicit different types of immune response (types 1, 2, 3, or cytotoxic), so that the most appropriate immune response is induced for effective elimination of the pathogen. The innate immune system not only participates in the initiation of adaptive T and B cell responses but also provides effector cells from the blood (for example, monocytes, eosinophils, and neutrophils) and reinforces pathways of the different types of immunity throughout infection. Early in the response, different subsets of innate lymphoid cells—already resident in tissues since fetal development—are activated by cytokines produced by innate sensor cells. This early activation of ILCs acts to constrain pathogen entry at the initial site of infection and prevent dissemination while the adaptive response develops. However, the more sensitive and specific actions of effector T cells and class-switched, affinity-matured antibodies are often required for the complete elimination of infection, known as **sterilizing immunity**. In this part of the chapter, we provide an overview of how the different phases of an immune response are orchestrated in space and time and then discuss how distinct cytokines from innate sensor cells activate different innate lymphoid cell subsets to restrain pathogen invasion and direct pathogen-specific defenses while the adaptive response is developing.

11-1 The course of an infection can be divided into several distinct phases.

Although some pathogen-associated molecular patterns (PAMPs) of different types of pathogens are shared, others are not. These differences contribute to the induction of four distinct patterns, or 'modules,' of innate and adaptive

immunity, which can be broadly grouped into two subsets, cytotoxic or helper responses, with the latter comprising types 1, 2, and 3, as will be discussed in the next section. Irrespective of the inciting pathogen and the pattern of immune response it provokes, however, the tempo of the host response is similar and can be broken down into various stages (see Fig. 11.1, and see Fig. 3.37).

In the first stage of infection, a new host is exposed to infectious agents either shed by an infected individual or present in the environment. The numbers, route of transmission, mode of transmission, and stability of an infectious agent outside the host determine its infectivity. The first contact with a new host occurs through an epithelial surface, such as the skin or the mucosal surfaces of the respiratory, gastrointestinal, or urogenital tracts. After making contact, an infectious agent must establish a focus of infection. It must either adhere to the epithelial surface and colonize it or penetrate it to replicate in the tissues (Fig. 11.2). Bites by arthropods (insects and ticks) and wounds breach the epidermal barrier and help some microorganisms gain entry through the skin.

Only when a microorganism has successfully established a focus of infection in the host does disease occur (see Fig. 11.2). With few exceptions, little damage will be caused unless the pathogen spreads from the original focus or secretes toxins that spread to other parts of the body. Extracellular pathogens spread by direct extension of the infection through the lymphatics or the bloodstream. Although some pathogens have evolved mechanisms to use blood cells to ferry them to other organs, spread into the bloodstream usually occurs only after the lymphatic system has been overwhelmed. Obligate intracellular pathogens spread from cell to cell; they do so either by direct transmission from one cell to the next or by release into the extracellular fluid and reinfection of both adjacent and distant cells. Facultative intracellular pathogens can do the same

Fig. 11.2 Infections and the responses to them can be divided into a series of stages. These stages are illustrated for a pathogenic microorganism (red) entering across a wound in an epithelium. The microorganism first adheres to epithelial cells and then invades beyond the epithelium into underlying tissues (first panel). A local innate immune response helps to contain the infection and delivers antigen and antigen-loaded dendritic cells to lymphatics (second panel) and then to local lymph nodes (third panel). This leads to an adaptive immune response in the lymph node that involves the activation and differentiation of T cells and B cells with the eventual production of effector T cells and antibody, which coordinate with innate immune cells to clear the infection (fourth panel).

after a period of survival in the extracellular environment. In contrast, some of the bacteria that cause gastroenteritis exert their effects without spreading into the tissues. They establish a site of infection on the luminal surface of the epithelium lining the gut and cause pathology by damaging the epithelium or by secreting toxins that cause damage either *in situ* or after crossing the epithelial barrier and entering the circulation.

The establishment of a focus of infection in tissues and the response of the innate immune system produces changes in the immediate environment. Many microorganisms are repelled or kept in check at this stage by innate defenses, which are triggered by stimulation of the various germline-encoded pattern-recognition receptors expressed by innate sensor cells—such as epithelial cells, tissue-resident mast cells, macrophages, and dendritic cells (see Chapters 2 and 3). Cytokines and chemokines produced by pathogen-activated innate sensor cells initiate local inflammation and activate ILCs. These responses are activated within minutes to hours and are sustained for at least several days. The inflammatory response is induced through activation of the endothelium of local postcapillary venules to express selectins, integrin ligands, and chemokines recognized by circulating granulocytes and monocytes (**myelomonocytic cells**; see Fig. 3.30). This leads to the recruitment of these circulating innate effector cells, particularly neutrophils and monocytes, thereby increasing the numbers of phagocytes available for microbe clearance. As monocytes enter tissue and become activated, additional inflammatory cells are attracted into the infected tissue so that the inflammatory response is maintained and reinforced. Leakiness of the inflamed endothelium also leads to the influx of serum proteins, including complement, activation of which in a primary infection occurs mainly via the alternative and lectin pathways (see Fig. 2.15). This results in the production of the anaphylatoxins C3a and C5a, which further activate the vascular endothelium, and C3b, which opsonizes microbes for more effective clearance by recruited phagocytes. Some aspects of this early phase of the inflammatory response are nonspecific for the type of pathogen, whereas others are not.

Concordant with the production of pro-inflammatory cytokines such as TNF-α and IL-1β, which activate nonspecific inflammation, innate sensor cells produce additional cytokines that differentially activate specific subsets of ILCs within the first hours of an infection. This is due to the expression of unique PAMPs—or unique combinations of PAMPs—by different types of pathogens, which elicit different patterns of cytokines from innate sensor cells. This has important consequences in directing the type of immune response that will be mounted against the pathogen, as subsets of ILCs are differentially activated to produce their own effector cytokines and chemokines contingent on the pattern of cytokines produced by innate sensor cells (**Fig. 11.3**).

The products of activated ILCs clearly amplify and coordinate local innate responses that are better tailored to resist specific types of pathogens, and they also alter the recruitment and maturation of different myelomonocytic (granulocyte–monocyte) innate effector cells at the site of infection. It is less clear whether cytokines produced by ILCs may also guide the development of naive T cells into distinct effector subsets (for example, T_H1, T_H2, or T_H17 cells)—either directly, by acting on activated naive T cells themselves, or indirectly, by modulating the activation of conventional dendritic cells (cDCs) that migrate to regional lymphoid tissues to prime naive T cells. The lack of experimental approaches to specifically deplete ILC subsets without similarly depleting corresponding T-cell subsets with which they share specific cytokines and transcription factors has made it difficult to assess the role of ILCs in guiding the development of effector T cells. However, although ILCs are found in secondary lymphoid organs in small numbers, they are highly abundant in barrier tissues, and it seems likely that if ILCs do play a role in effector T-cell lineage specification, it may be via effects of their cytokines on modulating activation

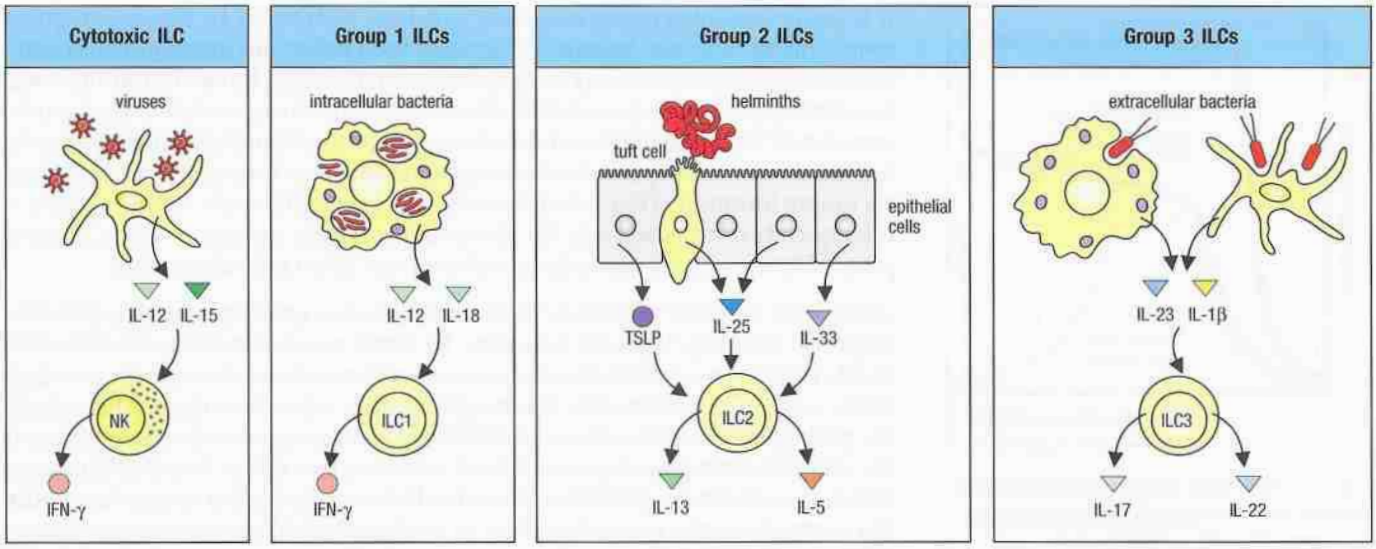

Fig. 11.3 Cytokines produced by innate sensor cells activate innate lymphoid cells (ILCs). The microbial-associated molecular patterns (MAMPs) expressed by different types of pathogens stimulate distinct cytokine responses from innate sensor cells, such as dendritic cells, macrophages, or epithelial cells—including specialized tuft cells present in mucosae that sense small molecules produced by helminths. These cells, in turn, stimulate different subsets of ILCs to produce different effector cytokines that act to coordinate and amplify the innate response.

of migratory cDCs. In any case, ILCs perform an important function during the first few days of an emerging immune response to coordinate the type of innate defense that is most effective at restraining pathogen growth while buying time for the adaptive response to occur.

Adaptive immunity is triggered when an infection eludes or overwhelms innate defenses (see Fig. 11.1). Adaptive immune responses are initiated in the local lymphoid tissue in response to antigens presented by dendritic cells activated during the course of the innate immune response (see Fig. 11.2, second and third panels). Antigen-specific effector T cells and antibody-secreting B cells are generated by clonal expansion and differentiation over several days, as innate responses orchestrated by ILCs 'buy time' for the adaptive response to mature. Within several days of infection, antigen-specific T cells and then antibodies are released into the blood and from there can enter the site of infection (see Fig. 11.2, fourth panel). Adaptive responses amplify innate defenses and confer antigen-specific targeting by innate effector mechanisms that can eliminate pathogens more precisely. For example, antibodies can activate complement to directly kill pathogens, can opsonize pathogens for enhanced phagocytosis, and can arm Fc-bearing innate effector cells for release of microbicidal factors or recruit the cytocidal actions of natural killer (NK) cells, an action called antibody-dependent cell-mediated cytotoxicity (ADCC). Effector CD8 T cells can directly kill antigen-bearing target cells via similar cytocidal cytotoxic actions, and effector CD4 T cells can directly release cytokines onto macrophages to enhance their microbicidal actions.

Resolution of the infection typically involves complete clearance of the pathogen—and thus the source of antigens—over the course of days to weeks, following which most effector lymphocytes die—a stage known as **clonal contraction** (see Section 9-9 and Section 11-16). What remains are long-lived antibody-producing plasma cells that sustain circulating antibodies for months to years and residual memory B and T cells that may also persist for years or even a lifetime, poised for an accelerated adaptive response in the event of future encounters with the same pathogen. Thus, in addition to clearing the infectious agent, an effective adaptive immune response prevents reinfection. For some infectious agents, this protection is essentially absolute, whereas for others infection is only reduced or attenuated on reexposure to the pathogen.

The red curve shows the rapid growth of microorganisms in the absence of innate immunity, when macrophages (MAC) and polymorphonuclear leukocytes (PMN) are lacking. The green curve shows the course of infection in mice and humans that have innate immunity but have no T or B lymphocytes and so lack adaptive immunity. The yellow curve shows the normal course of an infection in immunocompetent mice and humans.

Acquired Immune Deficiency Syndrome (AIDS)

It is not known how many infections are dealt with solely by the nonadaptive mechanisms of innate immunity, because such infections are eliminated early and produce little in the way of symptoms or pathology. Innate immunity does, however, seem to be essential for effective host defense, as shown by the progression of infection in mice that lack components of innate immunity despite having an intact adaptive immune system; adaptive immunity is dependent on innate immunity (Fig. 11.4). Conversely, many infections can be curbed—but typically not cleared—in the absence of adaptive immunity. Thus, the two arms of immunity are typically interlinked and often interdependent.

Little or no residual pathology follows an effective primary adaptive immune response to many types of infection. In some cases, however, the infection itself, or the response it induces, causes significant tissue damage. In yet other cases, such as infection with cytomegalovirus or *Mycobacterium tuberculosis*, the pathogen is contained but not eliminated and can persist in a latent form. If the adaptive immune response is later weakened, as it is in acquired immune deficiency syndrome (AIDS) or in medical interventions that impair immunity (for example, organ transplantation or treatment with certain biologic agents, such as anti-TNFs), these pathogens may resurface to cause virulent systemic infections. We will focus on the strategies used by certain pathogens to evade or subvert adaptive immunity, and thereby establish a persistent, or chronic, infection, in Chapter 13.

11-2 The effector mechanisms that are recruited to clear an infection can be organized into immune modules.

Most infections ultimately engage both T cell– and B cell–mediated adaptive immunity, and in many cases, both are helpful in clearing or containing the pathogen and setting up protective immunity. However, the relative importance of the different effector mechanisms, and the classes of antibody induced, vary with different pathogens. Different types of immune responses are coordinated through activation of distinct **immune effector modules** (see Section 1-19). In each type of immune response, a specific collection of innate and adaptive mechanisms acts together to eliminate a specific type of pathogen.

Broadly speaking, there are two major subsets of immune modules—cytotoxic and helper—that are generally aligned around the eradication of intracellular pathogens that do not require phagocytes for their elimination (for example, viruses) versus the eradication of extracellular pathogens (for example, bacteria, fungi, helminths) and those intracellular pathogens that require phagocytes for their elimination (for example, intracellular bacteria and some single-cell parasites, or protozoa), respectively. Cells in the cytotoxic module (for example, NK cells and CTLs) can kill infected targets directly, whereas cells in each of the helper modules (types 1–3) act indirectly to coordinate with subsets of circulating or tissue-resident myelomonocytic cells whose microbicidal functions they recruit and/or enhance (Fig. 11.5). Circulating myelomonocytic cells include, in order of their decreasing abundance in circulating blood, neutrophils, monocytes (which enter inflamed tissues and differentiate into macrophages), eosinophils, and basophils. Tissue-resident mast cells, which share many functions with basophils, are also included, as mast-cell precursors can be recruited to some tissues, such as intestine, during certain types of infections. To date, ILCs that correspond with additional T-cell subsets, such as T_{FH} and T_{reg} cells, have not been definitively identified, although this is an area of active study. The absence of ILC homologs of T_{FH} and T_{reg} cells may reflect the primary role of these T-cell subsets in influencing the development and function of other adaptive immune cells rather than innate immune cells. Of course, there are exceptions to this classification, and some pathogens recruit more than one module (for example, cytotoxic and type 1 responses are often

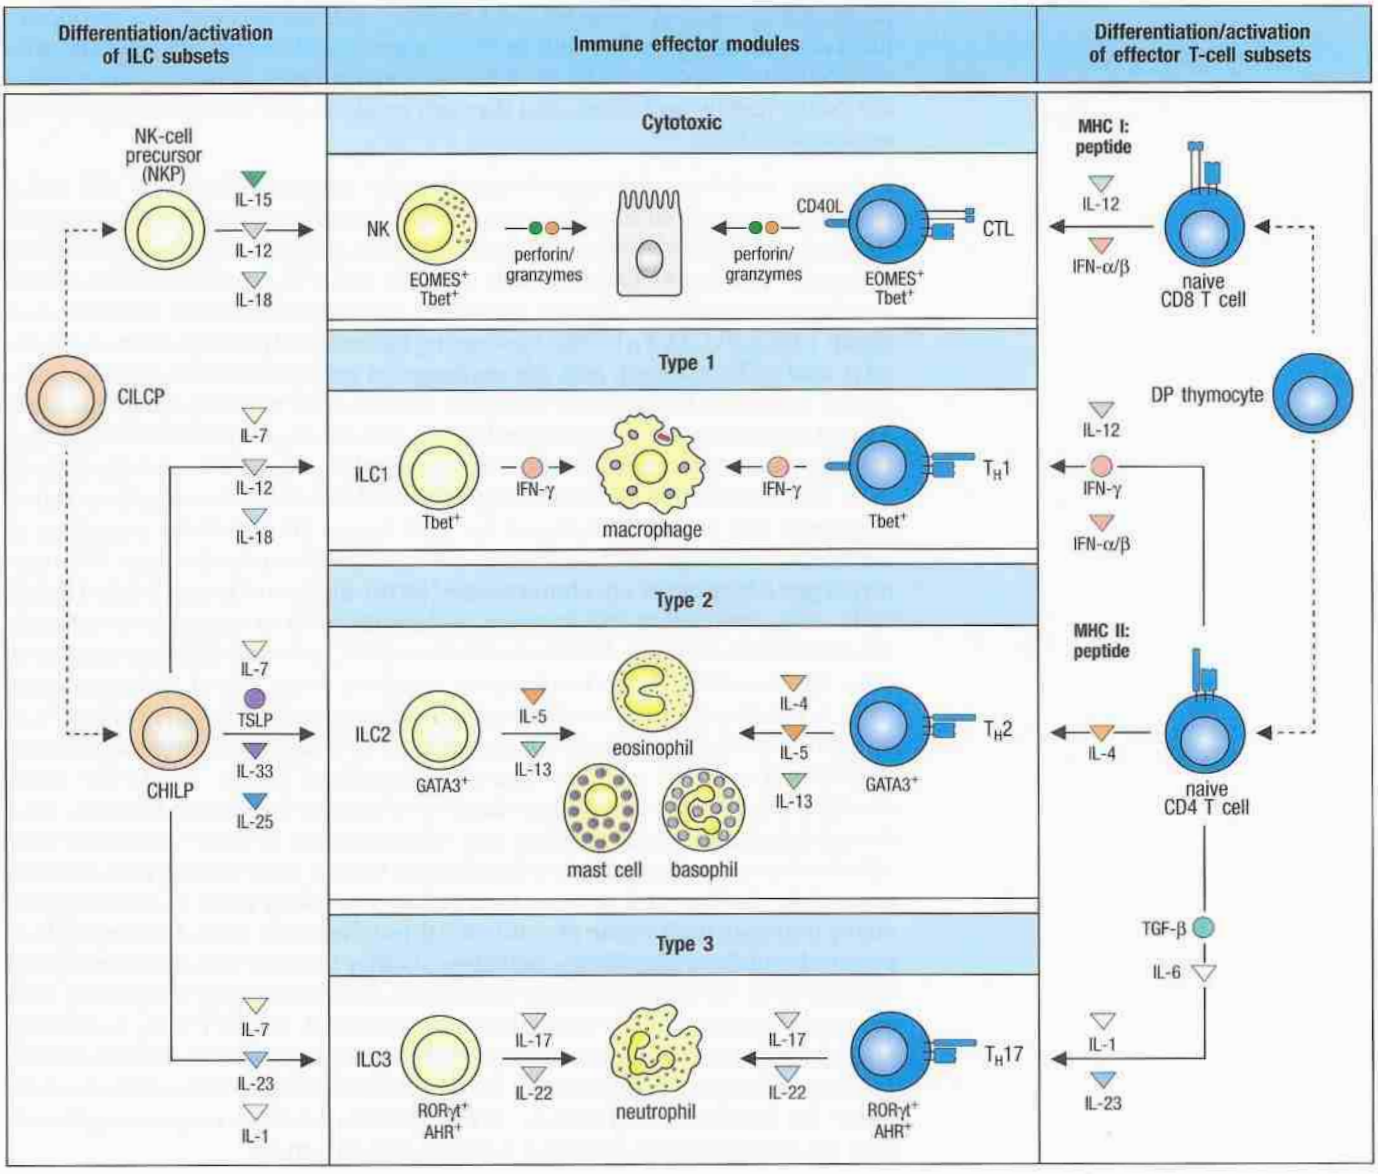

Fig. 11.5 Integration of ILCs, T-cell subsets, and innate effector cells into immune effector modules. The major inductive and effector cytokines and transcription factors (for example, EOMES, Tbet, GATA3, RORγt, and AHR) that are associated with each effector module are shown. See text for details. Although the developmental origins of ILCs are still under investigation, it appears that all ILCs are derived from a common ILC precursor (CILCP) that develops from the common lymphoid precursor (CLP) that also gives rise to the B- and T-cell lineages in the bone marrow (not shown). CILCPs diverge into either an NK-cell precursor (NKP) or a common helper-like ILC precursor (CHILP), which gives rise to ILC1, ILC2, and ILC3. This is analogous to the divergence of the CD4 and CD8 lineages from double-positive (DP) precursors in the thymus.

recruited together, and type 3 responses can transition to type 1 responses), but as a conceptual framework this is a useful system for understanding the integration of innate immunity and adaptive immunity.

Whereas natural killer (NK) cells and cytotoxic T lymphocytes (CTLs) evolved to eradicate their target pathogens primarily via cell-mediated cytotoxicity (see Section 3-24 and Section 9-21), the three interlinked helper ILC and CD4 T-cell modules (ILC1/ILC2/ILC3 and $T_H1/T_H2/T_H17$, respectively) appear to have evolved to enhance and coordinate the functions of, and integrate adaptive immunity with, different arms of the myelomonocytic pathway for optimal eradication of their target pathogens: monocyte/macrophages are enhanced by **ILC1** cells and T_H1 cells; eosinophils, basophils, and mast cells by **ILC2** cells and T_H2 cells; and neutrophils by **ILC3** cells and T_H17 cells. The cytokines

produced by each of these ILC and helper T-cell subsets also has important local actions on epithelial cells in the tissues in which they are resident or to which they are recruited. Each of the four major types of immune responses are controlled by and integrated through cytokine and chemokine networks, as discussed later.
